If a totally-symmetric electronic ground state is assumed, ($^1A_1$), the polarization results lead to the $^1B_1 \leftarrow {}^1A_1$ electronic assignment for the lowest absorption transition of NO_2^-.[16] The orbital assignment proposed by Trawick and Eberhardt is $n_N \rightarrow \pi_3$, which is in agreement with the fact that the transition is allowed by symmetry but is nevertheless weak ($\epsilon_{max} \cong 25$, $\lambda_{max} \cong 3550$ Å.[17]). The $n_O \rightarrow \pi^*$ transitions of carbonyl compounds are also weak, even though the transition may be formally allowed by symmetry, as in glyoxal[18] and biacetyl.[19] This is to be expected, since the n- and π-orbitals do not simultaneously possess large amplitude in the same regions of space, so that the integrand in the transition moment integral $\int (n)^* R (\pi) d\tau$ is everywhere small, and consequently leads to low intensity for $n \rightarrow \pi^*$ transitions. Furthermore, $n \rightarrow \pi^*$ transitions which are allowed by symmetry possess a transition moment which is necessarily perpendicular to the nodal plane of the π-orbitals, since the n-orbitals and the π-orbitals are, respectively, symmetric and antisymmetric with respect to reflection in the plane of the molecule. This has been verified experimentally in glyoxal from the analysis of the rotational structure.[18] Thus, the $^1B_2 \leftarrow {}^1A_1$, $n_N \rightarrow \pi_3$ assignment for the lowest transition of NO_2^- appears to be reasonable.

A qualitative orbital energy level diagram for

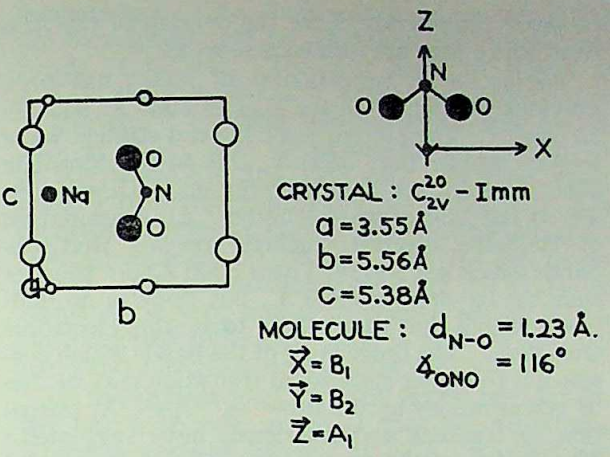

Fig. 3.—Crystal structure of $NaNO_2$ and molecular structure of NO_2^-. The clear circles are at $a = 0$, whereas the dark circles are displaced by $a/2$. The crystallographic axes are labelled according to Ziegler's notation.[13] The bond distance and bond angle of NO_2^- are from Carpenter's work.[14]

the n- and π-orbitals of the NO_2^- molecule is shown in Fig. 4, and orbital assignments of the three electronic transitions which are observed at wave lengths longer than 2000 Å. are also shown in the diagram.[17] It is assumed that the σ-bonding orbi-

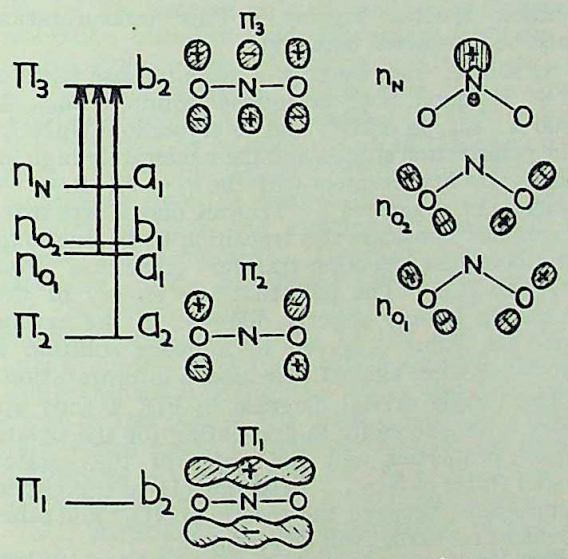

Fig. 4.—Schematic diagram of the one-electron n- and π-molecular orbitals of NO_2^-. The orbital transitions which may correspond to the observed electronic transitions of NO_2^- are shown in the diagram.

tals are lower than π_1, and the σ*-antibonding orbitals are higher than π_3. This is reasonable, since the hybridized AOs which form the σ-MOs overlap with each other more than the p-AOs which form the π-MOs, so that the energy difference between the σ- and σ*-MOs is greater than the energy difference between the π- and π*-MOs. The n-MOs are essentially AOs (which may be hybridized), since they are formed from orbitals which overlap very little with the σ-orbitals. Since O is more electronegative than N, the n_O orbitals are placed slightly below the n_N orbital.[4] The two n_O orbitals should

be nearly degenerate, since the overlap of the AOs from which they are formed is so small.

The $n_O \rightarrow \pi_3$ transition(s) of NO_2^- has been previously assigned[4] to the $\lambda_{max} \cong 3000$ Å., $\epsilon_{max} \cong 15$ band.[17] The present work has not studied wave lengths shorter than 3300 Å., due to the complete absorption by the double Pyrex glass Dewar vessels at the shorter wave lengths. An examination of Rodloff's spectral tracings[3] reveals that the bands which are observed near 3200 Å. are broader than the bands near 3800 Å., but there is no definite evidence that they belong to another electronic transition. The broadening of the bands which correspond to higher vibrational transition may be due to perturbations by the $n_O \rightarrow \pi_3$, $^1B_2 \leftarrow {}^1A_1$ transition, as Trawick and Eberhardt have suggested.[4] The absence of the $n_O \rightarrow \pi_3$ transition in the crystal spectrum is difficult to understand, but possibly it could be explained if the upper state were unstable. Absorption due to this transition would then be nearly continuous, and would not appear unless the crystal thickness were much greater than that which is necessary for detecting the very sharp $n_N \rightarrow \pi_3$ transition. The intensity due to a very diffuse transition at any individual wave length would thus be very much less than the intensity due to a sharp transition in the same region, even though the integrated intensities over the corresponding regions of absorption are similar, as the solution spectra suggest.[17] This interpretation must be considered tentative.

At shorter wave lengths, a more intense band of NO_2^- is found, both in aqueous solution ($\lambda_{max} \cong 2100$ Å., $\epsilon_{max} \cong 5500$[17]) and in crystalline $NaNO_2$[4]. The polarization studies and the moderately high intensity are in agreement with the $\pi_2 \rightarrow \pi_3$, $^1B_1 \leftarrow {}^1A_1$ assignment suggested by Trawick and Eberhardt.[4] Friedman[17] considers this transition to be due to an intermolecular electron-transfer transition from NO_2^- to H_2O. The fact that the energy of this transition is only slightly different in the crystal from the value observed in aqueous solution is strong evidence against Friedman's interpretation.

The simple orbital diagram in Fig. 4 thus appears to be successful in accounting for the polarization properties and the order of the excited singlet states of NO_2^-. In section (D) of this paper, comparisons between the spectra of NO_2^- and other isovalent molecules will be given.

(B) Analysis of the Vibrational and Lattice Structure.—In an electronic transition of a polyatomic molecule in the crystalline state, fine structure due to transitions involving simultaneous changes in the vibrational and lattice states usually appears in the spectrum. In order to resolve this structure, it is desirable to study the spectra at very low temperatures. If the vibrational fine structure can be analyzed, it is sometimes possible to determine how the arrangement of the nuclei and the bonding between them differs in the upper and lower electronic states. This leads to an understanding of valence and molecular structure which is deeper than that obtained either from the study of the vibrational spectrum of the ground electronic state alone or from the study of an electronic spectrum which is broad because of perturbations by the environment. The full power of the vibrational fine structure analysis in elucidating the molecular and electronic structure can be felt if the molecule is small and if isotopically substituted species are available. The recent availability[20] of isotopically pure N^{15} has enabled such a study to be performed for NO_2^-.

The lattice fine structure which appears in the electronic transitions of molecules in crystals and mixed crystals provides information about lattice oscillations, and should be valuable in understanding intermolecular forces in the solid state. So far, extensive interpretation of the lattice structure has not been made, although lattice frequencies in many molecular crystals and mixed crystals have been determined from the analysis of the electronic transitions.[10]

The analysis of the fine structure of the $n_N \rightarrow \pi_3$, $^1B_2 \leftarrow {}^1A_1$ absorption transition of NO_2^- in crystalline $NaN^{14}O_2$ and $NaN^{15}O_2$ at 4°K. is quite straightforward. At 77°K., the 0–0 band in both $NaN^{14}O_2$ and $NaN^{15}O_2$ is 25960 ± 8 cm.$^{-1}$, whereas at 4°K. the 0–0 band has shifted slightly to 25977 ± 3 cm.$^{-1}$ in both cases. It is possible that there is a calibration error in Rodloff's work,[3] since the work of Trawick and Eberhardt and of the present author are in agreement with respect to the 0–0 frequency at 77°K. The most prominent feature of the absorption transition in $NaN^{14}O_2$ is the progression of a single frequency of 632 ± 4 cm.$^{-1}$ (621 ± 4 cm.$^{-1}$ in $NaN^{15}O_2$) in which the intensity maximum is in the fourth band of the progression. This is seen most readily in the microphotometer tracings in Figs. 2 and 5 of ref. 3, in which the source is a hydrogen discharge tube, which provides a more uniform background than the tungsten filament lamp employed in this research. Besides the main progression, additions of a frequency of 1018 ± 4 cm.$^{-1}$ (1006 ± 4 cm.$^{-1}$ in $NaN^{15}O_2$) to each of the bands in the main progression are also seen in the spectrum. Rodloff has previously identified the main progression (A_1, B_1, C_1, D_1, etc., in Fig. 2, ref. 3), but he has not identified the 1018 cm.$^{-1}$ interval. It is clearly seen in his tracing, however (A_1, B_5; B_1, C_5; C_1, D_5; etc., in Fig. 2 of ref. 3). It is clear that this identification is correct, and that B_5 represents a vibrational addition to A_1 and not to B_1, since there is no band between A_1 and B_1 which corresponds to band B_5 between B_1 and C_1.

The analysis of the lattice structure in the absorption spectrum yields the values 65, 110, 155, 180 and 218 cm.$^{-1}$ for the lattice frequencies of $NaNO_2$ in $^1B_2$ at 4°K. Due to the greater diffuseness of the lattice additions, the lattice frequencies may be uncertain by ±15 cm.$^{-1}$. Within this limit of error, the lattice frequencies are indistinguishable in $NaN^{14}O_2$ and in $NaN^{15}O_2$.

The analysis of the fluorescence transition is also quite straightforward. The main progression in $NaN^{14}O_2$ is 829 ± 2 cm.$^{-1}$ (823 ± 2 cm.$^{-1}$ in $NaN^{15}O_2$). The 1325 ± 4 cm.$^{-1}$ frequency in $^1A_1$ of $NaN^{14}O_2$ corresponds to 1018 ± 4 cm.$^{-1}$ in $^1B_2$. Virtually all of the intensity in the fluorescence transition is contained in the bands of the 829

(20) W. Spindel and T. I. Taylor, *J. Chem. Phys.*, **24**, 626 (1956).

Digitized by Arya Samaj Foundation Chennai and eGangotri

cm.$^{-1}$ progression, in which the intensity maximum is in the fourth band. The bands corresponding to the 1325 cm.$^{-1}$ frequency and the lattice additions appear only very weakly in fluorescence. A correspondence between lattice frequencies in $^1A_1$ and $^1B_2$ is also found. The lattice frequencies (±15 cm.$^{-1}$) in $^1A_1$ of $NaN^{14}O_2$ and $NaN^{15}O_2$ at 4°K. are 45, 105, 165, 205 and 270 cm.$^{-1}$. In addition, a lattice frequency of 80 cm.$^{-1}$ possibly appears in $NaN^{15}O_2$. It is interesting to observe that the highest frequency lattice mode in $^1B_2$ and in $^1A_1$ is different by an amount which far exceeds the experimental error.

The absorption and fluorescence spectra, although very similar, do show some differences, so that they are not quite "mirror images" of each other. The lattice structure is much more prominent in absorption than in fluorescence, as can be seen from an examination of Figs. 1 and 2. It is interesting to note that the bands of the 632 cm.$^{-1}$ progression (in absorption) are accompanied by very pronounced lattice structure, but that the lattice structure is far less pronounced, or is even absent, in the 1018 cm.$^{-1}$ additions to the bands of the 632 cm.$^{-1}$ progression.

The detailed assignments of the vibrational states of $NaNO_2$ and the calculation of the force constants of NO_2^- are discussed in detail in the following paper.[21] A summary of the analyses of the absorption and fluorescence spectra is given in Table I. Anharmonic corrections in the ν_2 progression are negligible (<3 cm.$^{-1}$) for the first few members of the progression. In fluorescence, the anharmonic correction to $6\nu_2$ is approximately 20 cm.$^{-1}$.

(C) **The Effect of the Environment on the Electronic Transition.**—Since the lowest absorption transition of NO_2^- can be studied under a variety of conditions, it is possible to determine the relationship between the environment and the nature of the spectrum.

(1) **The Effect of Temperature.**—The increase in sharpness of the spectrum with decrease in temperature is seen in Fig. 1 of ref. 3. This is due to a decrease in the population of the excited lattice states. Even at 77°K., absorption due to molecules in the first excited state of the 110 cm.$^{-1}$ lattice mode can be detected in the spectrum. With the same crystal at 4°K., the bands corresponding to the "hot" lattice transition of the 110 cm.$^{-1}$ frequency are absent. The small shift of the bands when the temperature is decreased from 77 to 4°K. probably is due to further contraction of the lattice.

(2) **The Effect of Other Ions.**—The environment of the NO_2^- ion can be altered by changing the positive ion in the lattice or by dissolving it in the lattice of another crystal. In KNO_2, the bands at 77°K. are much broader than the bands in $NaNO_2$ at the same temperature. Even at 4°K., the KNO_2 bands are more diffuse than the $NaNO_2$ bands. The results found in this research for KNO_2 are in good agreement with the results of Rodloff,[3] who has given photographs and tracings of the KNO_2 absorption spectrum at low temperature. The fluorescence bands of KNO_2 are correspondingly broader than the fluorescence bands of $NaNO_2$. The 0–0 band in KNO_2 at 4°K. is 25412 ± 10 cm.$^{-1}$, which constitutes a shift of 565 cm.$^{-1}$ to lower frequencies relative to $NaNO_2$ at 4°K. The vibrational frequencies in $^1B_2$ of KNO_2 are 616 and 1015 cm.$^{-1}$, in good agreement with the frequencies in $^1B_2$ of $NaNO_2$. The lattice structure is partially resolved at 4°K., and a lattice frequency of 120 cm.$^{-1}$ (in $^1B_2$) can be detected. The vibrational envelope of the $^1B_2 \leftarrow {}^1A_1$ transition is very similar in $NaNO_2$ and in KNO_2, the principal difference being a shift of the 0–0 band and a decrease in sharpness in KNO_2.

In the environment of a still larger positive ion, the bands become so broad that the vibrational structure appears diffuse. At 77°K., it is not possible to resolve any vibrational structure in the $^1B_2 \leftarrow {}^1A_1$ transition in $CsNO_2$. Rodloff found no structure in the corresponding absorption transition of barium nitrite at 20°K.[3] In dilute mixed crystals of NO_2^- in KBr or in KCl,[22] the $^1B_2 \leftarrow {}^1A_1$ transition is shifted to lower frequencies (0–0 band = 25100 ± 100 cm.$^{-1}$ at 77°K.), and the bands are broader than in crystalline $NaNO_2$ at the same temperature.

The red shift and increase in diffuseness in the case of the larger positive ions can be understood on the basis of the MO description of the $n_N \rightarrow \pi_3$, $^1B_2 \leftarrow {}^1A_1$ transition. The $n_N \rightarrow \pi_3$ electronic transition transfers electronic charge from the nitrogen atom to the N–O bonds, and therefore leads to increased electronic charge near the O atoms. The dipole moment in the excited $^1B_2$ state is therefore expected to be higher than in the ground $^1A_1$ state. Since the larger positive ions are more polarizable than the smaller ones, they will preferentially stabilize the electronic state with the higher dipole moment. Therefore, the more polarizable positive ions should decrease the energy of the $^1B_2$ state relative to the $^1A_1$ state, as is observed. Greater coupling of the low frequency lattice vibrations of the positive ion with the electronic transition of the NO_2^- ion is also expected to occur in the case of the more polarizable positive ions, which might possibly account for the greater diffuseness of the bands of the $^1B_2 \leftarrow {}^1A_1$ transition in lattices containing K^+, Cs^+ and Ba^{++} ions.

(3) **Anomalies in the Polarization of the Absorption and Fluorescence Bands.**—An examination of Fig. 1 reveals that the vibrational and lattice structure of the $^1B_2 \leftarrow {}^1A_1$ transition shows a weak but definite intensity in the *c*-axis component of the crystal spectrum. A careful examination of the plate revealed that the 0–0 band appeared to be completely *a*-axis polarized, but that the lattice additions to the 0–0 band, which are weaker than the 0–0 band in the *a*-axis spectrum, did appear weakly in the *c*-axis spectrum. The lattice additions to the 0–0 band therefore lead to a partial depolarization of the absorption spectrum. Some of the intensity of the higher, more intense vibrational bands in the *c*-axis spectrum may be due to unavoidable errors involved in the optical

arrangement. However, in the regoin near the 0–0 band, the *c*-axis component of the lattice structure cannot be due to experimental error. Since the *c*-axis corresponds to a direction in the plane of the NO_2^- molecule, the excitation of lattice quanta in the electronic transition must therefore be accompanied by oscillations of the NO_2^- molecule about the molecular symmetry axis. Hexter and Dows[23] have discussed the effect upon the dichroic ratios, in the vibrational spectra of molecular crystals, of libration of molecules about axes perpendicular to that of the transition moment of the molecular vibration. These results are in qualitative agreement with Hexter and Dows' explanation.

The fluorescence spectrum of single crystals of $NaNO_2$ also shows anomalous polarization. Both spectroscopic examination and direct visual observation indicate that the fluorescence spectrum at 77°K. is strongly depolarized relative to the absorption spectrum. (The 0–0 band itself could not be observed in fluorescence, due to the presence of source lines in the same region of the spectrum.) The *c*-axis fluorescence is approximately 50% as intense as the *a*-axis fluorescence. The degree of depolarization of the fluorescence spectrum is so much greater than the degree of depolarization of the absorption spectrum that it appears necessary to explain it in a different way. In previous studies of the polarized absorption and fluorescence spectra of crystals and mixed crystals, it has been found that the fluorescence spectrum at low temperatures may be partially or completely depolarized with respect to the corresponding absorption spectrum.[9,24] The detailed explanation of this puzzling phenomenon has not yet been proposed, and additional work appears necessary.

(D) Comparison with the Electronic Spectra of Other Molecules.—Mulliken[25] and, more recently, Walsh[26] have discussed the orbitals and spectra of AB_2-type molecules. The results of this work on NO_2^- are in agreement with Walsh's $^1B_2 \leftarrow {}^1A_1$ assignment[27] for the lowest electronic absorption transition of other isovalent molecules, such as SO_2. However, the higher excited singlet states do not appear to correspond in all cases. In section (A), reasons were given for assigning the second transition of NO_2^- as $n_O \rightarrow \pi_3$, $^1B_2 \leftarrow {}^1A_1$. In SO_2, there is strong evidence, based on the appearance of both a_1 and b_1 vibrations in the electronic transition, that the second transition is of the $\pi \rightarrow \pi^*$ (or $n \rightarrow \sigma^*$ or $\sigma \rightarrow \sigma^*$) type, and that the upper state is either $^1A_1$ or $^1B_1$.[23]

The qualitative orbital energy level diagram for NO_2^- which is shown in Fig. 4 gives a reasonable description of the NO_2^- spectrum, although it differs in several respects from the diagram given by Walsh.[26] It is likely that the relative orbital energies will vary from one molecule to another, and

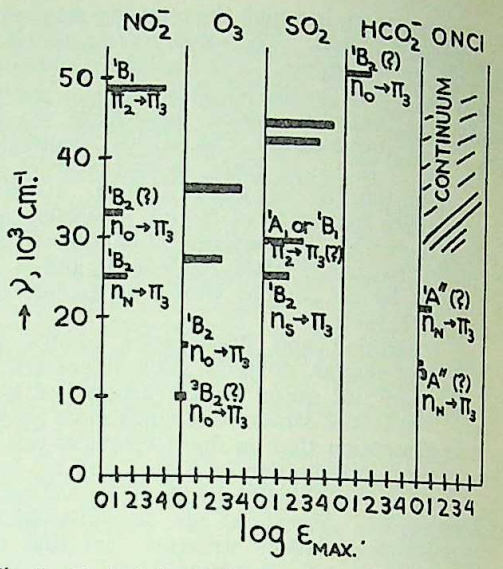

Fig. 5.—Excited electronic states of molecules which are isovalent with NO_2^-. References to the experimental data for O_3, SO_2 and ONCl are to be found in Walsh's paper.[26] The data for HCO_2^- are from Bielecki and Henri.[30] Some of the more certain assignments are shown, and others are given by Walsh.[26]

that appreciable differences may occur within this isovalent series. In the sequence HCO_2^-, NO_2^-, O_3, it is seen that the corresponding excited electronic states are lowered as the central atom becomes more electronegative. It is quite reasonable to expect that excited states derived from the $\pi_2 \rightarrow \pi_3$ configuration should decrease in energy when the central atom is more highly electronegative, since this will decrease the orbital energy of π_3 but will not affect the orbital energy of π_2. The $\pi_2 \rightarrow \pi_3$ transition has not been observed below 50000 cm.$^{-1}$ in HCO_2^-. In HCOOH[29] the strong absorption in the vicinity of 64500 cm.$^{-1}$ may be due to the $\pi \rightarrow \pi$ transition. The $\pi_2 \rightarrow \pi_3$ transition moves down to 49000 cm.$^{-1}$ in NO_2^- and moves down still further to either 27000 cm.$^{-1}$ or to 36000 cm.$^{-1}$, more probably the latter, in O_3. It is more difficult to predict the behavior of the $n \rightarrow \pi$ transitions, since the non-bonding orbital of the central atom and the antibonding π_3 orbital are both lowered in energy by an increase in the electronegativity of the central atom. However, the $n_O \rightarrow \pi_3$ transition involving the non-bonding orbitals of the end oxygen atoms should decrease in energy in the sequence HCO_2^-, NO_2^-, O_3. These simple considerations appear to be qualitatively capable of accounting for many of the spectral differences in Fig. 5. The molecules SO_2 and ONCl are included for completeness, but the bonding in these molecules is considerably different than in HCO_2^-, NO_2^- and O_3, inasmuch as S can employ 3d AOs whereas ONCl is asymmetric.

It should be emphasized that the simple one-electron LCAO-MO description of the electronic transitions is at best rather crude. In particular, it

is necessary to explicitly consider configurational interaction (CI) in treating the $n \rightarrow \pi$ transitions, since in NO_2^- both the $n_N \rightarrow \pi_3$ configuration and one of the $n_O \rightarrow \pi_3$ configurations belong to the B_2 representation of C_{2v}. The extent of CI will in general vary from molecule to molecule, and it is possible that this may be a prime consideration in determining the energies of the $n \rightarrow \pi$ transitions in these molecules.

Electronic and Vibrational States of the Nitrite Ion. II. Vibrational States[1]

BY JEROME W. SIDMAN[2]

RECEIVED AUGUST 16, 1956

The infrared absorption spectra of $NaN^{14}O_2$ and $NaN^{15}O_2$ have been examined. The vibrational frequencies and assignments deduced from the infrared absorption spectrum agree with the results of the fluorescence and Raman spectra. The vibrational assignments for the lowest ($^1A_1$) state are, for $NaN^{14}O_2$, $\nu_1 = 1325$ cm.$^{-1}$, $\nu_2 = 829$ cm.$^{-1}$, $\nu_3 = 1270$ cm.$^{-1}$, and, for $NaN^{15}O_2$, $\nu_1 = 1306$ cm.$^{-1}$, $\nu_2 = 824$ cm.$^{-1}$, $\nu_3 = 1243$ cm.$^{-1}$. A complete force constant calculation has been performed for NO_2^-, with the results, $f_d = 8.1_0$, $f_{dd} = 2.3_5$, $f_{d\alpha}/d^2 = 2.5$, $f_{d\alpha}/d = 0.9$, in units of 10^5 dyne cm.$^{-1}$. The partial vibrational assignments in the first excited singlet electronic state ($^1B_2$) are, for $NaN^{14}O_2$, $\nu_1 = 1018$ cm.$^{-1}$, $\nu_2 = 632$ cm.$^{-1}$, and, for $NaN^{15}O_2$, $\nu_1 = 1006$ cm.$^{-1}$, $\nu_2 = 621$ cm.$^{-1}$. From a quantitative application of the Franck–Condon principle, the bond angle in the excited state is calculated to change by approximately 9° for the 0–0 transition. The bond distance in the excited state changes little, if at all. The geometry and bonding are discussed. The vibrational frequencies and force constants are compared with the values in related molecules, such as O_3, HCO_2^- and SO_2. Some of the similarities and differences can be explained in terms of valence theory. However, the large value of f_{dd} in O_3 and in NO_2^-, but not in SO_2 or, presumably, in HCO_2^-, cannot be explained completely at the present time.

Introduction

The vibrational spectra of triatomic molecules have received considerable study during recent years. Although it might at first sight appear to be simple to identify and to assign the three fundamental vibrational frequencies of a triatomic molecule, a few molecules, of which O_3 is possibly the best known example, have tenaciously resisted analysis until very recently. A survey of the literature reveals that NO_2^-, which is iso-electronic with O_3 and geometrically very similar to it, is another triatomic molecule for which the vibrational assignment is uncertain.

In the previous paper,[3] the analysis of the vibrational fine structure of the $^1B_2$—$^1A_1$ electronic transition has been given for the absorption and fluorescence spectra of crystalline $NaN^{14}O_2$ and $NaN^{15}O_2$ at 4°K. In this paper, the infrared spectra, vibrational assignments and force constants of NO_2^- will be discussed.

Experimental

The preparation of $NaN^{15}O_2$ has been described in the previous paper.[3] Infrared absorption spectra were recorded on a Perkin–Elmer Double Beam Recording Spectrophotometer, Model 21, using a NaCl prism. Atmospheric H_2O and CO_2 absorption bands were used to calibrate the wave lengths.

The most convenient method for studying the infrared spectra was the KBr-pressed pellet. The $NaNO_2$ was ground in an agate mortar with Harshaw Chemical Company's Spectroscopic Grade KBr. Pressed pellets of 1 mm. thickness which contained 0.3% $NaNO_2$ were suitable. Comparison of the spectrum of the pressed pellet with the spectrum of the dilute mixed crystal of NO_2^- in KBr showed numerous differences between the spectra, indicating that the pressed pellet spectrum is due to $NaNO_2$ dispersed in KBr, and not to a solid solution of NO_2^- in KBr.[4] Furthermore, the infrared spectra of pressed KBr pellets of other nitrite salts showed differences between themselves, which is additional evidence that the spectra are not due to a solid solution of the nitrite salt in KBr, but are due to physically dispersed microcrystals.

A single recrystallization from H_2O yielded a sample of $NaNO_2$ which showed no trace of the intense NO_3^- band at 1300 cm.$^{-1}$.

Results

The infrared spectra of $NaN^{14}O_2$ and $NaN^{15}O_2$ are shown in Fig. 1. The assignments of the bands are given in Table I.

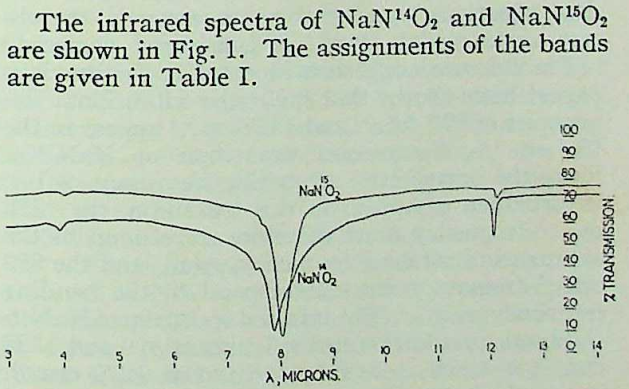

Fig. 1.—Infrared absorption spectra of $NaN^{14}O_2$ and $NaN^{15}O_2$ in KBr pressed pellets. The pure KBr pellet was used as a blank, and absorption due to traces of adsorbed H_2O have been subtracted out of the spectrum. Perkin–Elmer Model 21 Recording Infra-Red Spectrophotometer, NaCl prism, linear wave length scale. The spectra were calibrated against atmospheric H_2O and CO_2 absorption bands.

[a] It is suggested that the assignments based on the infrared spectrum of the single crystal are incorrect.

Discussion and Interpretation

(A) Assignment of the Vibrational Frequencies.—The previous data on the vibrational spectrum of NO_2^- are given in Table I, together with results which have been obtained in this work. Literature sources which report more bands than can be attributed to NO_2^- are not included in Table I. A unique vibrational assignment can be proposed from the very careful Raman data due to Langseth and Walles,[5] who have studied the Raman spectra of aqueous $NaN^{14}O_2$. The depolarization ratios of the Raman bands lead to the unexpected conclusion that ν_3, the asymmetric stretching frequency, which is broad and depolarized in the Raman spectrum, is lower than ν_1, the symmetric stretching frequency, which is sharp and polarized in the Raman spectrum. This led Langseth and Walles to propose a structure in which the bond angle was assumed to be nearly 90° and in which a formal bond between the O atoms was assumed. However, such a structure did not agree with the X-ray crystallographic results which were available at that time.[6] Although the more recent structure determinations have led to some revisions, the obtuse-angle model (116°) is considered correct.[7,8]

The fluorescence results reported in the previous paper[3] have shown that molecular vibrational frequencies of 829 cm.$^{-1}$ and 1325 cm.$^{-1}$ appear in the $^1B_2 \rightarrow {}^1A_1$ fluorescence transition of $NaN^{14}O_2$. Since the asymmetric stretching frequency, $\nu_3(b_1)$, is forbidden to appear in this transition, the 1325 cm.$^{-1}$ frequency must therefore correspond to the symmetric stretching frequency, $\nu_1(a_1)$, and the 829 cm.$^{-1}$ frequency must correspond to the bending frequency, $\nu_2(a_1)$. The infrared spectrum of $NaN^{14}O_2$ shows, in addition to the bands at 829 and 1325 cm.$^{-1}$, a much more intense band at 1270 cm.$^{-1}$, upon which the 1325 cm.$^{-1}$ band is superimposed (Fig. 1). The fluorescence, infrared and Raman data are in good agreement, and lead to the assignments shown in Table I. The intensity of ν_3 in infrared absorption is greater than that of ν_1, as is usually the case in triatomic molecules.

The numerical value of ν_3 given in this work does not agree with the work of Newman,[9] who has studied the polarized infrared spectrum of single crystals of $NaN^{14}O_2$ at 77°K. For radiation polarized along the *c*-axis in the *ac*-plane, Newman's spectra show total absorption from 1100 to 1400 cm.$^{-1}$, due to the insurmountable difficulties in preparing thin single crystals. Newman has chosen the high frequency peak at 1360 cm.$^{-1}$ as ν_3, but the low frequency peak at 1170 cm.$^{-1}$ has not been satisfactorily assigned. The *center* of the broad band is in the vicinity of 1270 cm.$^{-1}$, which agrees with the single peak observed in this work. The assignment ν_3 = 1270 cm.$^{-1}$ compares more favorably with the Raman spectrum of an aqueous solution of $NaNO_2$ (ν_3 = 1240 cm.$^{-1}$)[5] than does Newman's assignment ν_3 = 1360 cm.$^{-1}$

The polarized infrared crystal spectrum[9] shows incomplete dichroism for the 831 cm.$^{-1}$ band, even when parallel light is used. The appearance of the 831 cm.$^{-1}$ band in the *a*- and *c*-axis spectra may be induced by librations of the NO_2^- ion in the crystal,[10] since otherwise only the *b*-axis spectrum would be expected to show this band.

The assignments of the a_1 vibrational frequencies in the $^1B_2$ electronic state can be made readily, using the results of the previous paper.[3] The assignments are ν_1 = 1018 cm.$^{-1}$, ν_2 = 632 cm.$^{-1}$, for $NaN^{14}O_2$, and ν_1 = 1006 cm.$^{-1}$, ν_2 = 621 cm.$^{-1}$, for $NaN^{15}O_2$.

(B) Calculation of the Force Constants and Normal Coördinates of NO_2^- in the $^1A_1$ (Ground) Electronic State.—The observation that $\nu_3 < \nu_1$ indicates that the interaction constants are not negligible in NO_2^-. Earlier attempts to account for the vibrational potential energy on the basis of the simple valence or central force fields were not successful.[11] Using the observed frequencies for both $N^{14}O_2^-$ and $N^{15}O_2^-$ in $^1A_1$, it is possible to calculate the force constants for the most general potential function. The procedure for doing this has been described in detail by Polo and Wilson in connection with their calculations for SO_2.[12] The vibrational assignments in cm.$^{-1}$ for $N^{14}O_2^-$ are (without anharmonic corrections) ν_1 = 1325 ± 4, ν_2 = 829 ± 2, ν_3 = 1270 ± 4, and the geometrical data are α = 116 ± 3°, d = 1.23 ± 0.03 Å. Using these data, various sets of force constants which reproduce the frequencies of $N^{14}O_2^-$ can be calculated. The best set of force constants is determined by requiring

that the force constants reproduce the observed frequencies for $N^{15}O_2^-$: $\nu_1 = 1306 \pm 4$, $\nu_2 = 824 \pm 2$, $\nu_3 = 1243 \pm 4$. The experimental frequencies are in satisfactory agreement with the Teller–Redlich product rule. The best set of force constants, in units of 10^5 dyne/cm., is $f_d = 8.1_0$, $f_{dd} = 2.3_5$, $f_\alpha/d^2 = 2.5$, $f_{d\alpha}/d = 0.9$.

The normal coördinates readily can be determined, and will be important in connection with the calculations described in the next section. The internal coördinates of the A_1 class which have been used in this calculation are S_1, the symmetric stretching of the two N–O bonds, and S_2, the deformation of the O–N–O angle. The normal coördinates Q_1 and Q_2, which are associated, respectively, with the vibrations ν_1 and ν_2, are related to the symmetry coördinates S_1 and S_2 through the transformation $S_t = L_{kt}Q_k$. The results are $S_1 = 0.3_1Q_1 + 0.0_4Q_2$, $S_2 = -0.2_8Q_1 + 0.3_7Q_2$. The relative contribution of each symmetry coördinate S_t to a given normal coördinate Q_k is given by the ratio of the coefficients in the t column of the matrix whose elements are L_{kt}, inasmuch as $(\partial S_t/\partial Q_k)_{Q_{k'}} = L_{kt}$, where all other normal coördinates $Q_k'(k' \neq k)$ are held constant in the partial differentiation. It is thus seen that the normal coördinate Q_1 contains nearly equal amounts of the symmetric stretching of the N–O bonds (S_1) and the angle deformation (S_2). In Q_1, the stretching of the N–O bonds is accompanied by a decrease in the O–N–O angle. The normal coördinate Q_2 contains very little S_1, and may be described adequately as a deformation of the O–N–O angle (S_2).

(C) The Geometry and Bonding of NO_2^- in the $^1B_2$ (Excited) Electronic State.—Craig[13] has shown that it is possible to calculate the dimensions of the excited state of a polyatomic molecule if the intensity distribution in the vibrational structure of the electronic transition is known. The intensity distribution is very sensitive to the change of the molecular dimensions when the molecule undergoes an electronic transition, but it is much less sensitive to changes in the force constants.

In the case of NO_2^-, long progressions of ν_2 appear both in absorption and in fluorescence in the $^1B_2$–$^1A_1$ transition. The intensity maximum is in the 0-3 (and 3-0) band in the ν_2 progression. The ν_1 frequency does not form long progressions, and only a single quantum of it can be detected. In the $^1A_1$ state, the normal coördinate analysis described in the previous section indicates that the normal coördinate Q_2 is composed almost entirely of bending (S_2). Assuming[13] that k_α/ν_2 is approximately the same in $^1B_2$ and in $^1A_1$, the quantitative application of the Franck–Condon principle leads to the result that the bond angle has changed by about $9 \pm 4°$ in the $^1B_2$–$^1A_1$ transition. Lacking rotational structure, it is not possible to directly determine the sign of the change. Excitation of an electron from the n_N orbital to the π_3 orbital leads to an increase of electronic charge in the vicinity of the O atoms. This should cause an increase in the bond angle, due to increased electronic repulsion between the O atoms. If a 9° increase in the bond angle is accepted, then the results of this work tend to confirm many of Walsh's predictions for the lowest electronic transition in this class of molecules.[14] The appearance of ν_1 in the electronic–vibrational transition is attributed to the fact that Q_1 contains an appreciable fraction of S_2. It is thus reasonable to conclude that the principal geometry change in $^1B_2$ is a small increase of the bond angle, and that the bond distance changes slightly, if at all.

(D) The Bonding in the A_1 (Ground) Electronic State of NO_2^-; Comparison with Other Molecules.—The interpretation of the vibrational frequencies and force constants can provide useful information about the nature of the bonding in a molecule.[15] Such data are especially valuable if comparisons can be made with other molecules. Fortunately, accurate vibrational assignments have been proposed for O_3,[16,17] SO_2[12,18] and HCO_2^-.[19] Since these molecules are isovalent with respect to NO_2^-, a comparison can be of value. The pertinent data are shown in Table II.

TABLE II

VIBRATIONAL FREQUENCIES AND FORCE CONSTANTS OF MOLECULES RELATED TO NO_2^-

	$N^{14}O_2^-$	O_3	SO_2	HCO_2^-
d, Å.	1.23	1.276	1.432	d_{C-O} = 1.27
α, °	116	117	119.5	α(OCO) = 124°
ν_1, cm.$^{-1}$	1325	1110	1122	symm. C–O stretch = 1377
ν_2, cm.$^{-1}$	829	705	507	O–C–O bend = 784
ν_3, cm.$^{-1}$	1270	1043	1341	asymm. C–O stretch = 1584
$fd \times 10^5$, dyne/cm.	8.10	5.70	10.02	.....
$fdd \times 10^5$, dyne/cm.	2.35	1.52	0.03	.....
$f\alpha/d^2 \times 10^5$, dyne/cm.	2.5	1.28	0.793	.....
$fd\alpha/d \times 10^5$, dyne/cm.	0.9	0.332	0.20	.....

The molecules which are most similar are O_3 and NO_2^-. It is possible to relate the differences in their force constants to their molecular structure. The stretching and bending force constants are appreciably higher in NO_2^- than in O_3. This is related to the fact that the bond distance is shorter in NO_2^- (1.23 Å.) than in O_3 (1.276 Å.). The difference in electronegativity between O and N would give the bonds in NO_2^- higher ionic character, shorter bond distance, and higher stretching and bending force constants than the bonds in O_3, due to the possibility of increased ionic-covalent resonance in NO_2^-. The higher positive values of the interaction constants in NO_2^- are attributed to greater repulsion between the end oxygen atoms,[20] due both to the shorter distance between them and to the greater electronic charge on them relative to the end oxygen atoms in O_3.

Although the bond angle is very similar in all four molecules, it is seen that O_3 and NO_2^- differ

markedly from SO_2 and from HCO_2^- in one important respect. The asymmetric stretching frequency (ν_3) in O_3 and in NO_2^- is lower than the symmetric stretching frequency (ν_1), whereas in SO_2 and in HCO_2^- the reverse is true. As Bernstein and Powling have shown,[21] the ratio $(\nu_1/\nu_3)^2$ depends approximately on the relative magnitudes of the stretching force constant and the bond–bond interaction constant, and also on a term which involves the atomic masses and the bond angle. In the molecules NO_2^-, O_3, SO_2 and HCO_2^-, the latter term which involves the molecular geometry is less than unity. The geometrical term becomes close to unity only when the bond angle is nearly 90°. For obtuse angle AB_2 molecules in which the bond–bond interaction constant is negligible in comparison with the stretching force constant, the value of ν_1 is then lower than the value of ν_3. This is the usual case in most AB_2 molecules.[22] Although the data are not sufficiently complete to permit a force constant calculation for HCO_2^-, it is reasonable to expect that the bond–bond interaction constant for the C–O bonds will not be as large relative to the C–O stretching force constant as the corresponding interaction constant in NO_2^- and in O_3. The cases in which $\nu_3 < \nu_1$ are relatively few in number. Thus far, NO_2^-, O_3 and OF_2[21] appear to be definitely established cases of this sort. In NO_2^- and in O_3, the complete force constant analyses have indeed verified that the bond–bond interaction constant is large and positive, and presumably the same would be true for OF_2.

The origin of the interaction terms in the vibrational potential function has been discussed by Coulson, Duchesne and Manneback.[20] According to these authors, the resonance effect is expected to lead to a positive value of the bond–bond interaction constant in AB_2 molecules. However, it appears to be necessary to consider other features of the electronic structure in order to explain why NO_2^- and O_3 should behave differently from HCO_2^- and SO_2. One feature in which NO_2^- and O_3 differ from HCO_2^- is in the nature of the orbitals on the central atom. Whereas the central atom in NO_2^- and in O_3 possesses a non-bonding orbital, the carbon atom in HCO_2^- does not have such a non-bonding orbital. In addition, the C–H bending mode (b_1) could influence the frequency of the asymmetric C–O stretching mode (b_1). In SO_2, Moffitt[23] has shown that the sulfur atom employs the 3d atomic orbitals in building the molecular orbitals, so that the sulfur atom can form a full double bond with each oxygen atom. The observed force constants (Table II) are in agreement with this. A full double bond between the central atom and both end atoms cannot occur in O_3 or in NO_2^-, since the oxygen and nitrogen atoms can employ only the 2s and the three 2p AOs in building the MOs. The bonding in SO_2 may therefore be quite different from the other molecules in which the central atom is C, O or N. It is possible that the electrons in the non-bonding orbital on the central atom in O_3 and in NO_2^- may actually make some contribution to the bonding. SCF–MO calculations would be needed to test this hypothesis. In OF_2, an additional important effect contributing to f_{dd} may be the repulsion of the non-bonding electrons on the F atoms. Electrostatic repulsions between non-bonded atoms should lead to a positive contribution to f_{dd}.[20]

In conclusion, it does not appear possible at the present time to explain the wide variation of f_{dd} in NO_2^- and O_3 relative to SO_2 and, presumably, HCO_2^-. Other similarities and differences can be reasonably well accounted for in terms of valence theory. As additional complete force constant data for simple molecules become available, through the use of isotopes of C, N and O and through analysis of the centrifugal distortion coefficients from microwave spectroscopy, it is hoped that a clearer account of the details of the bonding in simple molecules and the relation of the force constants and interaction constants to the molecular structure will eventually emerge.

The Dimethylamino Radical[1]

BY FRANCIS OWEN RICE AND CHESTER J. GRELECKI

RECEIVED DECEMBER 26, 1956

A paramagnetic violet solid is obtained by passing dilute vapors of tetramethyltetrazene ($(CH_3)_2N—N=N—N(CH_3)_2$) over a tungsten filament heated to about 1300° and then quickly condensing the products onto a liquid nitrogen-cooled surface. This material changes suddenly and irreversibly to a white solid when warmed to about −160°. The resulting mixture contains substantial quantities of tetramethylhydrazine which presumably results from the condensation of two dimethylamino radicals, $2\,(CH_3)_2N\cdot \longrightarrow (CH_3)_2N—N(CH_3)_2$. These results strongly suggest that the violet material is the dimethylamino radical. The violet material also was prepared by irradiating the vapors of tetramethyltetrazene with intense ultraviolet light and quickly freezing the products with liquid nitrogen.

Audrieth and Ogg[2] have reviewed the chemistry of hydrazine and point out that tetra-substituted tetrazenes exhibit thermal instability and when heated yield nitrogen gas and tetra-substituted hydrazines. For example, azyl radicals have been postulated[3] as the intermediate which condenses to form the substituted hydrazine as

$$R_2N—N=N—NR_2 \longrightarrow 2R_2N\cdot + N_2$$

$$2R_2N\cdot \longrightarrow R_2N—NR_2$$

Our experiments were designed to stabilize the intermediates formed during the vapor phase decomposition of tetramethyltetrazene by quickly freezing the products of the reaction with liquid nitrogen. Under the proper conditions we found that it was possible to stabilize a very reactive violet material which appeared to be stable indefinitely at −196° but which changed suddenly to a white solid when allowed to warm up to about −160°.

Experimental

In preparing tetramethyltetrazene the method of Renouf[4] was modified slightly. An ethereal solution of unsymmetrical dimethylhydrazine was oxidized with silver oxide. The powdered silver oxide was added at a rate such that the solution refluxed gently. After the required amount of oxidizing agent had been added, the mixture was cooled and the crude product was obtained by filtering the solution, drying it over anhydrous potassium carbonate and then removing the ether under reduced pressure. The product was distilled *in vacuo* and the fraction boiling at 25° at 12 mm. was collected.

The Thermal Reaction.—Tetramethyltetrazene vapors at low pressure (~0.1 mm.) were passed over a tungsten filament heated to between 1200 and 1300° as determined by an optical pyrometer. The rate of flow was about 10^{-4} moles per minute and after a few minutes, a violet deposit collected on a liquid nitrogen-cooled finger which was about 3 cm. from the hot filament. If the finger was brought closer to the wire, adverse radiation effects were encountered and no violet material was obtained. Preliminary experiments had shown that the violet material is not formed when tetramethyltetrazene is passed through a quartz furnace in the usual way. Indeed, even with a tungsten filament, the geometry of the apparatus is important in obtaining the violet deposit.

The permanent gases formed during this phase of the reaction were removed from the system by means of a high speed diffusion pump and were collected in a gas buret. A sample of these gases was analyzed on the mass spectrometer and the following results were obtained: % N_2, 70.5, 71.5; % H_2, 24.8, 23.6; % CH_4, 4.5, 4.7. In a typical experiment 1.16×10^{-3} moles of tetramethyltetrazene produced 0.74×10^{-3} moles of permanent gas. Thus each mole of tetramethyltetrazene used produced 0.45 mole of N_2. If one makes the reasonable assumption that the nitrogen is produced mainly by the reaction $(CH_3)_2N—N=N—N(CH_3)_2 \rightarrow 2(CH_3)_2N\cdot + N_2$, then under the conditions of this experiment about half of the tetramethyltetrazene escapes decomposition.

The deposit which collected on the filter was a violet, paramagnetic solid and its appearance did not change after standing for several hours at −196°. The liquid nitrogen was removed from the finger and liquid propane at −190° was added and allowed to warm up slowly. When the temperature reached −160° the violet color disappeared quite suddenly and a white deposit resulted. No permanent gas was evolved during this transition.

The deposit was then warmed to −78° and by means of a mass spectrometric analysis, it was found that traces of all three methylamines vaporized at this temperature. When the deposit was finally warmed to room temperature all of the material was in the vapor phase and a representative sample of the vapors was analyzed on the mass spectrometer. The mass spectrum of the products contained a peak at $m/e = 88$ which is characteristic of tetramethylhydrazine. The products also contained a substantial amount of undecomposed tetramethyltetrazene, and the ratio of the peak at $m/e = 116$, which is characteristic of the tetramethyltetrazene, to the peak at $m/e = 88$ was 1.14. The exact concentrations of these two substances cannot be obtained simply by a comparison of these peaks, since the ratio of the ion concentrations need not be the same as the ratio of the concentrations of the two materials present. It can, however, be concluded that both tetramethyltetrazene and tetramethylhydrazine were present in comparable concentrations.

The Photolytic Reaction.—The vapors of tetramethyltetrazene were passed through a quartz tube which was irradiated with a low pressure mercury lamp. The mercury lamp consisted of a quartz tube 12 mm. in diameter and six feet long (the tube was coiled spherically in six coils and was placed concentrically about the reaction chamber which also consisted of a quartz tube 12 mm. in diameter). The two electrodes consisted of tungsten to quartz seals and were sealed to the ends of the spiral. The lamp contained a few drops of mercury and a few mm. of an inert starter gas. The cold finger was located at the exit end of the reaction tube about 2.5 cm. from the last coil of the lamp.

The flow characteristics of the system were the same as in the experiments where the hot tungsten filament was employed, but in the photolytic case a much larger amount of material had to be used before a good colored deposit was obtained. This was because, in the photolytic reaction, only 2–3% of the tetramethyltetrazene, as determined by the amount of nitrogen formed during the reaction, was decomposed.

The deposit appeared to be identical with the product formed during the thermal decomposition on the tungsten filament. The transition to a white solid took place at −160° when the violet deposit was warmed slowly. In a blank experiment where all conditions were the same except that the lamp was not on, the deposit which collected was

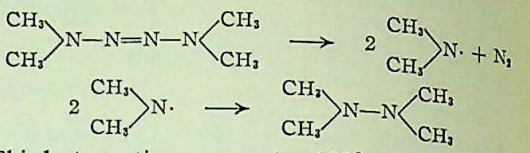
white and no transition could be observed when it was warmed to −160°.

The mass spectrum of the residue at room temperature indicated that a small but definite amount of tetramethylhydrazine was present in the products. The only other material which could be identified definitely was the undecomposed tetramethyltetrazene.

Discussion

The main products of the reaction were found to be nitrogen and tetramethylhydrazine and so it seems reasonable to assume that the following mechanism accounts for the main part of the reaction.



This last reaction occurs at −160° when the transition from violet to white is observed.

Rate Constants for the Recombination of Iodine Atoms in Liquid Hexane and Decane; Temperature Coefficient for the Recombination in Carbon Tetrachloride

BY SUKUMAR ADITYA[1] AND JOHN E. WILLARD

RECEIVED JANUARY 7, 1957

The rate constants for the combination of iodine atoms in CCl_4, n-C_6H_{12} and n-$C_{10}H_{22}$ at room temperature and in CCl_4 at 50° have been determined using flash photolysis techniques. The value of the constant is not greatly influenced by the chain length of the hydrocarbon solvent. The activation energy of the reaction in CCl_4 is about 3 kcal./mole.

By the methods of flash photolysis it is possible to measure directly the rates of atom recombination reactions. This has been done for iodine atoms[2] and bromine atoms[2c,2e] in the gas phase, as a function of temperature,[2b,2c] and for iodine atoms in carbon tetrachloride[2c,3,4] and heptane[3] solutions at room temperature. Values for the recombination rate of iodine atoms in carbon tetrachloride and in hexane have also been calculated[5] by combining photostationary state data[6] with quantum yield data,[5] and with lifetime measurements[7] made by the rotating sector technique. Values for the quantum yields for escape of iodine atoms from their parent molecular partnership have been determined both directly by flash photolysis[3,4] and by the use of a scavenger for iodine atoms.[5] Such data are gradually providing a more quantitative knowledge of the life history of atoms and radicals in solution.

In the present work the rate constants for the recombination of iodine atoms in hexane, decane and carbon tetrachloride at room temperature and in carbon tetrachloride at 50° have been determined by the flash photolysis method, using equipment and techniques similar to those reported elsewhere.[2c,4]

The solvents used were Mallinckrodt "AR low sulfur" carbon tetrachloride, Phillips "pure" grade hexane and Matheson decane. The hydrocarbons were further purified by fractional distillation and prolonged mechanical stirring with concentrated H_2SO_4, followed by washing and drying. They were degassed and transferred to the reaction cell under vacuum, the hexane being distilled through phosphorus pentoxide in the process.[8]

Solvent[a]	k, l. moles^{-1} sec.$^{-1}$ × 10^{-10} This work[b]	Marshall and Davidson[3]	Rabinowitch and Wood and Noyes and co-workers[5]	Strong and Willard[4]
CCl_4	0.69 ± 0.06	0.72 ± 0.01	0.84	0.57 ± 0.05[c]
CCl_4(50°)	1.03 ± 0.15			
n-C_6H_{12}	1.8 ± 0.6		1.56	
n-C_7H_{16}		2.2 ± 0.4	1.02	
n-$C_{10}H_{22}$	1.6 ± 0.4			

[a] All at room temperature except for the CCl_4 experiments at 50°. [b] The data are the average of 11 experiments for CCl_4 at 23°, 8 for CCl_4 at 50°, 32 for n-C_6H_{14} and 26 for n-$C_{10}H_{22}$. The limits given are the standard deviation. [c] The difference between this value and that obtained in the present work on the same instrument is of the order of the discontinuous instrumental variations previously described.[2e]

The results of this work and previous determinations of the rate constants (defined as k in $d[I_2]/dt = k[I]^2$) of atom recombinations in solution are given in Table I. Considering the difficulties of such experiments the degree of agreement between different workers and different methods for the carbon tetrachloride solutions and for similar hydrocarbons is gratifying.

Comparison of the rate constants which we have obtained in hexane and decane with each other and with the value of Marshall and Davidson[3] for heptane indicates that there is no large effect of chain length on the rate constant over this range. A small effect may exist within the error limits of these determinations.

Calculation of the apparent activation energy from the rate constants in CCl_4 at 23 and 50° gives a value of 3.2 kcal./mole. This is in the range which would be expected for a diffusion controlled process such as this. The activation energy for the diffusion of iodine molecules in CCl_4 has been found to be 3.3 kcal./mole.[9]

(9) E. W. Haycock, B. J. Alder and J. H. Hildebrand, *J. Chem. Phys.*, 21, 1601 (1953).

The activation energy found for the gas phase recombination of iodine atoms in the presence of argon is −1.4 kcal./mole,[2e] the negative value being ascribed to the decreasing stability of the two-body complex which is believed to play a role in the "three body" recombination process. In solution "third body" solvent molecules are always present so the rate of diffusion rather than the stability of the two body complex is rate controlling.

Kinetic Studies of Thiourea Derivatives. I. Methylthiourea

BY WILLIAM H. R. SHAW AND DAVID G. WALKER

RECEIVED DECEMBER 19, 1956

The decomposition of methylthiourea in aqueous media has been studied over a wide *p*H range. In acid solutions two parallel first-order reactions were observed and corresponding rate constants evaluated at several temperatures. Above *p*H 7 additional complicating reactions were encountered. The experimental results are compared with those previously reported for urea and thiourea. A possible mechanism is discussed.

Introduction

The isomerization of urea to ammonium cyanate has been investigated previously in this Laboratory.[1] Recently, analogous results were also reported for thiourea,[2] and the marked similarity of the two reaction systems noted. Since both reactions were found to be strictly first-order, presumably unimolecular, decompositions, it seemed desirable to obtain comparable data with related compounds. The present paper is the first in a series to be devoted to the kinetic study of urea and thiourea derivatives.

Although the fundamental organic chemistry of methylthiourea recently has been thoroughly discussed and reviewed by Sahasrabudhey and Singh,[3] no kinetic data on the decomposition of this compound could be found in the literature. Moreover, reasoning based on the mechanism previously postulated for the isomerization of thiourea indicated that the decomposition of the 1-methyl derivative should exhibit several novel features.

Experimental

Methylthiourea was prepared by the addition of ammonia to methyl isothiocyanate.[4] The crude product was recrystallized twice from water, m.p. 118.7–120.4° (lit.[4] m.p. 119–120.5°). Titration of weighed amounts of the purified material with standard mercuric nitrate[5] indicated that the compound was at least 99% pure.

Anal. Calcd. for $C_2H_6N_2S$: C, 26.60; H, 6.70; N, 31.07. Found: C, 26.65; H, 6.69; N, 30.82.

The apparatus and techniques utilized in this investigation were those employed in earlier work[1,2] except as noted below.

Reaction mixtures were analyzed for ammonia and methylamine by the following modification of the ion-exchange method previously described.[1,2,6] Samples of the reacted solutions were adjusted to *p*H 6–7 and passed through ion-exchange columns containing Dowex 50. After careful washing the adsorbed ammonium and methylammonium ions were eluted from the resin with dilute sodium hydroxide. After suitable *p*H adjustment separate aliquots were used to determine ammonia by nesslerization, and methylamine by a colorimetric analysis described in detail elsewhere.[7] The methylamine analysis was not affected by the amounts of ammonia present in the reaction mixtures. In the ammonia analysis, on the other hand, a moderate interference by methylamine was encountered. Suitable corrections could, however, be made by appropriate calibration of the Nessler reagent in the presence of the interfering substance. The average deviation of a set of 8 independent analyses of a 1.11 m*M* methylamine hydrochloride solution was 3.0%. Whereas the average deviation of a set of 8 analyses of 0.148 m*M* ammonium chloride that was also 0.286 m*M* in methylamine sulfate was found to be 4.4%.

Results

As in previous papers the reactions were studied by the method of initial rates. The equation

$$p_1/t = k_1\bar{u} \qquad (1)$$

was used in the analysis of experimental data. In this equation $\bar{u}$ is the average methylthiourea concentration; p_1 denotes the concentration of a particular product, P_1, formed in the reaction time, t; and k_1 is an empirical rate constant based on the rate of formation of P_1. Since very little reactant was consumed during the reaction period, $\bar{u}$ differed from the initial reactant concentration by less than 2%. The rates of formation of three reaction prod-

ucts: (1) thiocyanate ion, (2) ammonia and (3) methylamine were followed and corresponding empirical rate constants k_1, k_2 and k_3 were calculated by means of equation 1.

In acid solution all the k's were independent of reactant concentration and reaction time, establishing that the rates of formation of all products were first order with respect to methylthiourea. Measurements conducted with solutions varying in average methylthiourea ($\bar{u}$) from 44.5 to 444 mM, for reaction times from 11.8 to 24.8 hr. gave the following best values for the empirical first-order constants at 100.0 ±0.1°: k_1 = 0.57 ±0.07 × 10^{-7} sec.$^{-1}$, k_2 = 1.84 ±0.15 × 10^{-7} sec.$^{-1}$, k_3 = 2.49 ±0.25 × 10^{-7} sec.$^{-1}$. All of the experimental solutions used to obtain the above values were 0.01 M in H_2SO_4. The behavior of these constants with changing acidity of the media is displayed in Fig. 1. The constant based on the rate of thiocyanate production (k_1) was found to be independent of $\bar{u}$ and t in both acidic and basic solutions, nor was the magnitude of this parameter affected by pH changes over a very wide range. The behavior of the other two constants was considerably more complex. Above pH 7 these parameters were strongly dependent on pH, $\bar{u}$ and t. As indicated in the legend, the results plotted in Fig. 1 were obtained with a reactant concentration of 0.050 M and a reaction time of 36 hours.

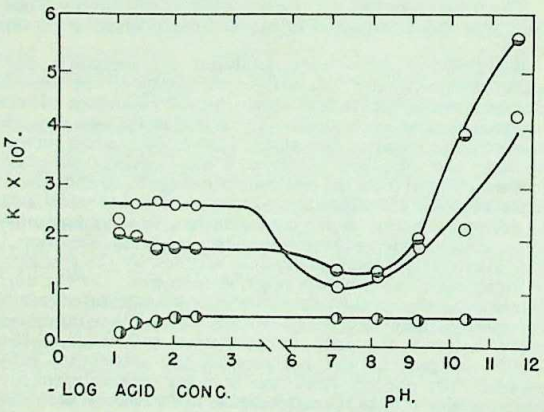

Fig. 1.—Empirical first-order rate constants as a function of acid concentration. The constants: k_1, k_2 and k_3 are based on the rate of formation of thiocyanate (◑), ammonia (◒), and methylamine (○), respectively. Runs above pH 7 were made in buffered 0.01 M borax solutions. Results recorded below pH 7 were based on data collected for HCl. All runs were made at 100.0 ± 0.1° at an initial methylthiourea concentration of 0.050 M and a reaction time of 36.0 hr.

The temperature dependencies of the constants based on thiocyanate production (k_1) and ammonia production (k_2) were also measured (Table I). These runs were made in acid media to eliminate the complexities mentioned in the preceding paragraph. The effect of ionic strength was likewise studied in media of low pH. Experiments were performed with solutions containing added sodium sulfate varying in concentration from 0.00 to 0.50 M at 100°. These solutions were also 0.01 M in H_2SO_4. A reaction time of 88.7 hr. was employed with an average methylthiourea concentration of 38 mM. No salt effects were observed.

As in the case of thiourea the reaction mixtures were subjected to a qualitative test for sulfide ion. Reacted samples obtained at all pH's studied were acidified (unless already acidic) and treated with mercuric nitrate solution. No precipitate was obtained with solutions that had reacted at pH's below 7, but those above pH 7 yielded a faint precipitate that became increasingly pronounced with increasing pH of reaction.

The rate constants recorded in Table I are reported to one more significant figure than is justified by the experimental data. The over-all average percentage deviations for k_1, k_2 and k_3 were approximately 10, 5 and 9%, respectively. Within a given run, however, much smaller deviations were encountered. In the extended reaction periods employed (as long as 89 hours) it was somewhat difficult to maintain precise temperature control, and, consequently, part of the lack of reproducibility from run to run could be attributed to this source of error. For these long reaction periods the temperature was controlled only to approximately ±0.1°.

TABLE I

RATE CONSTANTS OBTAINED AT VARIOUS TEMPERATURES IN ACID SOLUTIONS

Temp., °C. ±0.1	$\bar{u}$[a]	t[b]	First-order rate constants,[c] sec.$^{-1}$ × 10^7 k_1	k_2
	A. Medium, 0.01 M HCl			
100.0	49.3	29.5	0.65[d]	2.09[d]
110.1	49.2	9.82	2.40	7.55
120.2	48.8	4.00	8.13	24.8
130.0	48.3	1.90	24.7	68.8
140.0	46.7	1.40	86.0	197
	B. Medium, 0.015 M HNO_3			
100.0	100	6.55	0.62[d]	1.93[d]
110.0	49.5	6.17	2.30	7.02
120.0	24.4	4.58	8.20	25.1
130.0	9.43	3.62	28.1	74.0
140.0	8.96	2.78	78.9	169

[a] $\bar{u}$ is the average concentration of methylthiourea (millimoles/liter). [b] t is reaction time in hours. [c] The constants k_1 and k_2 are based on the rate of production of thiocyanate and ammonia, respectively. [d] For the least squares arrhenius analysis a value of 0.57 was used for k_1 and 1.84 for k_2 at this temperature. These values represent the average of all experimental data obtained at 100° whereas the values presented in Table I are based on 4 runs.

Discussion

The mechanism previously postulated for the thiourea decomposition assumed intramolecular hydrogen transfer and dissociation of the activated complex to form ammonia and thiocyanic acid. In this case hydrogen transfers from N to N′ and from N′ to N cannot be distinguished experimentally since the reaction products formed by both processes are identical. This degeneracy should, however, be removed in the decomposition of methylthiourea and different reaction products should result from these two different modes of hydrogen

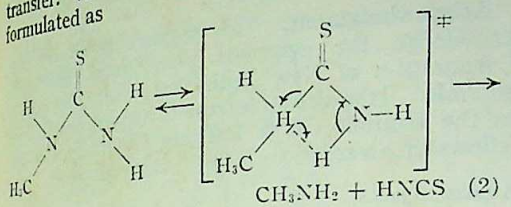
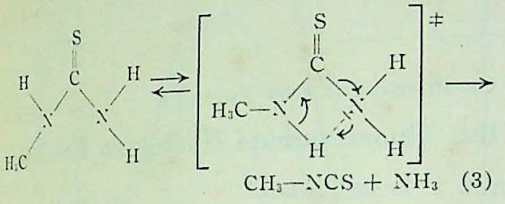
transfer. A tentative reaction scheme might be formulated as



$$CH_3NH_2 + HNCS \quad (2)$$



$$CH_3{-}NCS + NH_3 \quad (3)$$

Additional reaction by the products must also be considered.

$$HNCS \longrightarrow H^+ + NCS^- \quad (4)$$

$$CH_3 - NCS + H_2O \longrightarrow CH_3NH_2 + COS\uparrow \quad (5)$$

$$NH_3 + H^+ \rightleftharpoons NH_4^+ \quad (6)$$

$$CH_3NH_2 + H^+ \rightleftharpoons CH_3NH_3^+ \quad (7)$$

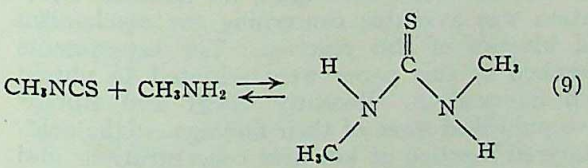
Since isothiocyanic acid is a strong acid,[8] equation 4 is written as an irreversible process. In acid, methyl isothiocyanate is converted[9] rapidly into methylamine and carbon oxysulfide (eq. 5). It follows, therefore, that the final products of reaction 2 in acid solution will be methylammonium ions and thiocyanate ions. From stoichiometric considerations the thiocyanate concentration produced by this reaction should be equal to the methylammonium ion simultaneously generated. Reaction 3 will yield ammonium and methylammonium ions in equimolar amounts. It becomes apparent, therefore, that the empirical first-order rate constant based on the production of thiocyanate, k_1, is the true rate constant for reaction 2. Similarly, k_3, based on ammonia production should be assigned to reaction 3. k_3, on the other hand, must be regarded as a composite constant; and, if the preceding reasoning is correct, it follows from the stoichiometry of reactions 2–7 that

$$k_3 = k_1 + k_2 \quad (8)$$

As previously mentioned (Results) the best values for the various constants at 100° are as follows: $k_1 = 0.57 \pm 0.07 \times 10^{-7}$ sec.$^{-1}$, $k_2 = 1.84 \pm 0.15 \times 10^{-7}$ sec.$^{-1}$, $k_3 = 2.49 \pm 0.25 \times 10^{-7}$ sec.$^{-1}$. It becomes apparent, therefore, that equation 8 correctly represents the experimental data. The decomposition of methylthiourea in acid solution must, consequently, be regarded as two parallel first-order reactions producing methylamine as a common product. The rate constant for these reactions can, however, be unambiguously assigned from experimental data on the rate of formation of other products (*e.g.*, SCN^- and NH_4^+).

A further examination of these results and those displayed in Table I reveals several points of interest. The rate constant (k_1) for reaction 2 is less than the constant (k_2) characterizing reaction 3. This generalization is true at all temperatures studied. Moreover, both of these constants differ significantly from the corresponding values reported for urea and thiourea particularly when statistical factors are also considered. In the most concentrated acid solutions studied (Fig. 1), k_1 falls off slightly and k_2 shows a corresponding increase. This same phenomenon was observed with thiourea and was attributed[2] to the conversion of thiocyanate to ammonium ion. With the addition of this known reaction, therefore, all the data obtained in acid solutions can be rationalized by the reaction scheme presented (equations 2–7). A least squares Arrhenius analysis of the data in Table I gave the following parameters describing the temperature dependence of k_1: $A = 9.87 \times 10^{14}$ sec.$^{-1}$, $E = 37.9$ kcal. Analogous parameters for k_2 are: $A = 3.37 \times 10^{13}$ sec.$^{-1}$, $E = 34.5$ kcal. The frequency factors and activation energies are reported to three figures solely for purposes of calculation of rate constants at various temperatures from the A and corresponding E. Because of the limited temperature range studied and experimental error (see Results) it is possible to select a wide variety of A's and corresponding E's that will give an adequate fit.

In solutions above *p*H 7 the empirical constants show a more complex behavior. As the hydrogen ion concentration is reduced, the equilibria described by eq. 6 and 7 will lie farther toward the left. The rate of conversion of methyl isothiocyanate to methylamine should also be diminished since this reaction is presumably acid catalyzed. Thus in media of slightly alkaline *p*H an increased ratio of methylamine to methylammonium ion should be encountered and methyl isothiocyanate should enjoy a longer lifetime than in solutions of greater acidity. Consequently, since the reverse of reaction 3 is a well known comparatively fast reaction, the decrease in k_2 and k_3 readily can be understood. The reaction



$$CH_3NCS + CH_3NH_2 \rightleftharpoons \quad (9)$$

is also most probably involved. Other evidence substantiates the existence of such complicating reactions. Thus, in alkaline media, the observed dependence of k_2 and k_3 on $\bar{n}$ and t can be interpreted on this same basis. In analogy to the thiourea case[2] the subsequent increase in these two empirical constants with increasing *p*H can be ascribed to the onset of a parallel base-catalyzed reaction that does not produce thiocyanate. The production of increasing amounts of sulfide precipitate (see Results) indicates, as before,[2] the onset of this reaction.

One rather striking aspect of the kinetic behavior of methylthiourea remains to be discussed—the remarkable *p*H independence of k_1. Since thiocyanic acid (unlike cyanic) is strong, the only species to be considered in water solutions in the *p*H range studied is the thiocyanate ion. However, according

to the mechanism presented, complicating reverse reactions occur through the un-ionized acid (see eq. 2 for example). Since no significant concentration of un-ionized thiocyanic acid is present in the solutions studied, the rate of thiocyanate production is independent of hydrogen ion concentration over a 10^9-fold change in this variable.

A more detailed theoretical account of the effect of methyl substitution on the rate of decomposition will be presented in the last paper of this series when additional data on other methylated thioureas has accumulated.

A Study of the Mechanism and Kinetics of the Thioacetamide Hydrolysis Reaction[1]

BY DONALD ROSENTHAL[2] AND T. IVAN TAYLOR

RECEIVED OCTOBER 3, 1956

The hydrolysis of thioacetamide to acetic acid, ammonia and hydrogen sulfide is catalyzed by both acids and bases. The base-catalyzed reaction was found to be the more rapid. Thioacetic acid was detected as an intermediate in both reactions. The relative importance of thioacetic acid and acetamide as intermediates is not known. A spectrophotometric investigation of the hydrolysis showed the rate of disappearance of thioacetamide to be first order with respect to thioacetamide concentration. The acid-catalyzed reaction was investigated in HCl and $HClO_4$ solutions at concentrations from 0.3 to 6 M at 35°. A maximum was observed in the first-order thioacetamide rate constant at an HCl concentration of about 4.5 M, and at an $HClO_4$ concentration of about 4 M. A mechanism involving the rapid and reversible addition of a proton followed by the rate-determining addition of water is consistent with the observed kinetics. The presence of a protonated thioacetamide ion in acid solution was detected spectrophotometrically. The observed first-order rate constants were not significantly different from those calculated using a rate expression $\log k = \log k_2K_1 + \log [H_3O^+] - \log(1 + K_1h_0) + BC$ derivable from the proposed detailed mechanism. In the above equation k is the first-order thioacetamide rate constant, h_0 is the antilog of minus the acidity function, C is the molar concentration of electrolyte, and K_1 and k_2 are simple or complex constants depending upon the detailed nature of the reaction. The BC term is presumably equal to the logarithm of an activity coefficients quotient. The maximum and observed rate constants for acetamide hydrolysis at 50° can also be explained in terms of a similar mechanism and rate expression.

Thioacetamide has been found useful in qualitative analysis[3] as a substitute for hydrogen sulfide gas.

The stoichiometric equation for the complete hydrolysis of thioacetamide is[4]

$$CH_3{-}\overset{\overset{S}{\|}}{C}{-}NH_2 + 2H_2O \longrightarrow CH_3{-}\overset{\overset{O}{\|}}{C}{-}OH + NH_3 + H_2S$$

When this study was begun, no detailed information was available concerning the mechanism and kinetics of this reaction. The experiments described in this paper were initiated to obtain such information. Recently, Swift and Butler[5] have published some of their findings on the acid-catalyzed reaction at low acid concentrations and elevated temperatures.

Intermediates in the Hydrolysis Reactions.—In the course of the hydrolysis reaction two chemical bonds must be broken, *viz.*, the carbon–nitrogen and carbon–sulfur bonds. Depending upon which bond is first broken, there are two possible intermediates in the reaction, thioacetic acid and acetamide. In both the base- and acid-catalyzed reactions thioacetic acid was found to be an intermediate. In the base-catalyzed reaction there was a gradual shift in the absorption maximum with time toward the wave length at which the thioacetate ion absorbs, 2450 Å. (see Fig. 1). In the acid-catalyzed reaction a substance was extracted which gave an identical spectrum to that of thioacetic acid when treated in the same manner (see Fig. 2). Acetamide has no characteristic absorption maximum above 2150 Å. and consequently could not be detected by these measurements.

The fact that thioacetic acid is an intermediate does not preclude the possibility that acetamide is also an intermediate, and that two competitive reactions are occurring. Indeed, Swift and Butler[5] were able to explain the observed change in pH upon the hydrolysis of thioacetamide at low acid concentrations and elevated temperatures by postulating acetamide as an intermediate. From the available evidence, it is not possible to evaluate the relative importance of acetamide and thioacetic acid as intermediates in the hydrolysis under the conditions of the experiments described herein.

Kinetics and Mechanism

Dependence of Rate upon Thioacetamide Concentration.—Preliminary experiments indicated that thioacetamide conforms to Beer's law for the range of concentration employed in these experiments, *ca.* 2×10^{-4} to 10^{-6} M, the absorption maximum at 2615 Å. being employed.

A plot of log absorbancy at 2615 A. *versus* time revealed the rate of the acid- and base-catalyzed

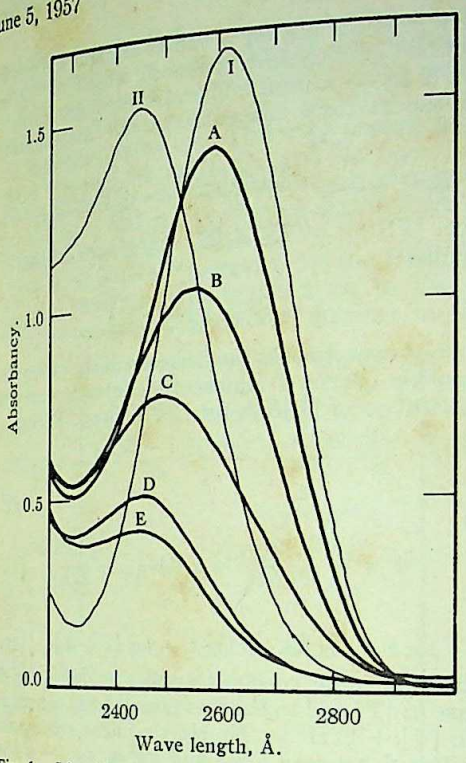

Fig. 1.—Identification of the intermediate in the base-catalyzed hydrolysis of thioacetamide; thioacetamide in 0.10 *N* NaOH: A, after 2.2 minutes; B, after 111 minutes; C, after 273 minutes; D, after 1521 minutes; E, after 7520 minutes; I, thioacetamide in water; II, thioacetic acid in water.

reactions to be first order with respect to thioacetamide concentration, *i.e.*

$$-d[T]/dt = k[T] \qquad (1)$$

where T = $CH_3-\overset{S}{\overset{\|}{C}}-NH_2$ (see Fig. 3).

The base-catalyzed reaction is much more rapid than the acid-catalyzed reaction (at 25° in 0.11 *M* NaOH k is 7×10^{-5} sec.$^{-1}$, in 0.1 *M* HCl k is 7×10^{-7} sec.$^{-1}$, and in distilled water $k < 4 \times 10^{-8}$ sec.$^{-1}$).

Dependence of Rate upon Hydrogen Ion Concentration.—A detailed investigation of the acid-catalyzed reaction at 35° revealed a non-linear increase of rate with increasing hydrogen ion concentration to a maximum at about 4.5 *M* HCl, or about 4 *M* $HClO_4$, and a subsequent decrease in rate (Tables I and III, column 2). Similar maxima have been found in the hydrolysis of amides[6] and in other cases.[7]

The cause and explanation of the amide maxima are not well understood.[6,8] Initially, the dependence of rate upon acid concentration at rates up to but not beyond the maximum will be considered. The maximum will be discussed in a later section of the paper.

If the rate-determining step in the hydrolysis

where M* is the critical complex in the Brønsted sense or a transition state in the absolute reaction rate theory. The rate is

$$-\frac{d[T]}{dt} = k_2[T][H_3O^+]\frac{f_T f_{H_3O^+}}{f_{M^*}} \quad (2)$$

where f refers to the molar concentration activity coefficients of the substance of the subscript. The thioacetamide rate constant is then

$$k = -\frac{1}{T}\frac{d[T]}{dt} = k_2[H_3O^+]\frac{f_T f_{H_3O^+}}{f_{M^*}} \quad (3)$$

from which

$$\log k = \log k_2 + \log [H_3O^+] + \log\frac{f_T f_{H_3O^+}}{f_{M^*}} \quad (4)$$

A plot of log k *versus* log $[H_3O^+]$ reveals that no simple linear relationship exists for the HCl or the $HClO_4$ catalyzed reaction (Fig. 4). That the last term is of importance was demonstrated by the

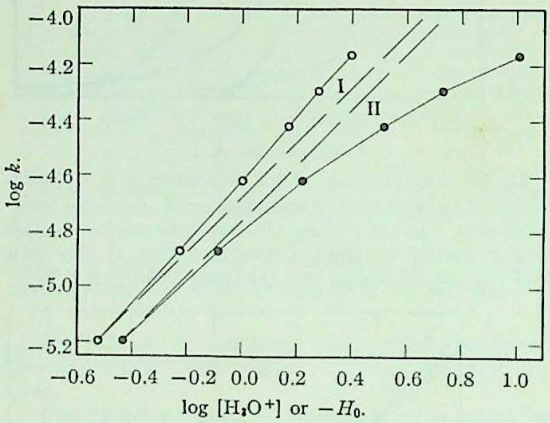

Fig. 4.—Plot of log k *vs.* log $[H_3O^+]$ and $-H_0$ for $HClO_4$ at 35°: ○, log k *vs.* log $[H_3O^+]$; ●, plot of log k *vs.* $-H_0$; I, plot of log k = log $[H_3O^+]$ + constant; II, plot of log $k = -H_0$ + constant. The experimental points are connected by straight lines.

significant increase in the rate of hydrolysis upon addition of NaCl to an HCl solution of thioacetamide (k was 6.79×10^{-5} sec.$^{-1}$ for a 1.45 M HCl–1.45 M NaCl solution at 35° compared to 4.29×10^{-5} sec.$^{-1}$ for a 1.50 M HCl solution). For acid concentrations below the maximum, the data could be represented reasonably well by eq. 4 by assuming the activity coefficients ratio to vary as a constant times the concentration of the acid as will be described later for another assumed mechanism.

A mechanism involving pre-equilibrium between thioacetamide and H_3O^+ followed by a unimolecular rate-determining step could be formulated as

$$T + H_3O^+ \overset{K_1}{\rightleftharpoons} TH^+ + H_2O \quad \text{(fast)}$$

$$TH^+ \rightleftharpoons (M^*) \xrightarrow{k_2} X^+ \quad \text{(slow)} \quad \text{(II)}$$

$$X^+ + H_2O \longrightarrow \text{products} \quad \text{(fast)}$$

The rate is

$$\frac{d(\text{products})}{dt} = -\frac{d([T] + [TH^+])}{dt} = k_2[TH^+]\frac{f_{TH^+}}{f_{M^*}} \quad (5)$$

$$= k_2K_1[T][H_3O^+]\frac{f_T f_{H_3O^+}}{f_{M^*}} = k_2K_1[T]h_0 \quad (6)$$

where h_0 is the antilog of minus Hammett's acidity function[9] applicable to cases in which M* differs from T by a proton. The rate constant k for the decrease in total concentration of thioacetamide, $[T] + [TH^+]$, is

$$k = \frac{1}{[T] + [TH^+]}\frac{d([T] + [TH^+])}{dt} = \frac{k_2K_1[T]h_0}{[T] + [TH^+]} \quad (7)$$

Since $[TH^+] = K_1[T][H_3O^+]f_T f_{H_3O^+}/f_{TH^+}a_{H_2O} = K_1[T]h_0$

$$k = k_2K_1h_0\left(\frac{1}{1 + K_1h_0}\right) \quad (8)$$

In our experiments the decrease in the concentration of the species T (thioacetamide) was measured. Substitution of $[T]K_1h_0$ for $[TH^+]$ in eq. 5 gives

$$-\frac{d([T] + [T]K_1h_0)}{dt} = -\frac{d[T](1 + K_1h_0)}{dt} = k_2K_1[T]h_0 \quad (9)$$

and

$$k = -\frac{1}{[T]}\frac{d[T]}{dt} = k_2K_1h_0\left(\frac{1}{1 + K_1h_0}\right) \quad (10)$$

or

$$\log k = \log k_2K_1 + \log h_0 - \log (1 + K_1h_0) \quad (11)$$

Thus, the same constant applies to both the decrease in [T] and to the decrease in total concentration, $[T] + [TH^+]$. No simple linear relationship was found between log k and log h_0, *i.e.*, $-H_0$ (see Fig. 4). If K_1 is sufficiently large, the inclusion of the last term in eq. 11 would result in a better fit than is obtained in Fig. 4, but this expression could only result in a limiting value of k equal to k_2 at large values of h_0 and would not explain the observed maximum.

Perhaps a more reasonable mechanism is one similar to that for the hydrolysis of the amides[10] in which the slow step is a bimolecular reaction between the protonated thioacetamide and water

$$T + H_3O^+ \overset{K_1}{\rightleftharpoons} TH^+ + H_2O \quad \text{(fast)}$$

$$TH^+ + H_2O \rightleftharpoons (M^*) \xrightarrow{k_2} \text{products} \quad \text{(slow)} \quad \text{(III)}$$

In this formulation, the transition state is one which differs from T, not only by a proton, but also by a water molecule. The rate is

$$\frac{d(\text{products})}{dt} = -\frac{d([T] + [TH^+])}{dt} = k_2[TH^+]\frac{a_{H_2O}f_{TH^+}}{f_{M^*}}$$

$$= k_2K_1[T][H_3O^+]\frac{f_T f_{H_3O^+}}{f_{M^*}} \quad (12)$$

and

$$-\frac{d[T]}{dt} = \frac{k_2K_1[T][H_3O^+]}{(1 + K_1h_0)}\frac{f_T f_{H_3O^+}}{f_{M^*}} \quad (13)$$

As shown previously, the rate constant determined from the decrease in total thioacetamide concentration ($[T] + [TH^+]$) or from the decrease in thioacetamide concentration is

$$k = k_2K_1[H_3O^+]\frac{1}{(1 + K_1h_0)} \times \frac{f_T f_{H_3O^+}}{f_{M^*}} \quad (14)$$

or

$$\log k = \log k_2K_1 + \log[H_3O^+] - \log (1 + K_1h_0) + BC \quad (15)$$

In eq. 15, $BC = \log f_T f_{H_3O^+}/f_{M^*}$, where B is a constant depending upon the nature of the non-electrolyte (thioacetamide) and the electrolyte (acid) present, and C is the "molar ionic strength" (acid concentration in moles/l.). This expression results from the fact that $\log f_T = B'C$ and $\log f_{H_3O^+}/f_{M^*}$ is relatively smaller in magnitude than the non-electrolyte term and can be written approximately equal to $B''C$ so that $B = B' + B''$.[11]

A plot of $\log k/[H_3O^+]$ *versus* C for the HCl and $HClO_4$ catalyzed reactions is presented in Fig. 5 for acid concentrations below the maxima in the rate of hydrolysis. In this plot, the data for each acid can be represented adequately by a straight line given by

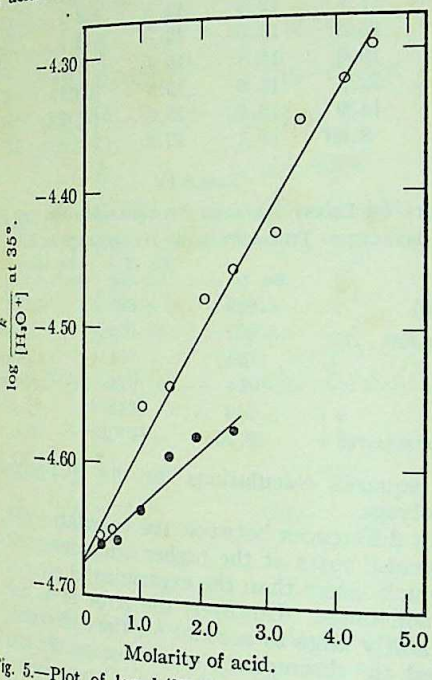

Fig. 5.—Plot of $\log k/[H_3O^+]$ *vs.* molarity of acid at 35°: k is the first-order thioacetamide rate constant in sec.$^{-1}$; O, HCl; ●, $HClO_4$.

$$\log k = \log k_2K_1 + \log[H_3O^+] + BC \qquad (16)$$

which is similar to eq. 4 except for the pre-equilibrium constant. The least squares values of the constants in eq. 16 were calculated and are given in the last columns of Tables II and IV. The experimental rate constants did not differ significantly from the values calculated using the least squares constants and eq. 16 as shown by the values in the next to the last columns in Tables I and III.

The least squares values of $\log k_2K_1$ are not significantly different for the HCl and $HClO_4$ data, while the B values are significantly different. This is expected since k_2 and K_1 should be independent of the acid used while the values of f_T and $f_{H_3O^+}/f_{M^*}$ may be different for acids with different anions. As the concentration of the acid approaches that for the maximum in the rate, this simplified eq. 16 does not satisfactorily represent the results.

(11) F. A. Long, F. B. Dunkel and W. F. McDevit, *J. Phys. Colloid Chem.*, **55**, 824 (1951).

Consideration of the Maximum.—Mechanism (III), usually referred to as A-2,[10] involves a pre-equilibrium in which TH^+ is in equilibrium with T (thioacetamide). Some evidence for the existence of the species TH^+ is presented in Fig. 6. In concentrated HCl solution a new absorption maximum appears at 2370 Å., presumably due to protonated thioacetamide (spectrum II, Fig. 6). Spectra III and IV demonstrate that this maximum is due to a species in equilibrium with thioacetamide and not to an irreversible intermediate in the reaction. A pK_1 of −1.76 was determined at room temperature (see Experimental section for details and assumptions involved in the calculations).

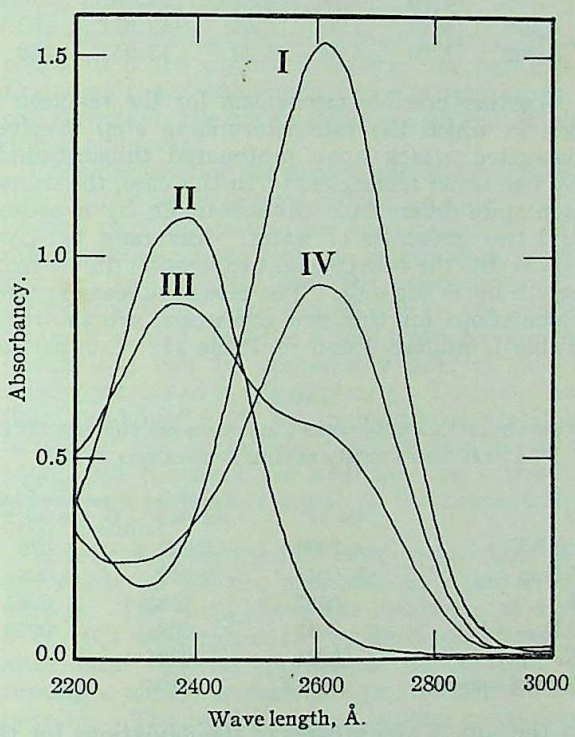

Fig. 6.—Spectrophotometric evidence for the existence of protonated thioacetamide: I, spectrum of *ca.* 6.4 × 10^{-5} *M* thioacetamide in water (2 cm. absorption cell); II, spectrum of *ca.* 6.4 × 10^{-5} *M* thioacetamide in 11.9 *M* HCl; III, spectrum of 1.6 × 10^{-4} *M* thioacetamide in 6 *M* HCl about 5 minutes after mixing (10 cm. absorption cell); IV, solution in III, diluted about one-half with water and run 16 minutes after original mixing.

The more complete expression for the rate constant for this mechanism (III) is given by eq. 15. Since h_0 increases more rapidly than $[H_3O^+]$ at the higher acid concentrations, the term $\log(1 + K_1h_0)$ becomes increasingly larger causing a decrease in k thus accounting for the observed maxima. The least squares values of the constants in eq. 15 were calculated for the $HClO_4$ data, including the data beyond the maximum. There are no significant differences between the experimental and the calculated rates employing the least squares values of the constants (Table I, column 3). The fact that the least squares value of K_1 of 0.028 is of the same relative order of magnitude as the value obtained at room temperature, 0.017, further supports the validity of the postulated rate eq. 15.

Another possible mechanism for the reaction is one in which the rate-determining step involves concerted attack upon protonated thioacetamide by two water molecules.[12] In this case, the transition state differs from thioacetamide by a proton and two molecules of water. Assuming $f_T f_{H_3O^+}/f_{M^*} = BC$ the rate constant expression differs from eq. 15 by + log a_{H_2O}. The results of least squares calculations for this new expression are shown in Table I, column 4 and in Table II. Comparison

TABLE II

RESULTS OF LEAST SQUARES CALCULATIONS FOR THE $HClO_4$ CATALYZED THIOACETAMIDE HYDROLYSIS AT 35°

Sum of squares	.00238	.0105	....

of the sum of the squares of the deviations for the bimolecular and termolecular expressions gives a ratio of 4.4 to 1. Assuming an F test can be applied to the results, it can be stated with 95% certainty that the bimolecular expression is significantly better than the termolecular expression in accounting for the observed results (F at the 95% level is 3.8).

Equation 15 is identical with eq. 16 when $K_1h_0 << 1$; *i.e.*, when the concentration of protonated thioacetamide is negligible compared to the concentration of thioacetamide. This was the assumption which was implicitly made in some of the earlier calculations. Comparison of the constants in Table II, columns 1 and 3 reveals that significantly different values of the least squares constants are obtained. Thus, despite the fact that the rates calculated assuming $K_1h_0 << 1$ are in good agreement with the experimental rates at hydrogen ion concentrations up to but not beyond the maximum, the constants so calculated are not in good agreement with the constants obtained from the more complete equation 15, nor is the assumption that $K_1h_0 << 1$ apparently valid.

Tables III and IV present the results of the

least squares calculations for the HCl-catalyzed hydrolysis.

The differences between the calculated and experimental rates at the higher acid concentrations are much larger than the experimental error of the rate constants. However, the error in h_0 may be sufficiently large to account for the differences,[13,14] so that the discrepancy is not necessarily attributable to the inadequacy of eq. 15. Comparison of the results of the least squares calculations reveals no significant difference between the results obtained assuming the bimolecular or termolecular expressions (ratio of sum of squares 1.1, F at 95% level is 3.2). While there was no significant difference between the log k_2K_1 calculated using eq. 15 and 16, there was, as in the $HClO_4$ calculations, a significant difference between the B values calculated from these two equations.

Summarizing the results for the $HClO_4$ and HCl hydrolysis reactions, the observed rates are consistent with the rates calculated assuming the mechanism (III) and rate expression 15. Further, the values of log k_2K_1 calculated from the $HClO_4$ and HCl catalyzed reactions are identical within experimental error; and the value of B for HCl is significantly different from the value for $HClO_4$. These results are what would be anticipated for the detailed reaction postulated. The values of K_1 calculated for the HCl and $HClO_4$ reactions are probably not significantly different, although it is difficult to obtain a good estimate of S.D.$_{K_1}$, and the values of K_1 are relatively of the same order of magnitude as the value calculated at room temperature.

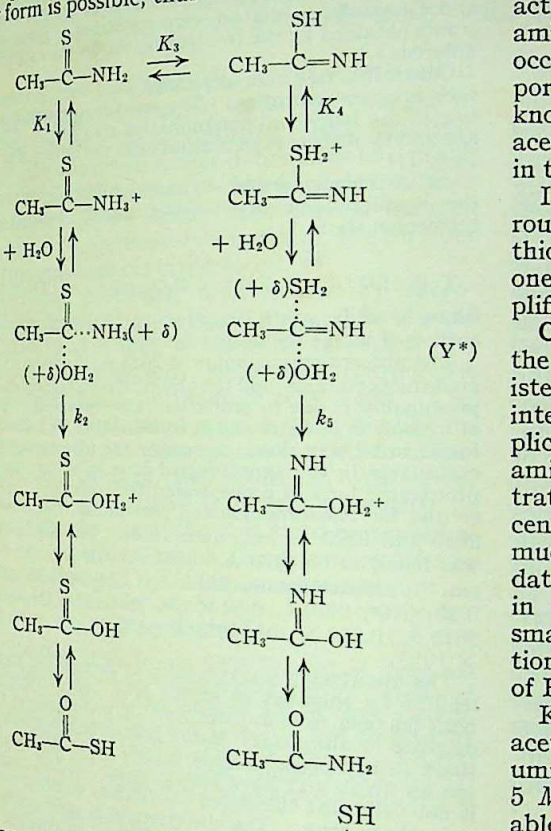
Consideration of Tautomerism, the Detailed Mechanism of Thioacetamide Hydrolysis.—One complication, which was neglected in the previous kinetic treatment, is that thioacetamide can be written in two tautomeric forms. The available evidence[15] seems to indicate that both forms are actually present in aqueous solution. Reaction *via* either form is possible, thus



It is assumed that species such as $CH_3\text{-}\overset{SH}{\overset{|}{C}}(OH)NH_2$ are present in negligibly small concentrations and do not affect the rate expression.

In terms of this mechanism the following rate expression (17) can be obtained

$$-\frac{dc}{dt} = k_2K_1\,[T][H_3O^+]\frac{f_T f_{H_3O^+}}{f_{M^*}} + k_5K_3K_4\,[T][H_3O^+]\frac{f_T f_{H_3O^+}}{f_{Y^*}} \quad (17)$$

where c is the sum of the concentrations of the two protonated and the two unprotonated species. Thus

$$c = [T] + K_3[T]\frac{f_T}{f_{TSH}} + K_1[T]h_0 + K_3K_4[T]h_0$$

where TSH is the thiolimido form of thioacetamide. Assuming the two activity quotients are equal, the expression is obtained

$$-\frac{d[T]}{dt} = \frac{(k_2K_1 + k_5K_3K_4)[T][H_3O^+]}{1 + K_3\frac{f_T}{f_{TSH}} + (K_1 + K_3K_4)h_0}\frac{f_T f_{H_3O^+}}{f_{M^*}} \quad (18)$$

Equation 18 is similar to eq. 13 except that the constants are now sums of products of more constants and the second term in the denominator is new. This expression can be written in a form identical with eq. 13, if $1 + K_3f_T/f_{TSH}$ is relatively constant under the conditions of the experiments, either because $K_3f_T/f_{TSH} << 1$ or because f_T/f_{TSH} is relatively constant. Further study is necessary before any detailed conclusions concerning eq. 17 and 18 can be drawn.

The detailed mechanism postulated leads to thioacetic acid as an intermediate product when reaction occurs *via* the thionamide form, and to acetamide as an intermediate product when reaction occurs *via* the thiolimido form. The relative importance of reaction *via* these two routes is not known and thus the relative importance of thioacetic acid and acetamide as intermediate products in the hydrolysis cannot be evaluated.

If the reaction proceeds predominantly by one route, or if the equilibria between the protonated thionamide and thiolimido forms is very much in one direction, the constants in eq. 18 can be simplified somewhat.

Consideration of the Hydrolysis of Amides.—In the hydrolysis of several different amides the existence of a maximum has been reported.[6] The interpretation of most of the kinetic data is complicated by the fact that the concentrations of amide employed were comparable to the concentrations of acid, and the actual hydrogen ion concentrations can be appreciably affected if very much protonated amide is formed. There are some data available[16,17] for the hydrolysis of acetamide in which the acetamide concentration is rather small and therefore the hydrogen ion concentration is approximately equal to the concentration of HCl added.

Kinetic data for the HCl-catalyzed hydrolysis of acetamide at 50° are presented in Table V, column 2. The rates above the maximum at 4 and 5 *M* HCl were calculated by extrapolating available data[17] to the appropriate temperature, assuming a simple Arrhenius type function was applicable. The results of least squares calculations are summarized in Tables V and VI.

TABLE VI

RESULTS OF LEAST SQUARES CALCULATIONS FOR THE HCl-CATALYZED ACETAMIDE HYDROLYSIS AT 50°

	Eq. 15	Eq. 15 + log a_{H_2O}	Eq. 15 assuming log $(1 + K_1h_0) = 0$
log k_2K_1	−3.966	−3.967	−3.960
S.D.$_{\log k_2K_1}$	<0.017	<0.005	0.006
B	− .0994	− .0832	− .1206
S.D.$_B$	< .0034	< .0034	.0059
K_1	.0147	.0121	....
Sum of squares	.00250	.00254	....

eq. 15 are in good agreement with each other (Table V, columns 2 and 3). The results assuming the bimolecular expression are not significantly better than those assuming the termolecular expression (ratio of sum of squares in Table VI is 1.02, F at the 95% level is 3.4). The B values calculated from eq. 16 using data only up to the maximum and from eq. 15 are significantly different from each other, but there is no significant difference between the log k_2K_1 values. Here, as before, the assumption which is implicitly made in using eq. 16 to describe the rate data up to the maximum, *i.e.*, $K_1h_0 << 1$, is not valid. The importance of looking for the presence of a maximum and considering the concentration of protonated species which may be present, whenever a mechanism such as (III) is proposed, is readily apparent from the present studies. Such considerations may be useful in distinguishing between mechanisms (I), (II) and (III). The presence of a maximum is not consistent with mechanism (II) and is only consistent with (I) if B is negative. A careful consideration of eq. 15 and 4 may be necessary to distinguish between mechanisms (I) and (III) unless the protonated species can be detected in substantial concentration.

Experimental Details and Calculations

Reagents.—Eastman Kodak Co. white label brand thioacetamide was purified by recrystallization from benzene. The resulting material was white in color and had a melting point range of 109.8 to 111.9°.

Reagent grade HCl and $HClO_4$ were employed.

Rate Measurements.—The following general procedure was employed in all the rate determinations at 35° with only minor modifications in specific instances. The reaction was initiated by bringing both reactants to 35° in a thermostated water-bath, mixing them together and then transferring the reaction mixture to a 10-cm. quartz cell in a specially designed thermistor controlled thermostated Beckman spectrophotometer compartment (to be described elsewhere). The temperature in this compartment was controlled at 35 ± 0.1°. Sufficient time (*ca.* 45 minutes) was allowed for the reaction solution to return to 35° before readings were taken.

The initial concentration of thioacetamide employed in these experiments was about 1×10^{-5} M. Absorbancy readings at 2615 Å. were taken five at a time, 200 seconds apart, at selected time intervals during the course of the reaction with a Beckman D.U. spectrophotometer. The time intervals were selected so that readings could be taken over a time period of several half-lives.

Upon completion of the experiment, a known volume of the reaction mixture was titrated with a standardized solution of sodium hydroxide to a methyl red–brom cresol green end-point, and the concentration of acid computed.

In some instances the absorbancy readings were corrected by determining the correction due to solvent or cell differences between the reaction and reference cells. In other instances the Guggenheim method[18] was employed to eliminate this source of error. The first-order rate constants were determined in each case by the method of least squares. At two different acid concentrations both the cell correction and Guggenheim method were employed. The rate constants obtained by the two techniques were not significantly different.

Generally, two rate determinations were performed at each acid concentration. The standard percentage deviation of the individual determination was 2.9%. The average values of these experimental rates are reported in Tables I and III.

pK of Thioacetamide.—The stoichiometric equation for the equilibrium between thioacetamide and protonated thioacetamide is

$$T + H_3O^+ \underset{}{\overset{K_1}{\rightleftharpoons}} TH^+ + H_2O \text{ and } K_1 = [TH^+]/[T]h_0$$

where $h_0 = f_T a_{H_3O^+}/f_{TH^+} a_{H_2O} = [a_{H^+}(f_T/f_{TH^+})]$ and h_0 is the antilog of minus the acidity function.

The absorption maximum at 2615 Å. is due to unprotonated thioacetamide, and the absorption maximum at 2370 Å. presumably is due to protonated thioacetamide. The rate of hydrolysis in water and in concentrated HCl solution was found to be very slow. Assuming the thioacetamide exists exclusively in the unprotonated form in water, and in the protonated form in concentrated HCl solution, the absorptivities for thioacetamide and protonated thioacetamide at 2615 and 2370 Å. were determined. The isosbestic point was found to be 2470 Å. (Absorptivities in liters mole^{-1} cm.$^{-1}$: thioacetamide, 2615 Å., 1.17×10^4; 2370 Å., 0.22×10^4; 2470 Å., 0.62×10^4; protonated thioacetamide, 2615 Å., 0.080×10^4; 2370 Å., 0.88×10^4; 2470 Å., 0.62×10^4.)

The absorbancy was measured at each of the three wave lengths for solutions of known HCl concentration where both maxima were in evidence. It was assumed that the decrease in absorbancy at the isosbestic point was due entirely to hydrolysis and not in any way due to tautomeric species which may have been present. If this assumption is not valid, the calculated equilibrium constants could be seriously in error. The absorbancies in each solution were multiplied by the appropriate factors to correct for hydrolysis. In 4.30 M HCl log $[TH^+]/[T]$ was −0.49 (2615 Å.), −0.25 (2370 Å.); log K_1 was −2.00 and −1.76, respectively. In 5.52 M HCl log $[TH^+]/[T]$ was 0.15 and 0.438; log K_1 was −1.79 and −1.50. $\overline{\log K_1} = -1.76$ and S.D.$_{\overline{\log K_1}} = 0.10$.

Calculation of the Least Squares Constants for Equation 15.—Since eq. 15 contains the non-linear term log $(1 + K_1h_0)$, simple linear regression methods cannot be employed. What was done was to assume a value for K_1, to evaluate log $(1 + K_1h_0)$ and then to calculate the least squares value of B and log k_2K_1 for the linear expression

$$(\log k + \log (1 + K_1h_0) - \log [H_3O^+]) = \log k_2K_1 + BC$$

The sum of the squares of the deviations of the experimental log k minus the calculated log k was computed. This operation was repeated for various values of K_1 and in this way those values of the constants K_1, B and log k_2K_1 for which the sum of the squares of the deviations was a minimum were computed. An estimate of S.D. of log k_2K_1 and B was calculated from the linear expression, in which it is assumed there is no error in K_1. The "true" S.D. is presumably less than these estimated values.

The Microwave Spectra and Structure of CF_2=CH_2, CF_2=CHD and CF_2=CD_2

BY WALTER F. EDGELL, PHILIP A. KINSEY[1] AND JONATHAN W. AMY

RECEIVED OCTOBER 27, 1956

The K-band microwave spectra of CF_2CH_2, CF_2CHD and CF_2CD_2 have been recorded and analyzed. With the assumptions that $\angle HCH=DCD = 120°$ and $r_{CD} = r_{CH} = 0.009$ Å., the following structural parameters have been calculated: $r_{CF} = 1.321 \pm 0.005$ Å., $r_{CC} = 1.311 \pm 0.005$ Å., $\angle FCF = 109° 15' \pm 25'$, $r_{CH} = 1.10 \pm 0.05$ Å.

The structure of CF_2CH_2 is of interest since it provides further information as to the changes in molecular configuration resulting from multiple fluorine substitution in simple hydrocarbons. Such information for the series of fluorinated methanes was summarized by Lide[1]; the carbon–halogen bonds become progressively shorter as the number of fluorine substituents is increased.

CF_2CH_2 has previously been studied by microwave spectroscopy[2] and by electron diffraction.[3] It was felt that it was worthwhile to repeat the microwave investigation, since the frequencies were measured to an accuracy of only 3 mc. The spectra of the deuterated species were studied to reduce the number of assumptions needed to calculate the structure of the molecule. However, with the data given here it is still necessary to assume a value for one of the structural parameters, and for the extent to which the geometry of the molecule is changed by isotopic substitution.

Experimental

The CF_2CH_2, CF_2CHD and CF_2CD_2 used in these experiments were part of the samples prepared by Edgell and Ultee[4] for the study of the infrared and Raman spectra. The purity of the CF_2CD_2 and CF_2CHD was checked by mass spectrographic analysis. The per cent. of CF_2CHD in CF_2CD_2 was 5.3%. The main impurity in CF_2CHD was 2% of CF_2CH_2. There was also evidence of about 0.4% of CF_2CD_2.

Observations were made with a Stark-effect sweep spectrometer of the Hughes–Wilson type[5] using a 100 kc. square wave for modulation.

	CF_2CH_2 Obsd.	CF_2CH_2 Calcd.
A	11,000.8	11,000.8
B	10,428.8	10,429.5
C	5,345.6	.....
$\Delta = I_C - (I_A - I_B)$	0.234	
$\kappa =$	0.79771	

The modulating voltages ranged up to about 800 practical volts. All measurements were made in a 10 ft. K-band wave guide absorption cell at Dry Ice temperature. 1N26 crystal detectors were used and a Bendix radio range compass (ARN-7) was modified for use as a receiver. The sensitivity of the system was sufficient to detect NH_3 lines with an intensity of 1×10^{-7} cm.$^{-1}$.

Frequency measurements were made using harmonics from a UHF signal source[6] which was calibrated by comparison with the standard frequencies broadcast by station WWV. It is felt that the frequencies given are accurate to ±0.3 mc., unless otherwise noted.

Analysis of the Spectra; CF_2CH_2.—As pointed out by Roberts and Edgell,[2] CF_2CH_2 is an oblate slightly asymmetric rotor, and to account for the microwave spectrum the dipole must be along the axis of the least moment of inertia. The two Q branch transitions which would be observed for the limiting symmetric rotor each split into a series of lines as a result of the asymmetry. The band heads of these two sub-branches are near 26,700 mc., and one series extends to higher, one to lower frequencies. In addition two R transitions should be found in the region near these Q sub-branch band heads. The whole region should also be covered with lines originating from high J transitions, or from other Q sub-branches whose origins are outside the region of observation.

An initial search of the region from 17,000 to 30,000 mc. yielded approximately 80 lines. Stark patterns indicated that most of these lines had fairly high J-values. Analysis of the spectrum essentially confirmed the assignments previously made.[2] In addition the $2_{02} \rightarrow 3_{03}$ and $2_{12} \rightarrow 3_{13}$ lines were found at the frequencies predicted on the basis of these assignments, and displayed the expected resolved Stark patterns. Table I gives the calculated and observed frequencies of all identified transitions. The observed but unidentified lines for CF_2CH_2 are listed in Table II. The rotational constants are (in mc./sec.) (table).

CF_2CD_2.—More than 50 lines were found in the spectrum of CF_2CD_2 in the region from 19,000 to 35,000 mc. Although it was possible to calculate the general pattern of the spectrum from the assumed model, the great density of lines in the spectrum made an unambiguous assignment of individual transitions difficult. The analysis was greatly facilitated by the fact that the $1_{01} \rightarrow 2_{02}$ and $1_{11} \rightarrow 2_{12}$ lines could be identified on the basis of their Stark patterns. Table I shows the observed and calculated frequencies based on the rotational constants given above.

5,086.7	.....	4,855.9	.....
0.262		0.235	
0.52692		0.44326	

CF_2CHD.—About 80 lines were seen in the spectrum of CF_2CHD in the region from 18,000 to 36,000 mc. After identifying the $1_{01} \rightarrow 2_{02}$ transition on the basis of its Stark pattern, the analysis was completed by assignment of Q branch transitions. The observed and calculated frequencies

[a] These lines were measured with an accuracy of ±1 mc.

based on the rotational constants above are given in Table I.

Structural Parameters.—For a planar molecule, the moment of inertia about the axis perpendicular to the plane should equal the sum of the other two moments. As a result of zero-point vibrations, this holds only approximately for actual molecules; the small value of the "defect" $\Delta = I_C - (I_A - I_B)$ given above confirms the assumed planarity of CF_2CH_2.

The moment of inertia around the C–C bond in CF_2CH_2 is a function of only two parameters: r_{FF}, the distance between fluorine atoms and r_{HH}, the distance between hydrogen atoms. With the assumption that the geometry of the molecule is unchanged by isotopic substitution one can calculate r_{FF} and r_{HH} directly from the A moments of inertia for CF_2CH_2 and CF_2CD_2. Since this assumption can only be approximately true, it seemed preferable to assume instead a value for δ, the shortening of the C–H distance with deuterium substitution. The value chosen was 0.009 Å., in agreement with the results of Miller, *et al.*,[7] for the methyl halides; it seems unlikely that δ would differ from this value by more than a few thousandths of an ångström. In these calculations it is assumed that the HCH angle is near 120°; the results are almost independent of the precise value.

r_{FF} proves to be very insensitive to δ, changing by only 0.002 Å. if δ is changed from 0 to 0.009 Å. The best value of r_{FF} is 2.154 Å.

The r_{HH} and r_{DD} distances, of course, are more sensitive to δ: for $\delta = 0$, $r_{HH} = r_{DD} = 1.881$ Å.; for $\delta = 0.009$ Å., $r_{HH} = 1.912$ Å., $r_{DD} = 1.897$ Å.

The B moment of inertia of CF_2CH_2 depends on three parameters which may be taken as the projection of the CF distance on the CC axis, the C–C distance and the HCH angle. Although three isotopic species were available, the equation relating the observed moment to these parameters for CF_2CHD is nearly a linear combination of the corresponding equations for CF_2CH_2 and CF_2CD_2, and gives no additional information. It is therefore necessary to assume a value for one parameter in order to determine a structure.

As a result of the small mass of the H atom, the moment depends only slightly on any assumption made about the configuration of the CH_2 group. If the HCH angle is chosen as 120° for all isotopic species, and the isotope effect on the CH distance

is the same as assumed above, the resulting parameters are those given below along with the results of the electron diffraction study.[3]

	This research	Electron diffraction[3]
∠FCF	109° 15′ ± 25′	110°
C-F	1.321 ± 0.005 Å.	1.321
C-C	1.311 ± 0.005 Å.	1.311 ± 0.035 Å.
∠HCH	120° (assumed)	117° ± 7°
C-H	1.10 ± 0.05 Å.	1.07 ± 0.02 Å.

The CH distance corresponding to our choice of the HCH angle is 1.10 Å. A change in the angle of 9° changes the CH distance by 0.05 Å., but only changes the other parameters by less than 0.005 Å. Thus the microwave data still leave the geometry of the CH_2 group somewhat uncertain, but defines the remaining parameters quite precisely, since the actual HCH angle can hardly be expected to differ so greatly from 120°.

The measured FCF angle is nearer to the tetrahedral value than to that of 120° expected on the usual assumption that the σ-bonds are formed with sp^2 hybrids. It is interesting to note that near-tetrahedral values of the corresponding angle are not unusual in the substituted ethylenes, though the angle reported for ethylene itself[8] is 119° 55′. The particularly small value of the FCF angle is also in line with that reported[1] for CH_2F_2.

Comparison of the C–C distance with that found for ethylene[8] indicates that there is appreciable triple-bond character in the bond, an effect that may be associated with the closing of the FCF angle.

Acknowledgment.—The authors would like to thank Dr. Norbert Muller for many helpful discussions and the Purdue Research Foundation, acting under Contract No. AT(11-1)-164 of the Atomic Energy Commission, who supported this research.

Experimental Investigation of the Distribution of Salicylic Acid between Cyclohexane and Water

BY JOHN J. BANEWICZ, CHARLES W. REED AND MARK E. LEVITCH

RECEIVED JANUARY 10, 1957

The distribution of salicylic acid between water and cyclohexane was investigated at various temperatures from 24.00 to 55.00° and at concentrations from 10^{-4} to 10^{-2} mole per liter in water and cyclohexane. The concentrations were determined spectrophotometrically. In the more dilute concentrations, the dimerization of salicylic acid in cyclohexane was found to be negligible; and from the data in this region the ionization and distribution constants were obtained. In the more concentrated regions the dimerization became appreciable; and from the data in this region the dimerization constant was calculated. With these constants known as a function of temperature, the heats, entropies and free energies of dimerization, distribution and ionization were calculated.

In spite of the numerous references to salicylic acid in the literature there are very few data on the dimerization of salicylic acid in non-polar solvents. By studying the distribution of salicylic acid between cyclohexane and water not only can the distribution coefficient be obtained, but also the ionization constant of the salicylic acid in water and the dimerization constant in cyclohexane. Furthermore if determinations are made at different temperatures the various enthalpy, free energy and entropy changes can be calculated.

Experimental

Materials.—Matheson practical grade cyclohexane was used. The cyclohexane was purified by passage through a column of activated silica gel in accordance with the procedure of Graff, O'Conner and Skau.[1] Salicylic acid was recrystallized from cyclohexane and then sublimed.

Spectrophotometric Measurements.—The concentrations of salicylic acid in both the cyclohexane and water layers were determined spectrophotometrically using a Beckman DU spectrophotometer. For each solvent, solutions of known concentration were prepared ranging from 10^{-4} to 10^{-2} mole per liter. The standard solutions in each solvent were saturated with respect to each other. Salicylic acid has absorption maxima in water at 231 and 296 mμ and in cyclohexane at 240 and 310 mμ. Beer's law was obeyed at all four peaks.

The following equations were found to relate A, the absorbance, to C_g, the concentration of salicylic acid in grams of acid per gram of solvent

Water	231 mμ	$C_g = 2.09 \times 10^{-5} A$
Cyclohexane	240 mμ	$C_g = 2.08 \times 10^{-5} A$
Water	296 mμ	$C_g = 3.96 \times 10^{-5} A$
Cyclohexane	310 mμ	$C_g = 4.32 \times 10^{-5} A$

All readings were taken in triplicate with an average variation of 0.002 absorbance units.

Distribution Method.—Preliminary measurements were made to determine the approximate relation between equilibrium concentrations of the aqueous and cyclohexane solutions of salicylic acid. With this information seven different mixtures were made up with concentrations varying from about 10^{-2} to 10^{-4} mole per liter. The mixtures were placed in glass-stoppered Pyrex bottles in a constant temperature bath and allowed to equilibrate for three days with occasional shaking. At the end of this time samples were withdrawn from each layer, diluted by weight if necessary to bring the concentration into the spectrophotometric range, and the absorbance determined.

This procedure was repeated daily until constant concentration values were obtained. Almost always equilibrium was obtained within a three-day period. Using the known dilution factor, the concentrations of salicylic acid in the water and cyclohexane layers were calculated. The concentrations were converted to moles per liter, assuming the solutions to be so dilute that the solvent and solution densities could be considered identical.

This procedure was repeated for all the solutions at seven different temperatures, 24.00, 29.50, 32.00, 36.00, 40.05, 47.13 and 55.00°. The temperature was controlled to within 0.01° by a Sargent Thermonitor unit.

Results

Representative data obtained for the 24.00° run are shown in Table I. Calculations of the

TABLE I

DATA OBTAINED CORRELATING CONCENTRATION OF SALICYLIC ACID IN WATER AND IN CYCLOHEXANE FOR TEMPERATURE OF 24.00°

Mixture	Molar concn. (moles/l.) C_w	C_c	C_w/C_c	$\sqrt{1/C_c}$
I	0.000650	0.0000261	35.3	183
II	.00135	.0000443	30.4	147
III	.00197	.0000758	26.0	115
IV	.00328	.000218	15.0	67.7
V	.00648	.000753	8.61	36.5
VI	.00777	.00106	7.33	30.7
VII	.00857	.00129	6.63	27.8
VIII	.0152	.00601	3.80	15.9

various equilibrium constants from these data were considerably simplified when it was found that at the most dilute concentrations the dimerization of salicylic acid in cyclohexane was negligibly small.

The three equilibria involved are, first the ionization of salicylic acid in water, second the dimerization of salicylic acid in cyclohexane, and last the distribution of the undimerized and undissociated salicylic acid between the water and the cyclohexane layers. If C_w is the spectrophotometric value obtained for the total concentration in moles per liter of the salicylic acid in water and a represents the moles per liter of the acid which have ionized, then the ionization constant, K_i, may be written as

$$K_i = \frac{a^2}{C_w - a} \qquad (1)$$

In the cyclohexane layer, if C_c represents the total concentration of acid and b the concentration of single molecules which have associated in moles per liter then the dimerization constant, K_{dim}, is

$$K_{dim} = \frac{1/2\, b}{(C_c - b)^2} \qquad (2)$$

The distribution constant, K_d, which involves undissociated and undimerized salicylic acid then becomes

$$K_d = \frac{C_w - a}{C_c - b} \qquad (3)$$

When the concentration of acid in cyclohexane is so low that b may be assumed to be negligibly small compared to C_c then (3) becomes

$$K_d = \frac{C_w - a}{C_c} \qquad (4)$$

Under these conditions equations 1, 2 and 4 may be combined to give

$$\frac{C_w}{C_c} = K_d + \sqrt{\frac{K_i K_d}{C_c}}$$

Hence, if dimerization can be neglected in the regions of extreme dilution a plot of C_w/C_c *vs.* $\sqrt{1/C_c}$ should be linear with a slope of $\sqrt{K_i K_d}$ and an intercept of K_d.

In Fig. 1 the curves obtained at the various temperatures are shown. Values of K_d and K_i were calculated from the linear portion of each plot; and then with these values, from the data in the curved region, the K_{dim}' s were calculated. These are shown in Table II.

TABLE II

EQUILIBRIUM CONSTANTS INVOLVED IN THE DISTRIBUTION OF SALICYLIC ACID BETWEEN CYCLOHEXANE AND WATER

Temp., °C.	Ionization constant $K_i \times 10^{-3}$	Distribution coefficient K_d	Dimerization constant K_{dim}
24.00	1.78	10.4	1393
29.50	2.32	7.25	619
32.00	2.68	6.42	446
36.00	3.18	5.05	243
40.05	3.91	3.98	143
47.13	5.18	2.80	61.0
55.00	6.88	1.83	23.7

The plots of log K *vs.* $1/T$ for each of the equilibrium constants gave good straight lines. The average deviation of the points from a straight line in each case was less than five parts per thousand. From the slopes of these lines, the corresponding values of $\Delta H°$ were calculated in accordance with the van't Hoff equation. These are listed in Table III. Values of $\Delta F°$ and $\Delta S°$ were also calculated and are included in Table III.

Discussion

Most of the previous determinations of the ionization constant of salicylic acid in water have been made at 25°.[2,3,4,5,6] All of the values noted by different investigators lie close to 1.0×10^{-3} at this temperature, while in this investigation 1.9×10^{-3} was observed. The reason for this difference is not known. It does not seem likely that the small amount of cyclohexane dissolved in the water would be enough to give rise to appreciable error. Also, since the value of K_i was obtained in the extremely dilute solution region, any discrepancy cannot be attributed to the deviation of the activity coefficients from unity. The heat of ionization is also much greater than that reported by Bradley and Lewis.[4] There are several excellent review articles concerned with the hydrogen bond and dimerization in which thermodynamic con-

55.00	3250	−395	−2068	14.9	−30.8	−68.4

stants are calculated and experimental methods discussed.[7-9] One objection to the distribution method is the possibility that the small amount of water present in the organic layer will form a hydrate with the acid being studied, increasing the solubility of the acid appreciably over that in the anhydrous organic solvent (see Lassettre[7]). Consequently, the solubility of salicylic acid in both anhydrous and water-saturated cyclohexane was investigated, but no significant difference found. Another objection is that the solvent in which the dimerization is taking place will influence the dimerization to some extent, and therefore the values obtained from solution studies will not necessarily agree with those from vapor studies. Indeed, the fact that the acid dissolves in the solvent indicates that some interaction between the two must take place and that the acid molecules will be partially solvated. Moelwyn-Hughes, Davies and their colleagues[10,11] have found that the magnitude of this effect is a function of the dielectric constant of the solvent, with the values of the heat and entropy of dimerization obtained by distribution methods approaching the vapor method values as the dielectric constant of the solvent decreases. In this respect cyclohexane should give better values than benzene or carbon tetrachloride.

Allen and Caldin have compiled values for the entropy and enthalpy changes involved in the dimerization of many different acids. For aliphatic acids, vapor phase measurements give values of $\Delta S°$ of about −36 e.u., and for $\Delta H°$ about −14 kcal./mole. They found that the value of $\Delta S°$ was in good agreement with the value based on the change in translational and rotational degrees of freedom in dimerization. In solution, as expected, the values are higher, $\Delta H°$ being about −8 kcal./mole and $\Delta S°$ ranging from −15 to −22 e.u. with concentrations expressed in moles/l. units or −21 to −28 in atmospheres. This variation in the entropy change then gives a measure of the increase in order of the monomers due to partial solvation.

Relatively little work has been done on aromatic acid. Many years ago Hendrixson[12] measured the $\Delta H°$ for both benzoic acid and salicylic acid by the investigation of the distribution of these acids between water and benzene, and water and chloroform. The values of $\Delta H°$ obtained for benzoic acid were −8.35 kcal./mole for the chloroform and −8.71 kcal./mole for the benzene systems. These values are in good agreement with those determined later by other investigators using different methods.[13,14]

The values of $\Delta H°$ for salicylic acid obtained by Hendrixson were −5.63 kcal./mole for benzene and −7.68 kcal./mole for chloroform.

The values obtained for $\Delta S°$ and $\Delta H°$ in this investigation of salicylic acid not only are considerably different from those obtained by Hendrixson, but they are also much different from the general values obtained for other acids. In the general reaction 2 monomer → dimer, the total entropy change can be considered to be made up of two parts.[15] The first is the change due to the translational and rotational degrees of freedom, and the second is the change due to the vibrational degrees. The first term must be negative since three translational and three rotational degrees of freedom are lost on association. The vibrational contribution, on the other hand, is positive since new vibrational degrees result from the association process. The value of the total entropy change on association for salicylic acid is about equal to the translational and vibrational contribution expected. The vibrational term, then, must be quite small indicating that the dimer bonds are very strong. This is consistent with the high value of the heat of dimerization observed.

Heat of Solution of Monocalcium Phosphate Monohydrate

By Edward P. Egan, Jr., Basil B. Luff and Zachary T. Wakefield

Received February 11, 1957

The heat of solution of monocalcium phosphate monohydrate(c) in phosphoric and hydrochloric acids was measured as a function of acid concentration at 25°. The hypothetical heat of solution at infinite dilution could not be fixed closer than within the range −3 to −4 kcal. mole^{-1}.

As part of a long-range study of the thermodynamic properties of the calcium phosphates, the heat of solution of monocalcium phosphate monohydrate in acid was measured as a function of the concentration of the solvent. The final value sought was the heat of solution at infinite dilution.

Two solvents, solutions of hydrochloric acid and of phosphoric acid, were used on the naive assumption that two independent extrapolations to zero concentration of acid thus could be obtained.

Materials and Apparatus.—The solution calorimeter and the method of preparing the monocalcium phosphate monohydrate have been described.[2]

The volume of acid solution was 850 ml. in each measurement. The acid was weighed from a special volumetric flask.

The samples of monocalcium phosphate monohydrate, 4 to 8 g., were suspended below the stirrer in thin-walled glass bulbs about 3.5 cm. in diameter that were sealed to a glass rod extending through the hollow stirrer shaft. The bulbs were broken against the bottom of the calorimeter flask at the beginning of the dissolution period. The calorimeter system was calibrated electrically immediately before and after the dissolution. The initial temperature was adjusted so that the dissolution ended within a few hundredths of a degree of 25°, and no temperature corrections were necessary. The ice point was taken as 273.16°K., and one defined calorie as 4.1840 abs. j. No trend of ΔH with change in weight of salt was observed.

Observations.—The observed heats of solution are listed in Table I, and the average values at each concentration of acid are plotted in Fig. 1. The curves in Fig. 1 do not follow the theoretical linear relation for low-valent electrolytes at high dilutions.[3] Some of the necessary information is lacking for an extended Debye–Hückel extrapolation at low concentrations of solvent acid.

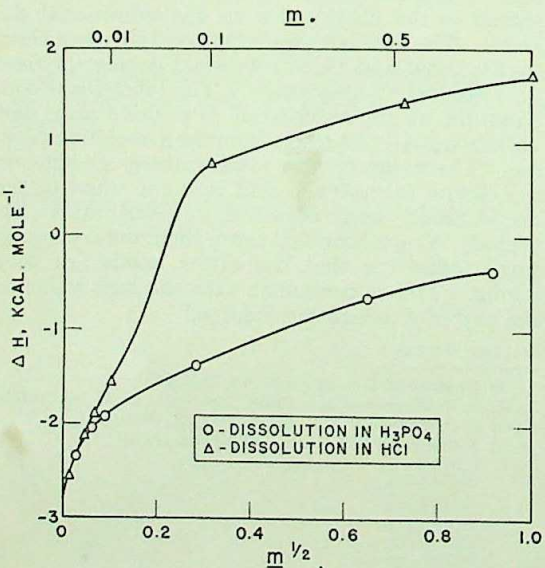

Fig. 1.—Heat of solution of $Ca(H_2PO_4)_2 \cdot H_2O$(c).

	−362				

A power series equation expressing ΔH as a function of $m^{1/2}$ extrapolates to a value of −2750 cal. mole^{-1} for ΔH at zero m. A plot of ΔH as a function of $m^{1/3}$ decreases the curvature of the lines, and a linear extrapolation through the ΔH values at the four lowest concentrations yields −2850 cal. mole^{-1} for ΔH at zero m. The observed ΔH, extrapolated to infinite dilution, is taken as −2800 cal. mole^{-1}. Since the curves in Fig. 1 approach the axis rather steeply, an extrapolation to zero m probably represents a lower limit in absolute magnitude for the heat of solution at infinite dilution.

The difference between the heats of solution in the two acids at the same molality is approximately constant at 2000 cal. mole^{-1} when the molality is greater than 0.1. The ΔH in solutions of hydrochloric acid is driven in the endothermic direction by an amount that apparently is equivalent to the endothermic heat of solution of calcium chloride. At molalities of less than 0.1, there is insufficient chloride ion in the solution of hydrochloric acid to

form calcium chloride with all the calcium, and the heats of solution approach those in solutions of phosphoric acid.

Substitution of the heats of formation, $Ca(H_2PO_4)_2 \cdot H_2O(c)$, $-816{,}820$; $Ca^{++}(aq)$,[4] $-129{,}770$; $H_2O(liq)$,[4] $-68{,}317$; $H_2PO_4^-(aq)$,[5] $-311{,}320$ cal. mole^{-1} in the equation

$$Ca(H_2PO_4)_2 \cdot H_2O(c) + (aq) = Ca(H_2PO_4)_2 \cdot H_2O(aq) = Ca^{++}(aq) + 2H_2PO_4^-(aq) + H_2O(liq)$$

yields a value of -3910 cal. mole^{-1} for the heat of solution of $Ca(H_2PO_4)_2 \cdot H_2O(c)$ at infinite dilution. This value represents the difference between large numbers; also, one of the values used in its derivation—the heat of formation of $H_2PO_4^-(aq)$—is uncertain. With the uncertainty involved in the extrapolation of the observed heats of solution to infinite dilution, the hypothetical heat of solution of $Ca(H_2PO_4)_2 \cdot H_2O(c)$ at infinite dilution can be fixed no closer than within the range -3 to -4 kcal. mole^{-1}.

Electrochemical Behavior of Aromatic N-Nitrosohydroxylamines

BY PHILIP J. ELVING AND EDWARD C. OLSON

RECEIVED JANUARY 9, 1957

The electrochemical behavior of three aromatic N-nitrosohydroxylamines was studied: N-nitrosophenylhydroxylamine N-nitroso-α-naphthylhydroxylamine and N-nitroso-*p*-xenylhydroxylamine, whose ammonium salts are known as cupferron, neocupferron and *p*-phenylcupferron, respectively; the last is a new compound. Three well-defined polarographic waves can occur in the *p*H region from −0.4 to 12. The first wave split (change from wave I to II) results from a tautomeric equilibrium between the nitroso hydroxy and amine oxide forms; the second wave split (change from wave II to III) is due to a typical acid–anion equilibrium. Coulometric studies, and isolation and identification of major reduction products by macroscale electrolysis at controlled potential indicate that the reduction in acidic solution (waves I and II) proceeds by a process, or processes, involving a total of 6 electrons to the aromatic hydrazine. In alkaline solution (wave III) only 4 electrons are involved with the final product being the aromatic hydrocarbon; the mechanism proposed has been substantiated by following the change in *p*H of the solution with electrolysis of the nitrosohydroxylamine. The apparent discrepancies in previous work have been elucidated.

A systematic study of the polarographic and coulometric behavior of N-nitrosophenylhydroxylamine,[1] N-nitroso-α-naphthylhydroxylamine (neocupferron) and a new compound, N-nitroso-*p*-xenylhydroxylamine (*p*-phenylcupferron), usually added as the ammonium salts, was undertaken to elucidate the reduction pattern and to resolve apparent differences in the literature.[2,3] Such an investigation also served as background for the development of analytical methods including amperometric titration methods employing cupferron as titrant.

Previous polarographic study[2] of N-nitrosophenylhydroxylamine indicated two waves in the *p*H range from 1.1 to 12.5. A similar study[3] of N-nitroso-α-naphthylhydroxylamine, the abstract of which appeared after the present investigation was underway, described four polarographic waves in the same *p*H region; the apparent differences in behavior between the two closely related structures was not too convincingly explained; even so, the explanations involved selective emphasis. Attempted coulometric studies were unsatisfactory and the results were not given.[3]

(1) The ammonium salt which is the form in which the compound is usually used, is called cupferron; for convenience, this name will hereafter be used to designate both the compound and its ammonium salt. The names, neocupferron and *p*-phenylcupferron, apply and will be used in the same sense.

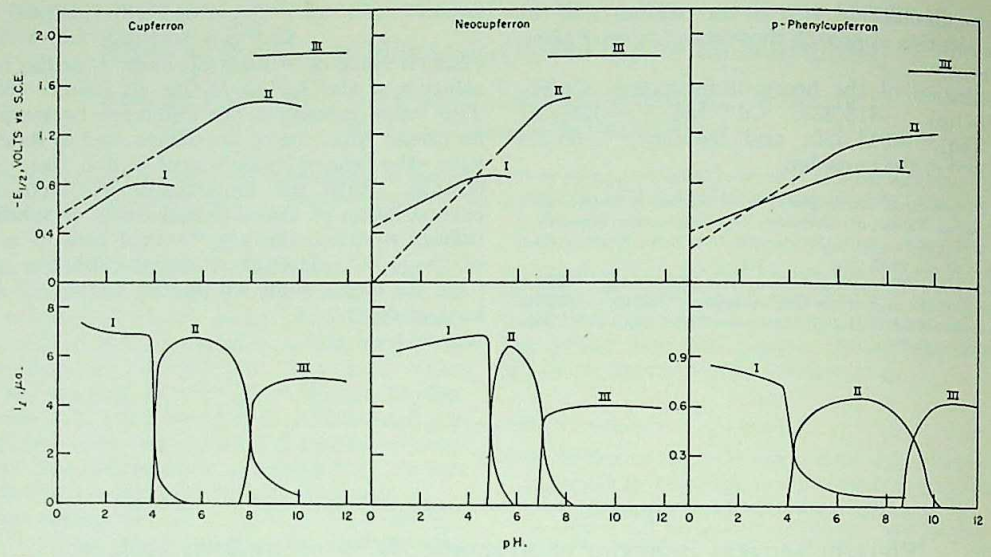

Fig. 1.—Variation with pH of half-wave potential and wave height of aromatic N-nitrosohydroxylamines. In each case curve I refers to wave I, II to wave II and III to Wave III. The concentrations are cupferron, 0.33 mM; neocupferron 0.32 mM; and phenylcupferron, 0.0062 mM.

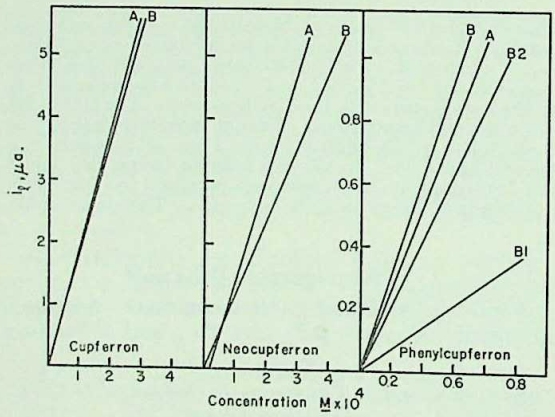

Fig. 2.—Variation of wave height with concentration for aromatic N-nitrosohydroxylamines. Cupferron: A, pH 2.80; B, pH 5.80. Neocupferron: A, pH 2.80; B, pH 5.69. Phenylcupferron: A, wave I at pH 2.80; B, sum of waves I and II at pH 6.76; B1, wave I at pH 6.76; B2, wave II at pH 6.76.

current, i_1, for each of the waves of the three cupferrons in solutions ranging in acidity from 10% sulfuric acid to pH 12. All three cupferrons give a single well-defined wave in strongly acidic solution. As the pH is increased, the wave splits into two at about pH 4 to 5. A second wave split occurs at somewhat higher pH. Extrapolation of the straight line portions of the plots of $E_{1/2}$ *vs.* pH to pH 0.00 for the first two waves of each compound leads to the expressions

Cupferron:

$$I^{E_{1/2}} = -0.42 - 0.132pH,\ II^{E_{1/2}} = -0.53 - 0.120pH$$
$$III^{E_{1/2}} = -1.85$$

Neocupferron:

$$I^{E_{1/2}} = -0.44 - 0.100pH,\ II^{E_{1/2}} = +0.03 - 0.201pH$$
$$III^{E_{1/2}} = -1.82$$

Phenylcupferron:

$$I^{E_{1/2}} = -0.40 - 0.081pH,\ II^{E_{1/2}} = -0.26 - 0.130pH$$
$$III^{E_{1/2}} = -1.75$$

The significance of the coefficient of the pH is not clear. A coefficient of about 0.12 indicates that $E_{1/2}$ varies with the square of the hydrogen ion concentration; for a reversible reaction, this might be interpreted to mean that two hydrogen ions are involved per electron transferred. $E_{1/2}$ for the third wave is pH-independent in all three cases. Kolthoff and Liberti[2] give for the similar equation for their first cupferron wave, $_IE_{1/2} = -0.58 - 0.128\ pH$; this would tend to indicate that their first wave and the present second wave are identical.

Wave height is directly proportional to concentration (Fig. 2); $E_{1/2}$ is unaffected by change in concentration. Increasing the ionic strength at pH 1.08 from 0.1 to 1.0 shifts $E_{1/2}$ about 0.02 v. in a more positive direction for each compound.

Current-controlling Processes.—Because of the importance of the nature of the current-controlling process (diffusion, rate or adsorption) relative to the possible origins and reduction mechanisms of the waves, the variations of i_1 with both drop-time and temperature were determined in pH regions where wave I alone, both waves I and II, wave II alone, and waves II and III were present.

The proportionality of i_1 of the first two waves for all three compounds to the square root of the height of the mercury column and the magnitudes of the temperature coefficients of i_1 for the same waves indicate that the processes resulting in these waves are diffusion controlled, with the following exceptions: wave II in the region where waves II and III coexist is at least partially kinetic in nature; lack of indication of any kinetic character for wave I may be due to inability to resolve that wave more clearly in the presence of wave II.

Calzolari and Donda[3] found their first, second and [illegible] neocupferron waves to be diffusion-

controlled at *p*H values where only a single wave was observed, *e.g.*, *p*H 1.9, 6.7 and 9.2; measurements made in regions of multiple waves did not yield interpretable results. Kolthoff and Liberti[2] found their first cupferron wave (already identified with the present wave II) to be kinetic controlled at *p*H 8.25 and the second wave to be diffusion controlled; they used the Brdicka–Wiesner equation[5] to calculate the kinetic current and found reasonable agreement between experimental and calculated values.

Logarithmic Analysis of the Waves.—Logarithmic analysis of the polarograms shows a multiplicity of processes to be occurring at the electrode (Fig. 3). Even in strongly acidic solution, the plot of log $[i/(i_d - i)]$ *vs.* E for each wave shows more than one straight-line segment.

The irreversible nature of the electrochemical reduction of aromatic N-nitrosohydroxylamines at the D.M.E. is shown by the values of the reciprocal slopes of the various straight-line segments; in no case does α, calculated from the slope as being equal at 25° to $0.059/\alpha$, have a value approaching 2. Likewise, the sum of the α values, when more than one process is involved, is never much greater than 2, although coulometric reduction (*cf.* next section) shows 6 electrons to be involved in the reduction in acidic solution and 4 in alkaline solution.

Coulometric and Other Macroscale Reductions

Coulometric *n* Values.—Coulometry at *p*H 3.50 show 6 electrons to be involved in the reduc-

tion in acidic solution (experimental n values: cupferron—6.1, 5.9, 5.9, 5.9; neocupferron—5.8, 6.0, 5.9, 5.9; phenylcupferron—5.9, 6.0, 5.9, 5.9).

Constant n values were obtained only after correcting the observed values for decomposition and for unreduced compound remaining at the end of the electrolysis period. The former correction was computed by determining the rate of decomposition of the compounds in the coulometer under conditions identical to those during a coulometric run except that no current was passed through the cell. The correction for unreduced nitrosohydroxylamine was found to be necessary when electrolysis rates were measured.

In alkaline solution a correction for decomposition was unnecessary; however, more consistent results could be obtained by determining the residual concentration of reducible material after a fixed period of electrolysis than by carrying the reduction to completion. The number of electrons involved in reduction at pH 11.7 was found to be 4 (experimental n values: cupferron—4.2, 3.8; neocupferron—4.1, 4.3, 4.0, 3.7, 4.4, 4.2; phenylcupferron—4.1, 3.8).

Identification of Reduction Products.—The chief reduction product or one of its common derivatives was isolated and identified for each aromatic N-nitrosohydroxylamine in both acidic and alkaline solution. The melting points of the isolated benzaldehyde adducts and the coulometric n values show conclusively that in acidic solution aromatic N-nitrosohydroxylamines are reduced by a process or combination of processes involving a total of 6 electrons to the corresponding aromatic hydrazine.

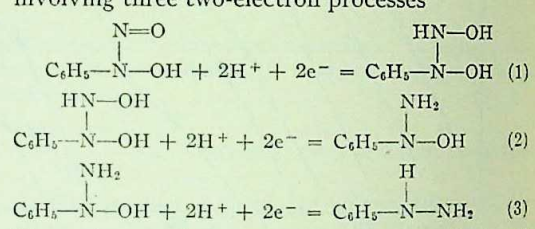
In alkaline solution the results indicate a four-electron reduction to the hydrocarbon. In all runs a strong odor of the aromatic hydrocarbon became apparent shortly after electrolysis began. In the cases of neo- and p-phenylcupferron, the naphthalene and biphenyl formed were filtered and recrystallized, and a melting point taken. In several runs the crude product was isolated, dried and weighed; between 40 and 60% of the weight of hydrocarbon anticipated was isolated. Low results could result from a number of factors, *e.g.*, the difficulties inherent in handling such small quantities of precipitate in the large apparatus required for electrolysis, the high vapor pressure of naphthalene and biphenyl coupled with the fact that a rapid stream of nitrogen was passed through the solution during the entire electrolysis period, and the possible reduction of the cupferrons by more than one mechanism resulting in the formation of some soluble reduction product; loss due to entrainment in the nitrogen stream would seem to be the major factor.

Several of the coulometer solutions after electrolysis under alkaline conditions were made strongly acidic and were then extracted several times with ether and chloroform to remove hydrocarbon and unreduced starting material. The resultant aqueous solution failed to give a test for an aromatic amine when tested with bromine water after neutralization, thus eliminating the possibility of reduction by a four-electron or other process to an aromatic amine.

pH Change During Electrolysis.—To examine the consequences of the subsequently proposed mechanism of reduction in alkaline solution, coulometric type runs were made in unbuffered alkaline solution, the purpose of which was to compare the experimentally observed rate of hydroxide ion production relative to hydroxylamine consumed to that predicted by the proposed mechanism. The data (Fig. 4) will be discussed subsequently.

Nature of Reduction Path

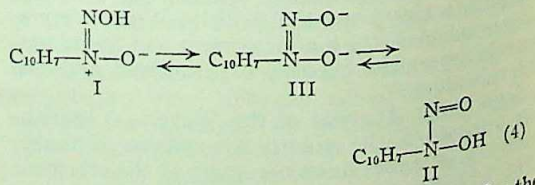
By assuming the diffusion coefficient of N-nitrosophenylhydroxylamine to equal that of benzoate ion and then calculating the number of electrons involved from the Ilkovic equation, Kolthoff and Liberti[2] considered the reduction of cupferron in acidic solution to be a six-electron process and postulated the reduction product to be phenylhydrazine. They proposed a reduction scheme involving three two-electron processes



They also concluded that in alkaline solution the reduction involves four electrons inasmuch as the polarographic wave height is two-thirds of that in acidic medium and suggested that the reduction product is an N-aminohydroxylamine.

Calzolari and Donda[3] in their similar neocupferron study suggested that the reduction proceeds in only two stages: a $4e^-$ reduction of the amine oxide or nitrosohydroxy forms to the aminohydroxylamine (combination of equations 1 and 2) and then a $2e^-$ reduction to the hydrazine (equation 3). The results of the present investigation, as subsequently discussed, indicate that both mechanisms may be operative in different restricted pH regions, but that a third mechanism is operative in the alkaline region.

Kolthoff and Liberti ascribed the first of the two cupferron waves they observed to reduction of the undissociated form of nitrosohydroxylamine and the second wave to reduction of its anion. Calzolari and Donda explain their four waves on the basis of a more complicated picture. The substitution of phenyl by naphthyl is assumed to facilitate the possibility of occurrence of both the amine oxide (I) and nitroso hydroxy (II) forms of neocupferron



They also assume the dissociation constant for the equilibrium I $\rightleftarrows$ III + H^+, to be greater than that

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

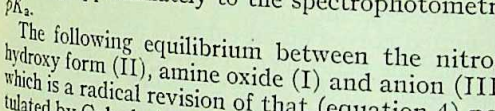
Digitized by Arya Samaj Foundation Chennai and eGangotri

for II ⇌ III + H$^+$, I to be more readily reducible than II, and the anion III to be common for both equilibria. Their first wave, assumed due to 4e$^-$ reduction of I, decreases with increasing *p*H due to formation of anion III. The latter then recombines with H$^+$ to form the less highly dissociated II whose 4e$^-$ reduction results in the second wave. The third wave, which is very ill-defined, is ascribed to the further 2e$^-$ reduction of the 4e$^-$ reduction products of I and II. The fourth wave which occurs in the alkaline region and is more or less *p*H-independent is assigned to the reduction of III.

Relation of Wave Pattern to Equilibrium Processes

Since the aromatic N-nitrosohydroxylamines are weak acids, a double polarographic wave observed in the *p*H region corresponding to or somewhat greater than the pK_a of the nitrosohydroxylamine in question may be due to the fact that an acid and its anion are usually reduced at different potentials.[6] The pK_a of cupferron has been estimated[2,7a] as 4.28 in solution of low ionic strength; it is also given as 5.3.[7b] The large extent of acid dissociation has been cited as evidence for the existence of cupferron largely in the amine oxide rather than in the nitroso hydroxy form.[7b] For use in the present investigation, the apparent ionization constants were determined spectrophotometrically at an ionic strength of 1; these pK_a values are 4.11, 3.92 and 3.97 for cupferron, neocupferron and *p*-phenyl cupferron, respectively.[8] Examination of Fig. 1 reveals the appearance of a second polarographic wave for each compound in the *p*H region corresponding approximately to the spectrophotometric pK_a.

The following equilibrium between the nitroso hydroxy form (II), amine oxide (I) and anion (III), which is a radical revision of that (equation 4) postulated by Calzolari and Donda,[3] is, as subsequently discussed, in harmony with the data of Figs. 1 and 3, and furnishes a basis for the formulation of the reduction mechanism



II I III (5)

Waves I and II.—Since no decrease in diffusion current accompanies the first wave split, the latter would seem to result from the two acid forms of the cupferron which can exist in tautomeric equilibrium. Additional support for this postulate comes from the *p*H dependence of waves I and II, and the expected relative ease of reduction and the acidic strengths of the two forms. The apparently diffusion controlled nature of wave I may result from a relatively slow rate of interconversion of the two forms, as well as from failure to resolve waves I and II clearly. The present authors tend, in common with others, to favor the amine oxide being the predominant form in solutions varying

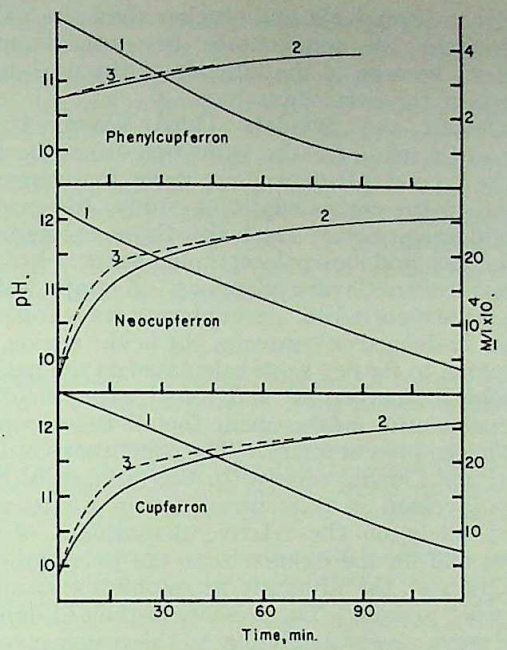


Fig. 4.—Rates of electrolysis and of increase in *p*H during the electrolysis of aromatic N-nitrosohydroxylamines in unbuffered alkaline solution: 1, rate of electrolysis; 2, calculated rate of increase in *p*H for liberation of 5 moles of hydroxide ion per mole of compound reduced; 3, measured rate of increase in *p*H.

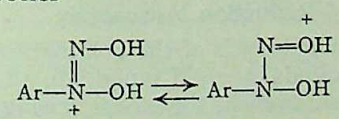
from neutral to slightly acidic (*p*H 4); in more strongly acidic solution (*p*H 1–2) the nitroso hydroxy form appears to predominate.

The present assignment of wave I to the nitroso hydroxy form and of wave II to the amine oxide form is contrary to that of Calzolari and Donda, but is in harmony with the facts cited. The mechanism for the interconversion of I and II in acidic solution rather than proceeding through a common anion as postulated by Calzolari and Donda more likely occurs through the cyclic form resulting from hydrogen bonding or through a protonated species



(6)

The polarographic waves of the two tautomeric forms of cupferron coexist over a very narrow *p*H region; the height of the wave is the same before and after the first wave split (Fig. 1). For these reasons, an unfortunate choice of a buffer interval from *p*H 3.1 to 4.4 (at which the first wave has virtually disappeared) resulted in the failure of the previous investigators[2] to find an equilibrium corresponding to I ⇌ II. They postulated, and quite correctly for their data, a very large kinetic current for cupferron in the *p*H range of 4 to 8. However, on the basis of the present investigation it appears that their second wave actually corresponds to the third cupferron wave and that the *p*H of 7.2 reported by them as that where the two cupferron waves are equal, actually refers to the second and third waves. Quite commonly the apparent polarographic $\frac{1}{2}K$ of an acid is found to lie from a few

tenths to several *p*H units higher than the values determined by conductance or potentiometric methods because of the kinetics of the acid-anion process at the electrode surface.

Calzolari and Donda's Third Wave.—If allowance is made for the transition from the first to the second *p*H-dependent wave inadvertently missed in the earlier cupferron study, the present general wave picture reconciles those encountered in the two previous polarographic studies[2,3] of the aromatic nitrosohydroxylamines. A major difference is the reported $4e^-$ neocupferron wave followed by an ill-defined $2e^-$ wave in the acidic region,[3] as compared to the $6e^-$ wave calculated on the basis of analogy for cupferron[2] and found experimentally by coulometric measurement for all three cupferrons in the present study. The conclusions of Calzolari and Donda[3] relative to the number of electrons involved in their neocupferron waves were based solely on the relative magnitudes of the waves and on the opinion that the polarographic reduction of the aromatic nitrosohydroxylamines was a $6e^-$ process. The presence of their ill-defined third wave was probably due to the rather complicated buffer systems employed which resulted, as *p*H was changed, in considerable variation not only in ionic strength but also in the relative amounts of the various phosphate, citrate and borate species, many of which may interact with the reducible organic functional grouping to alter its ease of reduction and perhaps even to affect its polarographic wave pattern by separating the potentials required for the various steps in the over-all reduction process, *e.g.*, the sequence of three steps described in equations 1 to 3.

On the basis of the preceding discussion, it is interesting to compare the wave patterns found by Calzolari and Donda with the logarithmic analysis of the waves (Fig. 3); within the *p*H region in which they observed the appearance and disappearance of their third wave, the slope analyses show a change from three to two straight-line segments.

Reduction Mechanism

Logarithmic analysis of the polarographic waves of the compounds over *p*H range 1 to 12.5 (Fig. 3) indicates that, even in the steeply rising region of the polarographic wave which was the region analyzed, marked changes occur. Neo- and *p*-phenylcupferron show a single straight line in very strongly acidic media, but at *p*H 2 there are in all cases two distinct straight-line segments to the log plot. As the *p*H is increased, three straight-line segments appear in every case in the *p*H region immediately preceding the first wave split. After appearance of the second wave, analysis of the first wave gives only a single straight line, but analysis of the second wave again produces two straight lines. Only two straight lines are formed after the disappearance of the first wave.

Therefore, there seems to exist a *p*H region, *ca.* 2 to 7, in which the reduction proceeds *via* three $2e^-$ steps, as suggested for cupferron by Kolthoff and Liberti,[2] and *p*H regions, *ca.* 0 to 2 and *ca.* 7 to 10, in which a $4e^-$ reduction is probably followed by a $2e^-$ reduction, as suggested for neocupferron by Calzolari and Donda.[3] In very strongly acidic solution the reduction of the α-naphthyl and *p*-xenyl derivatives appears to take place in a single $6e^-$ step; no such region was found for the phenyl compound.

Wave in Alkaline Solution.—The third wave at higher *p*H represents the $4e^-$ reduction of the anion to the aromatic hydrocarbon. Inasmuch as logarithmic analysis of the polarographic waves after the second wave split gives only a single straight line, reduction in alkaline solution occurs in an effectively single $4e^-$ step, *i.e.*, the processes involving the transfer of all four electrons are controlled by a single step

(7)

If equation 7 is correct, 5 moles of hydroxide ion should be produced for each mole of aromatic N-nitrosohydroxylamine reduced. By carrying out the reduction at controlled potential in unbuffered alkaline solution, it was possible to follow both the increase in *p*H of the solution and the decrease in concentration of N-nitrosohydroxylamine. On comparing the measured *p*H as a function of time with that calculated from the measured decrease in concentration of reducible compound on the basis of 5 moles of hydroxide ion produced per mole of N-nitrosohydroxylamine consumed (Fig. 4), good agreement is found except in the region corresponding to the beginning of the electrolysis. Furthermore, by calculating the *p*H assuming production of 4 and 6 moles of hydroxide ion per molecule reduced and plotting the experimental and calculated curves on an enlarged scale, it is apparent that the experimental curve corresponds much more closely to the curve calculated for 5 hydroxyl ions per mole of reduced N-nitrosohydroxylamine than to either of the other curves.

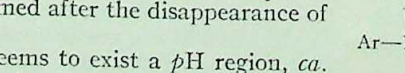
It is possible to postulate a stepwise reduction to an aromatic hydroxyhydrazine followed by rearrangement in alkaline solution to the hydrocarbon, nitrogen and water since this rearrangement is known to occur in the presence of alkali[9]

(8)

(9)

(10)

(11)



(12)

The over-all reaction (equation 12) is obviously identical with that previously proposed (equation 7).

Relative Ease of Reduction.—The general pattern for the waves of all three compounds is that of phenylcupferron being the most easily reducible and neocupferron the most difficultly reducible. This pattern correlates with the *p*-xenyl group being the most electron-withdrawing and the naphthyl group the least.

Possible Analytical Applications

Determination of an Individual Cupferron.—Since single well-defined polarographic waves are obtained for the aromatic N-nitrosohydroxylamines only below about *p*H 3.5 (Fig. 1), only the diffusion current constant values below *p*H 4 are pertinent for their polarographic determinations (Table I). The direct proportionality of diffusion current to concentration permits the ready determination of the individual compounds. The analytical precision ranges from about ±2 for cupferron to ±4 for neocupferron. The rapid decomposition of neocupferron in acidic solution is probably the major cause of the lack of precision in its polarographic determination.

The potential regions subtended by the polarographic waves of these compounds in acidic solution below *p*H 4 are so low, *i.e.*, −0.4 to −0.8 v. *vs.* S.C.E., that there should be few interferences among the organic compounds usually associated with the aromatic N-nitrosohydroxylamines.

$E_{1/2}$ values for the various cupferrons are sufficiently close to one another at a given *p*H to make the individual determination of any one cupferron in the presence of any other impossible, except perhaps by derivative polarography.

Basis for Amperometric Titration.—The previous discussion indicates use of aromatic N-nitrosohydroxylamines as reagents for titrations employing amperometric detection of the equivalence point to be practical. Kolthoff and Liberti[10] described the use of cupferron in the amperometric titration of Fe(III) and Cu(II), although the titration was preferably performed at potentials at which only the reduction current due to the metal ion was measured.

Use of neocupferron as a titrant is somewhat limited by its extremely rapid rate of decomposition in strongly acidic solution, as indicated by failure of the straight-line relation between concentration and i_l at *p*H 2.80 to pass through zero current at zero concentration (Fig. 2). Use of neocupferron is also limited by the fact that oxygen-free aqueous solutions of neocupferron decompose much more rapidly than do similar solutions of cupferron or phenylcupferron.

The use of *p*-phenylcupferron is restricted to the titration of minute amounts of metals since the solubility of the reagent is much less than that of either cupferron or neocupferron. An aqueous solution of the ammonium salt of N-nitroso-*p*-xenylhydroxylamine, saturated at 25°, contains only about 0.65 mg./ml. (approximately 3.1×10^{-3} *M*). The solubility of the free acid is, however, much less, being about one-fiftieth of this value. Oxygen-free aqueous solutions of this compound are considerably more stable than those of either cupferron or neocupferron. This increase in stability would be advantageous for the titration of very low concentrations of metals as would the lower solubility of the metal salts of *p*-phenylcupferron.[8]

Because of the low solubility of *p*-phenylcupferron and the instability of neocupferron, cupferron is considered best suited of the three N-nitrosohydroxylamines for the development of general titration procedures in spite of the somewhat greater solubility of its metallic salts. Procedures for amperometric titration of Group IVB metal ions with cupferron have been published.[11]

Experimental

Cupferrons.—G. F. Smith Chemical Co. reagent grade cupferron (ammonium salt of N-nitrosophenylhydroxylamine) was recrystallized twice from ethanol after treatment with Norit and finally once more from ethanol; the dried crystals (m.p. 162.5–163.5°) so purified are essentially 100.0% pure.[11a] Neocupferron (ammonium salt of N-nitroso-α-naphthylhydroxylamine) was prepared essentially by Smith's method[12] (m.p. 124–126°).

p-Phenylcupferron (ammonium salt of N-nitroso-*p*-xenylhydroxylamine) is a new compound which was prepared as follows: 10 g. of *p*-nitrobiphenyl was dissolved in a mixture of 500 ml. of 95% ethanol, 60 ml. of water and 6 g. of NH_4Cl; 10 g. of zinc dust was then added in one-gram portions with vigorous mechanical stirring and continuous cooling with tap water. After the reaction was complete, as indicated by a decrease in temperature of the reaction mixture, stirring was continued at room temperature for 30 min. The solution was then filtered into 30 ml. of glacial acetic acid, which appears to stabilize the hydroxylamine[13]; the resulting solution was then poured into a liter of cold water. The *p*-xenylhydroxylamine was filtered by suction and dissolved at once in 300 ml. of ether. After being dried over anhydrous sodium sulfate, the ether layer was filtered, cooled to 0° and saturated with ammonia gas. Freshly prepared *n*-butyl nitrite[14] was rapidly added dropwise, with vigorous mechanical stirring and passage of a rapid stream of ammonia, until 0.56 g. of butyl nitrite had been added for each gram of *p*-xenylhydroxylamine. The amonium salt of N-nitroso-*p*-xenylhydroxylamine which precipitated as very pale yellow platelets was filtered, washed with several portions of ether, and dried (m.p. 177–179°); yield was 64% of theory.

Anal. Calcd.: C, 62.13; H, 5.41; N, 18.23. Found: C, 62.33; H, 5.63; N, 18.23.

All three cupferrons were stored in the dark over ammonium carbonate; solutions of desired concentrations were prepared immediately before use by dissolving weighed portions of the crystalline salts in oxygen-free water.

Other Reagents.—Eastman Kodak white label grade tetramethylammonium bromide was purified by recrystallization. The salt was dissolved in the minimum amount of boiling reagent grade methanol and filtered, while hot, into an equal volume of reagent grade acetone. The mixture was then cooled to 0°; the crystals which formed were filtered, washed with cold 1:1 methanol–acetone and dried. This procedure gave a salt of sufficient purity to be used as a polarographic background electrolyte for potentials as negative as −2.2 v. *vs.* S.C.E.

A stock solution of tetramethylammonium hydroxide was prepared from purified bromide and freshly precipitated silver hydroxide.[15]

Nitrogen used for purging solutions of oxygen was first passed through chromous sulfate solutions to remove residual oxygen, then through distilled water to remove spray and finally through a portion of the solution to be purged

in order to obtain vapor pressure equilibration. All other chemicals, including those used in buffer preparation, were of reagent or C.P. grade and were used without further purification; they were "polarographically pure."

Apparatus.—A Sargent Model XXI Polarograph, a Leeds & Northrup Model E Electro-Chemograph and a Fisher Elecdropode were used; potentials were checked with a Leeds & Northrup Type K potentiometer. A thermostated, jacketed H-type polarographic cell[16] containing a saturated calomel reference electrode was used. When changing from one temperature to another (20, 25 or 30 ± 0.1°), at least 24 hr. was allowed for the S.C.E. to reach thermal equilibrium. Capillaries, prepared from Corning marine barometer tubing, had $m^{2/3}t^{1/6}$ values at open circuit in water at 25° at 68 cm. mercury head of (1) 2.06, (2) 2.17 and (3) 2.04 mg.$^{2/3}$ sec.$^{-1/2}$; one capillary used only in drop-time studies had $m^{2/3}t^{1/6} = 1.75$ at 81 cm.

The coulometric apparatus was a modification of that of Lingane,[17] employing a water-jacketed (25 ± 0.1°) electrolysis cell, a stirred massive mercury electrode, a large external silver anode and an oxygen–hydrogen coulometer. The cathode potential was measured against S.C.E. with the Type K potentiometer.

A Beckman Model G *p*H meter was used to measure *p*H; in the alkaline region a Type E electrode was employed.

Polarographic Procedure.—A weighed portion of the reducible compound was dissolved in oxygen-free water and then diluted to the desired concentration with a stock solution of background electrolyte which had also been purged with nitrogen. The polarographic cell was rinsed twice with the test solution and then filled; the capillary was introduced and a rapid stream of nitrogen passed through the cell for 2 to 3 min., during which time the initial potential was set at the desired value. Nitrogen was passed over the solution during the polarographic run. All test solutions contained from 0.01 to 0.02% gelatin as a maximum suppressor. Potentials are reported *vs.* S.C.E. and at 25° unless otherwise noted; cell iR drops were negligible.

Constant ionic strength MacIlvaine buffers (Table II) were used between *p*H 2 and 7.6. Buffers of ionic strength 0.2 and 0.3 for use between *p*H 7 and 12 were prepared by titrating a solution of 0.05 M H_3PO_4 with 0.1 M tetramethylammonium hydroxide to the desired *p*H; both the acid and hydroxide solutions were approximately 0.1 M in tetramethylammonium bromide.

Coulometric and Macroscale Electrolysis Procedures.—The background electrolyte was deoxygenated in the electrolysis cell with a rapid nitrogen stream which was maintained throughout the experiment. The cathode mercury was then added; the bridge from the reference S.C.E. was adjusted so that it just touched the vigorously stirred mercury surface; the gas coulometer, in which the solution had just been saturated with hydrogen and oxygen,[17] was connected in series with the cell. The potential of the mercury cathode was made several tenths of a volt more negative than that at which the run was to be made; electrolysis was continued until the last traces of reducible impurities had been removed as indicated by the decrease in current.

Without breaking the circuit, the applied potential was reduced until the cathode potential attained the desired value; the coulometer buret was read; the deoxygenated sample solution was added to the cell and the potential readjusted to the desired value which was maintained during electrolysis.

After electrolysis had proceeded for 2.0 to 2.5 hr., the circuit was opened, a sample of the cell solution withdrawn and the residual aromatic N-nitrosohydroxylamine concentration determined polarographically. From the decrease in concentration and the volume of gas evolved, the number of electrons involved in the electrode reaction was calculated after making the necessary corrections,[17] including, if required, those for the homogeneous decomposition of the cupferron. In addition, the main product of the electrolytic reduction was isolated and identified as follows.

In the case of an acidic solution, the solution was drained from the cell and 2 or 3 drops of benzaldehyde was added followed by sufficient ethanol to take the benzaldehyde into solution; the mixture was then set aside. In all cases a precipitate appeared within 15 or 20 min.; however, additional time was allowed for the reaction to proceed to completion. After about 2 hr., an equal volume of water was added and the mixture cooled to 0° in an ice-bath. The precipitate was isolated and recrystallized at least twice from ethanol-water mixture; after drying, its melting point was determined. The benzaldehyde adducts isolated from the solutions of the products formed by electrolysis in acidic solution had the following melting points (literature values in parentheses for the RHN–NH_2–benzaldehyde condensation products where R is phenyl, α-naphthyl or *p*-xenyl): cupferron, 156–158° (155–156°); neocupferron, 143–144° (144–145°); *p*-phenylcupferron, 151–152° (153°).

In alkaline solution, the reduction product precipitated from the electrolysis solution and could be isolated by filtration. The product precipitated from neocupferron solution melted at 78–79° (m.p. of naphthalene, 80.2°) and the product from *p*-phenylcupferron solution at 68–69° (m.p. of biphenyl, 69–70°).

Acknowledgment.—The authors wish to thank the Atomic Energy Commission which helped support the work described.

A Spectrophotometric Study of the Indium–Bromide Complex Ions[1]

BY EUGENE A. BURNS AND DAVID N. HUME

RECEIVED JULY 9, 1956

The aqueous bromide complexes of indium have been investigated by means of ultraviolet spectrophotometry. The spectra obtained can best be interpreted by terms of the mono-, di-, tri- and tetrabromoindium ions whose stepwise formation constants have been evaluated at an ionic strength of 4.00 M. Analysis of the data by five distinct methods gives average values for the stepwise formation of $InBr^{++}$, $InBr_2^+$, $InBr_3$ and $InBr_4^-$ of 120, 19, 4 and 7, respectively.

In the past three years, fourteen articles have appeared in the literature concerning the nature of indium(III) in halide media, twelve specifically dealing with the bromide system. Table I lists the values of the consecutive formation constants of the indium bromide system observed by these workers, together with the values obtained in this investigation. The considerable lack of agreement among previous workers prompted the present investigation using spectrophotometric methods which are not subject to some of the difficulties in other methods.

Experimental

Metallic indium was obtained both from the Indium Corporation of America, Utica, N. Y. (99.97% pure) and from Fisher Scientific Company, N. Y. (99.9+% pure). The metal was dissolved in concentrated nitric acid and fumed down to near dryness with perchloric acid five times. The resulting solutions were tested for the presence of chloride and nitrate ions. It was observed that every attempt to dissolve indium metal in perchloric acid (which proceeded slowly) caused the reduction of some perchlorate to chloride. The dissolving of indium in 70% perchloric acid proceeded fairly rapidly if it was performed in a platinum dish, but still there was a detectable amount of chloride formed. The molarity of the indium was checked gravimetrically by precipitation with ammonium hydroxide followed by ignition at 1000°. The perchloric acid concentration was calculated by titration with standard sodium hydroxide to a phenolphthalein end-point and subtraction of the known equivalents of indium that were present.

Fisher C.P. sodium perchlorate (once recrystallized) and Mallinckrodt analytical reagent sodium bromide and perchloric acid were the chemicals employed.

All absorbance measurements were made using a Beckman model DU quartz photoelectric spectrophotometer with an ultraviolet attachment in a room whose temperature was controlled at 21.7 ± 0.6°. Matched silica cells of 0.100, 1.000 and 10.00 cm. lengths were employed. The corrections for scattered light were determined by observing the differences in absorbance of water when present in each of the cells and then applied to the appropriate observed absorbance in each cell.

Results

The solutions of indium perchlorate, and varying amounts of an excess of sodium bromide, gave spectra with maxima between 220 and 235 mμ, depending on the concentration of the two reactants. The initial studies showed that the absorption of the solutions changed with time, and on standing overnight the solutions became yellow in color. Chemical tests proved this to be due to free bromine being formed.

Several factors in the production of bromine were examined qualitatively. It became evident that: (1) indium was not necessary; (2) the solution had to be acidic, for concentrated solutions of sodium perchlorate and sodium bromide were relatively stable and (3) sodium perchlorate had to be present. Air was shown not to be the cause of the difficulty and the possibility of chlorate impurity in the sodium perchlorate was eliminated. Indium appeared to catalyze the oxidation, since when the spectra of indium solutions containing excess bromide at high ionic strength were examined with reference to identical solutions, not containing indium perchlorate, it was observed that the peak at 270–280 mμ grew as a function of time and in 90 minutes completely obliterated the peak at 235 mμ.

The addition of small amounts of sodium sulfite (to give about 5×10^{-4} *M* sulfurous acid) eliminated the bromine absorption peak, and the solutions remained colorless for 12 to 24 hours. No evidence for complex formation between sulfite and indium was found under these conditions: the weak absorption spectrum of sulfite was unaffected by the presence of indium.

The complexing of indium with sulfate that is formed as the sulfite is oxidized by the bromine was also considered. Assuming all of the sulfite (10^{-4} *M* in the experiments described below) to be converted to sulfate, and taking Sunden's[5,6] values for the formation constants of the indium sulfate and bromide complexes, it was found that the ratio of $InBr^{++}$ to $InSO_4^+$ was over 3000. Thus, since it was observed that indium in sulfate media does not absorb in the regions examined, the amount complexed as the sulfate is negligible and will not affect the spectra of indium in bromide media.

In the initial exploratory work it was observed that, as would be expected from the plus three oxidation state of indium, the ionic strength of the solutions examined was quite an important factor. This pronounced effect is illustrated in Fig. 1, which shows the effect of ionic strength on the absorption spectra of indium in the presence of a large excess of bromide.

Continuous Variations.—To get a general idea of what complexes might be seen by their absorption, continuous variations experiments were done over a range of concentration, wave length and ionic strength. The results are shown in Fig. 2. It is known[10,11] that the method of continuous variations may not be valid if more than one absorbing complex is present or if the complex being studied is not fairly stable in comparison with the others. Inasmuch as it was shown later that more than one complex showed absorption in this region, and that the formation constants were not greatly different from each other, the system is not ideally suited to study by this method. The work is, however, sug-

gestive that the mono- and tetrabromo complexes, and possibly others, are formed in solutions containing both indium and bromide ions.

Spectra of Indium in Excess Bromide.—Using the results of the experiments in the previous sections as a guide, the determination of the successive formation constants of the indium bromide complexes at an ionic strength of 4.00 *M* was attempted. An ionic strength of 4.00 *M* was chosen, since it would therefore be possible to have a maximum bromide concentration of 3.90 *M*, (all solutions were 0.100 *M* in perchloric acid). Higher bromide concentrations had been observed to lead to no significant further increase in the absorbance of the 235 mμ peak. The concentration of indium perchlorate was 2.5×10^{-4} *M*; sodium sulfite, 1.0×10^{-4} *M*; perchloric acid, 0.100 *M*; and the ionic strength was maintained with sodium perchlorate. The location of the peak was constant at 235 ± 1 mμ for the range of bromide concentration of 0.200 to 3.900 *M*. Approximately 15 minutes were required to obtain the spectrum of one of these solutions, beginning at higher and moving toward lower wave lengths. Absorption by bromide ion places a lower limit on the wave length at which the spectra can be measured. The slit width, which was often as wide as 1.2 mm., was always kept constant in the region of the maximum.

In order to obtain better resolution at shorter wave lengths, the indium concentration was increased ten-fold in some experiments and 0.100 cm. cells used. Figure 3 shows how the resulting decrease in background bromide absorption allows the spectra to be taken to shorter wave lengths and a wider range of concentrations to be studied. Good agreement between molar absorptiv-

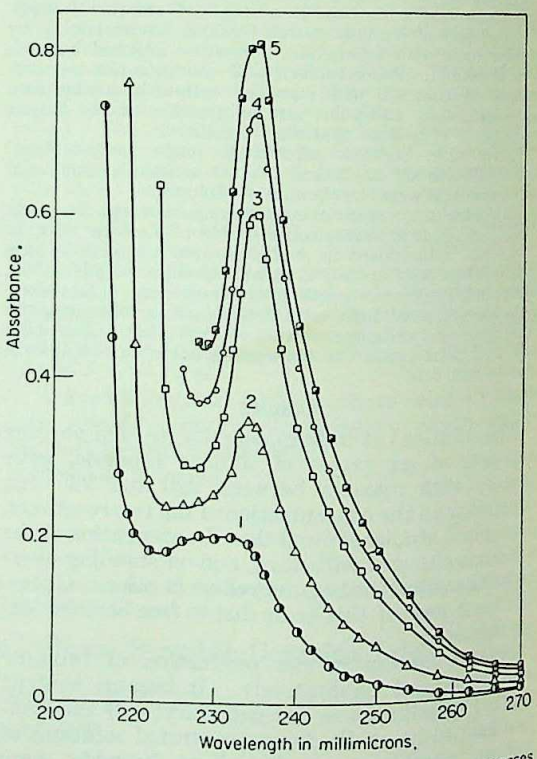

Fig. 3.—Spectra of indium in the presence of large excesses of bromide using 0.100 cm. silica cells. Conditions: 2.00×10^{-3} *M* $In(ClO_4)_3$, 0.100 *M* $HClO_4$, 5.00×10^{-4} *M* Na_2SO_3, $\mu = 4.00$ *M*. Curve 1, 0.100 *M* NaBr; curve 2, 0.200 *M* NaBr; curve 3, 0.500 *M* NaBr; curve 4, 1.000 *M* NaBr; curve 5, 3.90 *M* NaBr. When 1.00 cm. cells are used, the spectra have cutoffs between 225–234 mμ, depending on the concentration of bromide in the blank.

ities (extinction coefficients) measured under the two sets of conditions.

Determination of the First Stability Constant.—Modified McConnell–Davidson[12] techniques were employed to evaluate the first two stability constants. In order to determine the first formation constant, an excess of indium was added to ensure that only three absorbing species were present: *i.e.*, In^{+++}, $InBr^{++}$ and Br^-. Assuming that all three species absorb, and incorporating the mass-action expression, $k_1 = (InBr^{++})/(In^{+++})(Br^-)$, the resulting expression can be derived for a specific wave length

$$\frac{ab}{A_0 - A_a - A_b} = \frac{1}{(\epsilon_\alpha - \epsilon_a - \epsilon_b)k_1} + \frac{a}{(\epsilon_\alpha - \epsilon_a - \epsilon_b)} \quad (1)$$

where ϵ_α, ϵ_a, and ϵ_b are the molar absorptivities of the complex, indic and bromide ions, respectively; a and b are the analytical concentrations of indic and bromide ions, respectively; A_0 is the observed absorbance of the solution containing the mixture of indium and bromide ions; and A_a and A_b are the absorbances of solution containing only a concentration of indium perchlorate and b concentration of sodium bromide, respectively. When $ab/(A_0 - A_a - A_b)$ is plotted *vs.* a, a straight line results, and the ratio of the slope to the intercept of the line is equal to the formation constant.

In the work performed in this section, each solution was 0.00200 M in sodium bromide, 0.100 M in perchloric acid, the concentration of indium perchlorate was varied from 0.006 to 0.100 M, and the ionic strength was maintained at 4.00 M by use of sodium perchlorate. The use of sodium sulfite was found to be unnecessary; bromide at these low concentrations was not appreciably oxidized. Table II shows the results of the McConnell–Davidson plots, all of which gave good straight lines.

TABLE II

McCONNELL–DAVIDSON DETERMINATION OF THE FIRST FORMATION CONSTANT

Wave length, mμ	$\epsilon_{InBr^{++}}$	ϵ_{Br^-}	$\epsilon_{In^{+++}}$	k_1

231.0	86.1	30.5	5.0	122
232.0	73.0	29.0	4.3	133
	Av. $k_1 = 123$		Std. dev. = 4.9	

Determination of the Second Stability Constant.—If the experimental conditions are altered slightly to give a small excess of bromide, the species $InBr_2^+$ will also be present. It is then possible to evaluate the second "stepwise" formation constant. If the second stepwise equilibrium is considered, the exact eq. 2 results

$$\frac{a}{D} = \frac{1}{(\epsilon_\beta - \epsilon_a - 2\epsilon_b)k_2} G + \frac{1}{(\epsilon_\beta - \epsilon_a - 2\epsilon_D)} \quad (2)$$

where $D = A_0 - A_a - A_b$, $k_2 = (InBr_2^+)/(InBr^{++})\cdot(Br^-)$, ϵ_β = molar absorptivity of the $InBr_2^+$ ion, and G is a function of the ligand concentration

$$G = \frac{1}{k_1 X^2} + \frac{1}{X} + \frac{(\epsilon_\alpha - \epsilon_a - \epsilon_b)a}{DX}$$

where X represents the equilibrium concentration of bromide. All that is needed is to plot a/D *vs.* G and k_2 can be determined from the resulting curve, for k_2 is equal to the intercept divided by the slope.

The spectra for indium in the presence of a slight excess of bromide (with water as the reference solution), for wave lengths 226–240 mμ at an ionic strength of 4.00 M were determined. The concentration of indium perchlorate was 2.00 mM, perchloric acid concentration was 0.100 M, and the bromide was varied at concentrations of 5.00, 10.00, 15.00, 20.00, 25.00 and 30.00 mM. It is obvious that the equilibrium concentration of halide and thus the values of G must be estimated from the six different estimated values of X. It was found that after the third approximation of X, a 10% difference in the estimated k_2 gave rise to less than half of 1% change in G, and less than 0.3% difference in the value of X. The equilibrium concentrations of bromide under the above conditions were calculated to be 4.24, 8.74, 13.37, 18.12, 22.92 and 27.73 mM, respectively. The approximation was performed only at 230 mμ; and since the resulting values of k_2 all differed by less than 10%, the above values of X were used at all wave lengths considered to calculate the function G. The results of the good straight lines that were obtained using this interpretation for the wave lengths 226–240 mμ are shown in Table III. The values of the molar absorptivities of the first complex at these wave lengths found in the determination of the first stability constant were used.

TABLE III

McCONNELL–DAVIDSON DETERMINATION OF THE SECOND FORMATION CONSTANT

Wave length, mμ	$\epsilon_{InBr^{++}}$	k_2
226.0[a]	1460	18.3
228.0[a]	1370	19.5
230.0	1310	18.6
232.0	1040	19.0
234.0	839	18.2
236.0	595	18.5
238.0	401	18.2

Av. $k_2 = 18.7$ $s = 0.51$

[a] Only 3 points determined this line.

Determination of Higher Complexes.—Further work was performed on solutions containing large excesses of bromide, in an effort to evaluate the stability constants of the higher complexes whose existence was suggested by the method of continuous variations. The data obtained were interpreted in a manner similar to that of Kingery and Hume[13]. At high halide concentrations, the stability constant for the highest complex can be determined on the basis of the reaction

$$InBr_r^{+3-r} + n Br^- = InBr_{r+n}^{+3-r-n} \quad (4)$$

(12) H. McConnell and N. Davidson, THIS JOURNAL, **72**, 3164 (1956).

(13) W. D. Kingery and D. N. Hume, *ibid.*, **71**, 2393 (1949).

and

$$k_{r+n} = \frac{(InBr_{r+n}^{+3-r-n}}{(InBr_r^{+3-r})(Br^-)^n} \qquad (5)$$

If the higher complex is the only absorbing species, and the next lower complex is the only other species of indium present in appreciable amounts, an equation results

$$\log \frac{A_i}{A_L - A_i} = n(\log X_i) + \log k_{r+n} \qquad (6)$$

where A_i is the observed absorbance for a concentration X_i of bromide and A_L is the asymptotic limit of absorbance of A_i as X_i approaches infinity. By plotting $\log A_i/(A_L - A_i)$ *vs.* $\log X_i$, it is seen that the slope reveals the value of n, and the intercept, when $\log X_i$ is zero, is the formation constant, k_{r+n}. In this work, the bromide absorbs quite strongly due to its high concentration, and its absorbance was compensated for in the reference cell.

Figure 4 shows three typical curves in the determination of A_L. The plot of $\log A_i/(A_L - A_i)$ *vs.*

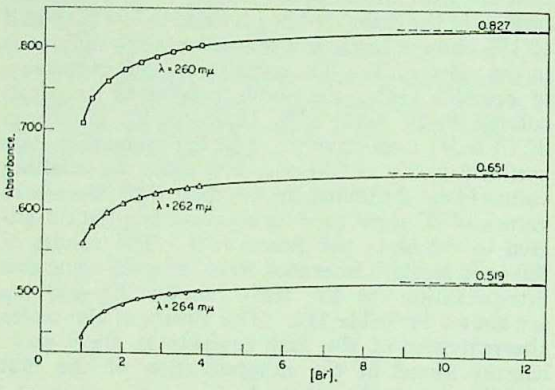

Fig. 4.—Typical determinations of the molar absorptivity. Conditions: 2.50×10^{-4} *M* $In(ClO_4)_3$, 0.100 *M* $HClO_4$, 1.00×10^{-4} *M* Na_2SO_3, $\mu = 4.00$ *M*, and 10.00 cm. cells.

$\log X_i$ was linear for 20 wave lengths between 235 and 270 mμ. All of these data were obtained using 2.50×10^{-4} *M* indium perchlorate, 0.100 *M* perchloric acid, 1.00×10^{-4} *M* sodium sulfite, and the bromide concentration was varied at 1.00, 1.20, 1.60, 2.00, 2.40, 2.80, 3.20, 3.60 and 3.90 *M*. Ten-centimeter cells enabled readings to be taken at wave lengths from 260 to 270 mμ, where it is felt the lower complex would not be absorbing, and readings were taken between 235 and 250 mμ with one-centimeter cells. Since the ratio $A_i/(A_L - A_i)$ was relatively constant in the two ranges for a particular bromide concentration, it can be concluded that the lower complex is not absorbing in the 235–250 range.

The formation constant for the addition of the last ligand was evaluated to be 6.1. The slope, 1.19, indicated that only one bromide was added.

The fact that the ratio $A_i/(A_L - A_i)$ at a particular value of X_i was relatively constant over the whole wave length range that was examined shows that the same species is absorbing throughout the range. The fact that the same method yielded a straight line shows that the method is valid, and hence the lower species does not absorb throughout the wave length range.

Since the continuous variation work suggested an $InBr_4^-$ species, it is reasonable to interpret the preceding work on the assumption that $k_{r+n} = k_4$. If this is the case, since $n = 1$, the lower species—*i.e.*, $InBr_3$—must exist in solution, and the third formation constant, k_3, can be determined by a difference technique. The fraction of the indium in the form of the fourth complex is

$$\frac{(InBr_4^-)}{(\Sigma In^{+++})} = \frac{k_1k_2k_3k_4X^4}{1 + k_1X + k_1k_2X^2 + k_1k_2k_3X^3 + k_1k_2k_4X^4} \qquad (7)$$

If $InBr_4^-$ is the only absorbing species, then the ratio $(InBr_4^-)/(\Sigma In^{+++})$ will equal A_i/A_L, where A_i and A_L have the same meaning as before. If the equilibrium concentration of bromide is large with respect to the equilibrium concentrations of the complexed indium, then the equilibrium concentration approximates the analytical concentration of bromide.

Absorbance measurements were taken as previously, with an ionic strength of 4.00 *M*, 2.50×10^{-4} *M* indium perchlorate, 1.00×10^{-4} *M* sodium sulfite, 0.100 *M* perchloric acid, and varying the sodium bromide concentration at 0.050, 0.100, 0.150, 0.200, 0.300, 0.400, 0.500, 0.600, 0.700 and 1.000 *M*. At these concentrations it was felt that the missing complex could be detected using the 1.000 and 10.00 cm. silica cells in the wave length ranges 240–250 and 260–270 mμ, respectively. Utilizing the limiting absorbances that had been determined before, the ratio A_i/A_L was determined for a particular bromide ion concentration as a function of wave length. With the exception of wave lengths below 244 mμ (particularly at low bromide concentrations), this ratio was constant.

Table IV lists the average values of the ratio A_i/A_L over the wave length regions examined as a function of the bromide concentration and cells employed. Since the values are in reasonably good agreement, it can be concluded that only one species is present and absorbing in these regions. The fact that the data obtained with the 10.00 cm. cells show a lower standard deviation—and give lower values for each respective bromide ion concentration, indicates that lower complexes are absorbing in the 240–250 mμ range, although not enough to change the ratio appreciably.

TABLE IV

FRACTION OF INDIUM COMPLEXED IN THE HIGHEST FORM

	1.000 cm. cells			10.00 cm. cells

Knowing k_1, k_2, k_4 and A_i/A_L as a function of the bromide concentration, it is possible to solve for k_3 (Table IV shows the resulting values of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

k_3. The diminishing trend with decreasing bromide concentration is believed to be caused by (1) errors in the "known" (k_1, k_2 and k_4) formation constants, and (2) amplification of a small effect by taking the difference of two large numbers. To avoid the latter effect only the results in the range 0.05 to 0.4 M bromide were averaged to give the most probable value of 4.8 for k_3.

Alternative Treatments of the Data.—The data of this investigation have been treated by several alternative methods described in a recent publication by Rossotti and Rossotti,[14] in order to compare the efficacy of the various methods used and to establish the best possible values of formation constants from the experimental results at hand.

In the first of these, by defining f_c as the fraction of the metal complexed as MX_c, we have

$$f_c = \frac{MX_c}{\Sigma M} = \frac{K_c X^c}{1 + \Sigma K_n X^n} \qquad (8)$$

where K_n is the over-all formation constant $k_1 \cdot k_2 k_3 \ldots k_n$. Taking logarithms, differentiating and substituting Bjerrum's $\bar{n}$ expression for the average number of ligands attached to the metal ion[15] we obtain

$$\frac{d(\log f_c)}{d(\log X)} = c - \bar{n} \qquad (9)$$

The continuous variations experiments indicate that the maximum value of c is probably 4; however, it is seen that this method just described will in turn evaluate c when data obtained during the determination of the second formation constant are employed in conjunction with the data of Table IV. Log f_c was plotted *vs.* log Br^- for bromide concentrations 0.050–1.000 M, as is shown in Fig. 5, and the slopes were determined as a function of the bromide ion concentration. The values of $c - \bar{n}$ are given in Table V, together with values of $\bar{n}$ (calculated assuming c to be 3, 4 and 5).

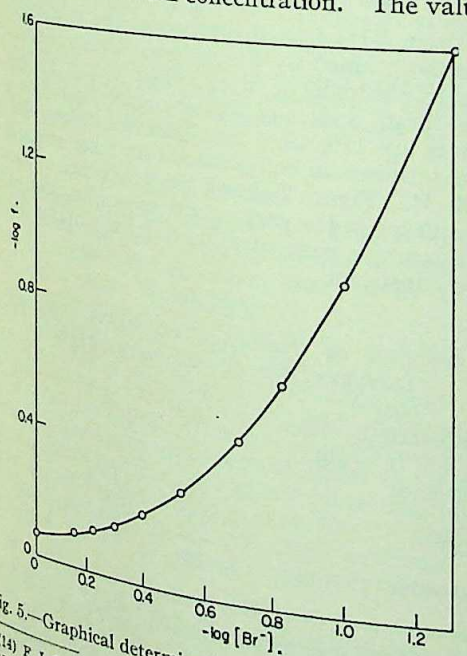

Fig. 5.—Graphical determination of the ligand number, $\bar{n}$.

$\bar{n}$ VALUES EVALUATED FROM DATA OBTAINED IN DETERMINATION OF SECOND CONSTANT

Indium $\times 10^3$	Total Bromide $\times 10^3$	Equilibrium bromide $\times 10^3$	$-\log Br^-$	$\bar{n}$
2.00	5.00	4.24	2.301	0.38
2.00	10.00	8.74	2.000	.63
2.00	15.00	13.37	1.824	.82
2.00	20.00	18.12	1.699	.94
2.00	25.00	22.92	1.602	1.05
2.00	30.00	27.73	1.523	1.14

Using the data obtained in the McConnell–Davidson determination of the second stability constant, $\bar{n}$ was calculated for a bromide range of 0.005–0.030 M.

Figure 6 shows the formation curve of indium in bromide medium: that is, $\bar{n}$ as a function of log Br^-.

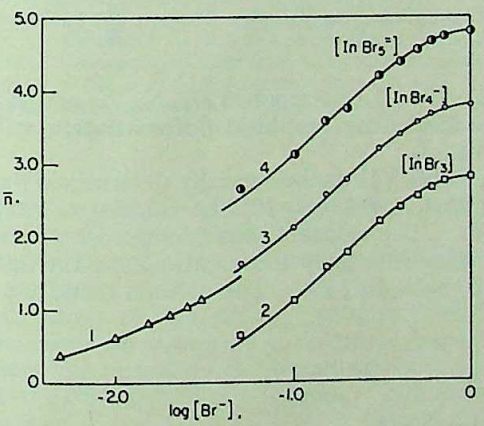

Fig. 6.—Formation curve of indium in a bromide medium. Curves 1, $\bar{n}$ calculated from data obtained in the determination of the second constant; 2, $\bar{n}$ calculated on the assumption that $InBr_3$ is absorbing species; 3, $\bar{n}$ calculated on the assumption that $InBr_4^-$ is absorbing species; 4, $\bar{n}$ calculated on the assumption that $InBr_5^=$ is absorbing species.

It is seen from this figure that assuming the absorbing species to be $InBr_3$ or $InBr_5^=$ leads to inconsistent results. A smooth curve can be drawn connecting the two sets of data only if $InBr_4^-$ is the species absorbing.

Using the values of $\bar{n}$ as a function of the bromide concentration, it is also possible to evaluate

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the formation constants by a graphical method outlined by Rossotti and Rossotti.[14]

$$J_1(X) = K_1 + \left(\frac{2-\bar{n}}{1-\bar{n}}\right) K_2X + \left(\frac{3-\bar{n}}{1-\bar{n}}\right) K_3X^2 + \left(\frac{4-\bar{n}}{1-\bar{n}}\right) K_4X^3 \ldots \quad (10)$$

The value of $J_1(X)$ when extrapolated to $X = 0$ is equal to k_1. In a similar manner, defining

$$J_2(X) = [J_1(X) - K_1]\left(\frac{1-\bar{n}}{2-\bar{n}}\right)\frac{1}{X}$$

it is seen that the value of $J_2(X)$ when extrapolated to $X = 0$ is equal to K_2, and so on for higher orders of $J(X)$.

Table VI lists the values of the $J(X)$ functions. When $J_3(X)$ was plotted *vs.* X, a very low value for K_3 was obtained which was felt to be in error. Only the values of $J_3(X)$ at low bromide concentrations were used in evaluating the intercept, at which concentrations very little $InBr_3$ exists, and they had twice been differentiated graphically. To obviate this problem, it was seen that all the values of $J_3(X)$ could be used if $J_3(X)$ were plotted *vs.* $[(4 - \bar{n})/(3 - \bar{n})](Br^-)$, and therefore the intercept would still equal K_3; but now K_4 could be evaluated, since it was equal to the slope of the resulting straight line. The fact that a relatively good straight line was obtained substantiates the fact that $InBr_4^-$ is the highest species existing in this system. The stepwise constants for the first four complexes were calculated to be 120, 19.0, 2.9 and 8.5, respectively.

The data obtained showing the fraction of indium complexed as $InBr_4^-$ can be used to evaluate the formation constants in yet a different manner. Rossotti and Rossotti[14] have derived the expression

$$H_0(X) = \frac{X^4}{f} = \frac{1}{K_4} + \frac{K_1}{K_4}X + \frac{K_2}{K_4}X^2 + \frac{K_3}{K_4}X^3 + X^4 \quad (11)$$

from which the parameters K_1, K_2, K_3 and K_4 may be evaluated by graphical differentiation with respect to X.

In Table VII experimentally determined f values are given, together with the calculated values of $H_J(X)$. The values obtained for the "stepwise" formation constants by this treatment of the data are ~110, ~18, 3.7, 7.4. The method turns out to be not very good for k_1 or k_2 since the intercepts of $H_0(X)$ and $H_1(X)$ are very small and not very accurately known.

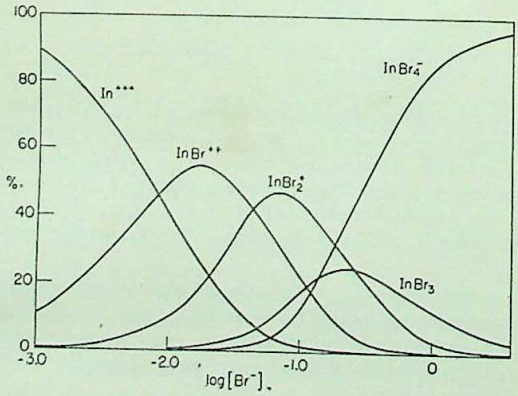

Fig. 7.—Percentage of indium in its various forms as a function of the free bromide concentration at $\mu = 4.00$.

Table VIII lists the values of the stability constants obtained by the different treatments of the spectrophotometric data. The values chosen as the "best" values of the successive formation constants are 120, 19, 4 and 7 for the mono-, di-, tri- and tetrabromo complexes at an ionic strength of 4.00 *M*. Figure 7 shows the percentage of indium complexed in the various species as a function of the free bromide concentration using the above formation constants.

TABLE VIII

COMPARISON OF FORMATION CONSTANTS OBTAINED BY DIFFERENT SPECTROPHOTOMETRIC METHODS

Method	k_1	k_2	k_3	k_4
McConnell–Davidson	123	18.7	..	..
$\log A_i/(A_L - A_i)$	..	..	..	6.1

$J(X)$	120	19.2	2.9	8.5
$H(X)$	~110	~18	3.7	7.4
Best value	120	19	4	7

Discussion

From the spectrophotometric study, it is definite that four species, $InBr^{++}$, $InBr_2^+$, $InBr_3$ and $InBr_4^-$ are present in aqueous solutions under the conditions examined: *i.e.*, ionic strength of 4.00 *M*, 0.100 *M* perchloric acid, and 5×10^{-4} *M* sodium sulfite. The fact that the fourth complex is

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

present in appreciable amounts is contrary to the findings of Irving and Rosotti[9] who were the only other workers to observe the existence of the fourth complex. In all previous studies, any small error in the determination of the equilibrium concentration of indium and/or a graphically determined quantity might be amplified on successive graphical treatment with the result that the information on the highest complexes would be least accurate. The spectrophotometric method, however, is unique in that a direct measure of the fourth complex in aqueous solution is possible. The formation constants for the first three complexes obtained in this investigation agree reasonably well with those of previous authors.

The evidence was so clear-cut for the four monomeric species that it was not necessary to consider the possibility of dimerization. The dimeric species observed by Irving and Rossotti were found only for "macro" amounts of indium in high hydrobromic acid concentrations, conditions not strictly comparable to ours.

The fact that Woodward and Bill,[16] from a study of the Raman spectra of indium salts in the presence of a large excess of bromide, concluded no tetrahedral $InBr_4^-$ ion to be present in aqueous solution, does not necessarily contradict the present findings. Indium frequently shows hexacoördination, and one would expect to find $[In(H_2O)_2Br_4]^-$ ions in solutions such as ours. The case of iron is a pertinent analogy. It is extracted from hydrochloric acid solutions by ether and other solvents in the form of $HFeCl_4$, which is described as tetracoördination,[17] although some water is also extracted. The stoichiometric solubility of KCl in anhydrous ethyl acetate solutions of $FeCl_3$ to form the compound $KFeCl_4$ appears to be a clean-cut example of tetracoördination of iron[18]; yet in aqueous media, the octahedral character of ferric complexes is beyond question.[19]

Electrode Potential Studies of Liquid–Solid Equilibrium in Zn–Cd and Zn–In Alloys

BY R. W. BOHL[1] AND V. D. HILDEBRANDT

RECEIVED DECEMBER 14, 1956

Thermodynamic properties of liquid alloys were determined in binary Zn–Cd and Zn–In alloys by the measurement of electrode potentials of galvanic cells of the type: Zn(liq)/$ZnCl_2$(in KCl–LiCl liq)/Zn(in liq soln.). Measurements were carried out over a range of temperatures from 420 to 530°. Liquid–solid phase equilibrium was calculated by finding the temperature at which activities of zinc in the solid state and in liquid alloys were equal. The activity of zinc in the solid was calculated from heat of fusion and heat capacity data for pure zinc. The e.m.f. data were used in turn to calculate the heat of fusion of pure zinc, based on published values of liquidus point. Values thus determined showed much less scatter than published values based on calorimetric techniques. The properties of the liquid alloys were examined with regard to solution theory, and Zn–Cd alloys were shown to closely approach regular behavior, while Zn–In alloys showed some deviation from this behavior. Both systems showed positive deviations from Raoult's Law, and positive heats of solution over the entire composition range.

Introduction

Electrode potential studies have long been used to evaluate thermodynamic properties of solutions, but this technique has seldom been applied to the study of phase equilibrium in metal systems. Early applications of electrode potential studies to metal systems by Lindeck[2] and Richards[3] were limited to the study of thermodynamic properties of amalgams. Later, Taylor[4] and Hildebrand[5] used the principles of e.m.f. measurements in studying the thermodynamics of liquid metal solutions. Seltz and his co-workers[6] were among the first to apply the technique to the problem of phase equilibrium in binary metal systems. An excellent review of recent experimental results, techniques, and methods of calculation in this field is given by Dunkerley and Mills.[7]

In this investigation, accurate and precise e.m.f. measurements were made on galvanic cells of liquid alloys of the binary systems Zn–Cd and Zn–In, and the data used to calculate the thermodynamic properties of the liquid alloys and determine the liquid–solid equilibrium. The cells were of the type

$$\text{Zn(liq)}/Zn^{++}/\text{Zn(in liq soln.)} \qquad (1)$$

If the cell reaction, Zn(liq) → Zn(in liq soln.), is reversible and unique, and only Zn^{++} ions carry the current, the following relation applies to the reaction

$$\Delta\bar{F}_{Zn} = -2E\mathfrak{F} \qquad (2)$$

where $\mathfrak{F}$ is the Faraday constant and E is the e.m.f. in volts. If pure liquid zinc is taken as the standard state, the activity of Zn, the more electropositive component of the cell, can be calculated

for the entire composition range from the relation

$$\ln a_{Zn} = \Delta\bar{F}_{Zn}/RT \qquad (3)$$

The activity of the second component of the system can then be determined by graphical integration of the Gibbs–Duhem equation

$$\log(a_2/N_2) = -\int_{N_{Zn}=0}^{N_{Zn}} (N_{Zn}/N_2)\log(a_{Zn}/N_{Zn}) \qquad (4)$$

If measurements are carried out over a sufficient temperature range, the slope of the e.m.f. *vs.* temperature curve can be established, and the enthalpy of the cell reaction can be calculated by the Gibbs–Helmholtz equation

$$T(dE/dT) = E - \Delta H/2\mathfrak{F} \qquad (5)$$

where $H = \bar{H}_{Zn} - H_{Zn}°$, and is usually designated as $\bar{L}_{Zn}$.

Graphical integration again facilitates calculation of the partial molar enthalpy of the second component of the cell, $\bar{L}_2$

$$L_2 = -\int_{N_{Zn}=0}^{N_{Zn}} (N_{Zn}/N_2)d\bar{L}_{Zn} \qquad (6)$$

The partial molar entropies of the reactions can be calculated from the relationship

$$\Delta \bar{F}_i = \Delta \bar{H}_i - T\Delta S_i \qquad (7)$$

The integral molar quantities can be calculated from the partial molar functions by means of the general relation

$$G = N_1 G_1 + N_2 G_2 \qquad (8)$$

Experimental

The alloys studied were prepared from high purity metal obtained from commercial sources. The electrolyte, consisting of an eutectic mixture of potassium and lithium chlorides to which was added about 5% zinc chloride, was prepared from reagent grade chemicals.

The cell consisted of a water-cooled brass top sealed with black wax to an outer 64 mm. Pyrex tube. The top brass fitting was provided with openings through which seven electrodes could be placed in addition to a thermocouple well and an opening to a vacuum system. The alloy electrodes were contained in bulbs prepared from 13 mm. Pyrex tubing with tungsten wire leads sealed in 3 mm. tubing. The cell was assembled so that the electrode containers could be moved from the water-cooled section of the cell into the electrolyte without breaking the vacuum on the cell.

The cell was heated in a furnace consisting of a 5-in. i.d. Alundum core non-inductively wound with Kanthal, and surrounded by 3 inches of Sil-o-cel insulation.

A steel pot containing a low melting nitrate–nitrite salt bath was placed inside the Alundum core, and the cell was immerserd in this bath to a depth near the water-cooled section. This arrangement provided very uniform heating of the cell, and the large thermal mass of the furnace protected against temperature fluctuations. The temperature of the furnace was controlled by a variable transformer. The water cooled top of the cell which projected out of the furnace was maintained at ambient temperatures. Thermocouples in the cell and at various positions in the furnace salt bath checked within 1°, ensuring against the presence of thermal gradients.

With seven electrodes, e.m.f. measurements between five alloys and a pure zinc electrode could be taken simultaneously; the seventh was a pure zinc electrode permitting measurement of the e.m.f. between two pure zinc electrodes. This measurement provided a check against spurious readings due to changes in electrolyte composition, thermal gradients, etc.

Tungsten leads from the electrodes were connected through a selector switch to a L and N Type K-2 potentiometer. The vacuum was provided by a mechanical pump operating through a pressure regulator. The system contained a three-way valve for admitting helium to the system.

The procedure followed in preparing the alloys consisted first of melting the as received metals under vacuum and casting them into sticks. The alloys were then weighed out, sealed under vacuum in Pyrex tubes, and again melted. The alloys thus prepared were cut into pieces for charging into the electrode containers described above. Weight checks made after alloying and after the experimental runs were completed showed a negligible change, and the analyses given are the as weighed analyses.

The electrolyte was melted in an open beaker to which a small pellet of zinc was added, and then cast into a 57 mm. Pyrex tube which fit inside the cell. The use of this inner cell was a precaution taken to avoid the danger of cracking the outer cell.

The cell was assembled with the electrode bulbs positioned in the water-cooled section of the cell. This assembly was placed in the salt pot furnace at a temperature just under the melting point of the electrolyte under a vacuum of 20 μ for a period of ten days prior to the actual experimental run in order to out-gas and desiccate the electrolyte and break up any complex chlorate ions which may have been present.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

When the period of electrolyte desiccation was complete, the temperature of the furnace was raised to about 450° and the electrodes lowered from the cold zone into the molten electrolyte without breaking the vacuum on the system. The pressure regulator was set at about 8 mm. and retained for one hour after the alloys were melted to remove any dissolved gases. Helium was then flushed through the cell several times before the cell, containing about one-half atmosphere of helium, was sealed from the vacuum system. The cell was held overnight at constant temperature to attain equilibrium before readings were begun. Readings were repeated at each temperature at 10 minute intervals until a constant e.m.f. was obtained for each alloy. The temperature of the cell was then changed and the process repeated. Readings were made over a temperature range of 420 to 530°.

As a test of reversibility of the cell reaction, data were taken on both heating and cooling cycles. Readings on heating and cooling were as reproducible as were the readings at constant temperature; *i.e.*, within 0.02 mv. This reproducibility is taken as an excellent criterion of reversibility. The e.m.f. measured between the two pure zinc electrodes was 0.00 ± 0.03 mv. for all runs.

Discussion of Results

The e.m.f. measured between pure zinc and a series of Zn–Cd and Zn–In alloys as a function of temperature is given in Table I. These data lay on straight lines within the experimental accuracy of the readings. The equations of the lines were calculated by the method of least squares, and from the equations dE/dT and the e.m.f. at particular temperatures were determined. Subsequent calculations of thermodynamic properties were based on these values. Figures 1 and 2 show the activities of the components as a function of composition, while Table II gives the values of selected thermodynamic properties calculated at 470° about midway in the temperature range investigated. Both systems studied show positive deviation from Raoult's law, and positive heats of mixing.

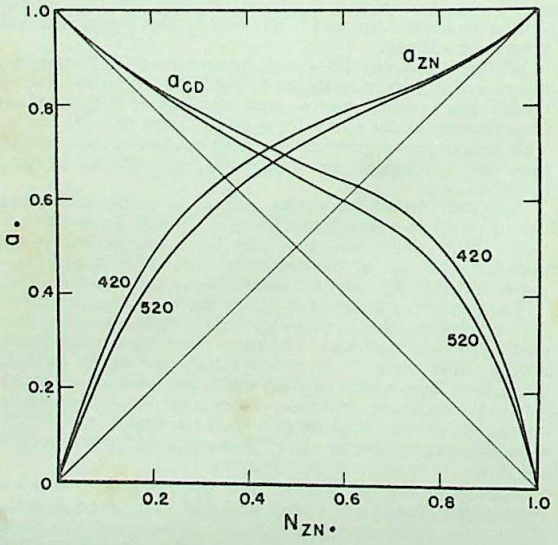

Fig. 1.—Activity *vs.* atom fraction for Zn–Cd alloys at 420 and 520°.

The liquid–solid equilibrium was determined by finding the temperature at which the activity of zinc in the liquid phase equalled that in the solid. A graphical solution was obtained by plotting

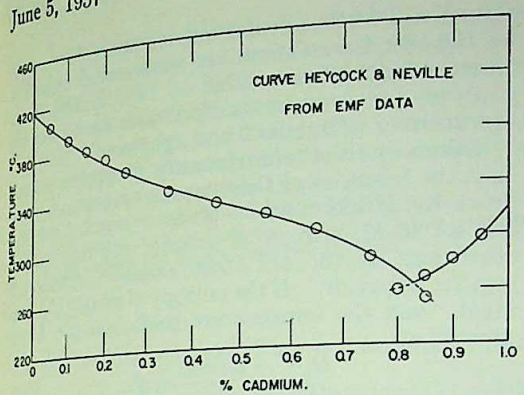

Fig. 4.—Comparison of calculated liquidus points in Zn–Cd system with data of Heycock and Neville.

$-R \ln a_{Zn}$ against $1/T$. Since, according to the Gibbs-Helmholtz equation

$$\frac{d(\Delta F/T)}{d(1/T)} = -\Delta H \text{ and } \Delta F/T = -R \ln a_{Zn} \quad (9)$$

such a plot should yield a straight line if ΔH is constant over the temperature range considered.

Values of $-R \ln a_{Zn}$ for the liquid alloys are readily calculated from the e.m.f. data. The value of $-R \ln a'_{Zn}$ (the prime indicates the solid phase) can be calculated from available thermodynamic data by application of another form of the Gibbs-Helmholtz equation to the reaction Zn(liq) → Zn(solid)

$$d(\Delta F/T) = -(\Delta H/T^2)\, dT \quad (10)$$

Using specific heat and heat of fusion data for pure zinc, this expression can be evaluated as

$$\Delta F/T = -7.6551 \log T + 0.2256 \times 10^{-2} T - 0.0023 \times 10^{-4} T^2 + 287.1/T + 19.8781 \quad (11)$$

The activity calculated by this expression must be multiplied by the composition of the α-solid–solution zinc phase to correct for the small amount of solubility which zinc has for the solute element. This correction assumes that Raoult's law is obeyed in the solid phase—a reasonable assumption in such a dilute solution. The solid solubility data for the Zn–Cd system were taken from the work of Stockdale,[8] and for the Zn–In system from Rhines and Grobe.[9]

The method is illustrated in Fig. 3 for the determination of the Zn-rich liquidus in the Zn–Cd system. Curves of $-R \ln a$ for the liquid alloys were extrapolated until they intersect the curve for the solid phase, the points of intersection giving the temperatures of the liquidus points.

Good agreement has been obtained with the generally accepted Zn–Cd liquidus of Heycock and Neville[10] as determined by thermal analysis. Figure 4 shows their curve, and the liquidus points calculated from the e.m.f. data are shown as experimental points. The comparative eutectic temperatures and compositions are 266° and 82.5% Zn by Heycock and Neville, and 265° and 82.5% calculated from these data as the intersection of the Zn-rich and Cd-rich liquidus curves.

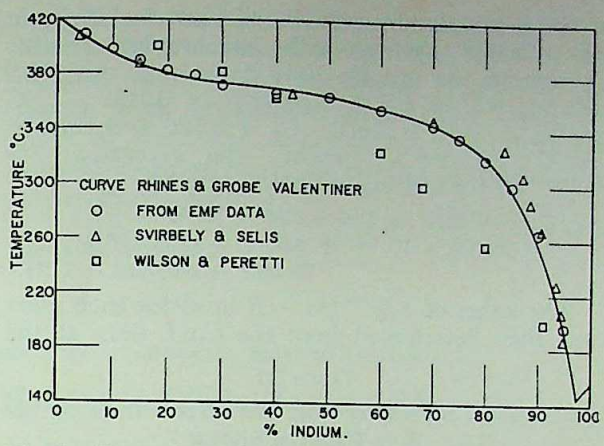

Fig. 5.—Comparison of calculated liquidus points in Zn–In system with data from other investigators.

The In–Zn phase diagram has been determined by Rhines and Grobe,[9] Valentiner,[11] Wilson and Peretti,[12] and Svirbely and Selis.[13] The curve shown in Fig. 5 is drawn from the data of the first two references, and represents the most widely accepted values. Values from the latter two investigations as well as from this study are shown as plotted points in the figure. Again the liquidus determined from these data agrees very well with the published values of the other investigators.

The results of Svirbely and Selis were also based on e.m.f. studies. In their work, e.m.f. data were taken below the melting point of Zn, with pure solid Zn as one electrode (Type II cells) as well as above the melting point (Type I cells) as in this study. The results of their work agree quite well with this study, although a different procedure requiring a more complicated graphical analysis was followed in the liquidus determinations. In their work the a_{Zn} in pure solid zinc and in liquid alloys was calculated with pure liquid Zn as the standard state. Phase equilibrium was then determined by simultaneous solution of plots of a_{Zn} *vs.* temperature for solid Zn and a_{Zn} *vs.* N_{Zn} at various temperatures for the liquid alloys.

Determination of liquidus points by either method depends on accurate values of specific heat and heat of fusion for pure Zn. Values of heat of fusion quoted in the literature, however, are widely scattered as might be expected in view of the experimental difficulties of high temperature calorimetry. The value chosen to calculate the activity of supercooled liquid Zn in this research is the result of a recent evaluation by the National Bureau of Standards.[14] Other sources quote values from 1504[15] to 1765[16] cal./mole. These discrepancies suggest the application of the e.m.f. data to evaluate the heat of fusion. The evaluation can be made by essentially the same method as the determination of the liquidus, but with ΔH_f of Zn as the unknown, and using reliable values of liquidus temperatures.

Such calculations were carried out for alloys in the Zn–Cd system with encouraging results. Accepting the specific heat data from the NBS (Zn(c): $C_p = 5.202 + 0.3238 \times 10^{-2}T - 0.01038 \times 10^{-4}T^2$: Zn(l): $C_p = 8.526 - 0.1274 \times 10^{-2}T$ cal./deg. g. atom), the expression for $\Delta F/T$ for the melting of Zn was derived

$$\Delta F/T = -7.6552 \log T + 0.2256 \times 10^{-2}T - 0.0023 \times 10^{-4}T^2 + \Delta H_f/T - 1362.9/T + 22.2601 - \Delta H_f/692.7 \quad (12)$$

The value of $\Delta F/T$ ($= -R \ln a$) for each alloy was then determined from the e.m.f. data at the liquidus temperature given by the phase diagram and corrected for the solubility of Cd in solid Zn. With this value, ΔH_f was evaluated from the above equation. Such calculations made for four alloys in the Zn–Cd system are given in Table III. These results give a value of 1.64 ± 0.03 kcal./g. atom compared to the best evaluation from the literature of 1.66 ± 0.10 kcal./g. atom.

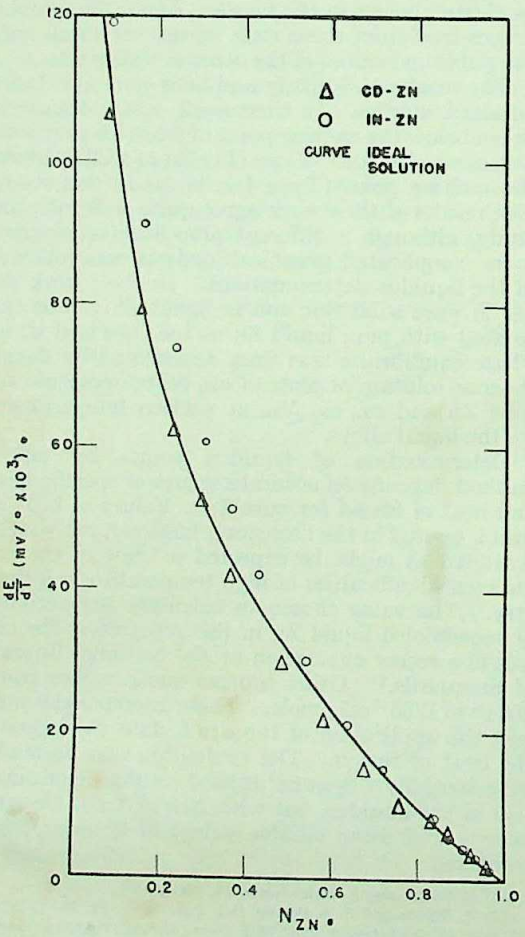

Fig. 6.—Curve shows dE/dT for cell whose components have ideal entropy of mixing. Experimental data shown as plotted points.

Values of the thermodynamic properties suggest that the behavior of these systems is regular, as defined by Hildebrand.[17] Since a regular solution has an ideal entropy of mixing, the temperature coefficient of the cell is an excellent criterion of regular behavior. If the entropy of mixing is indeed ideal, then the temperature coefficient can be expressed as

$$\frac{dE}{dT} = \frac{-2.303R}{n\mathfrak{F}} \log N_{Zn} \quad (13)$$

This curve is plotted in Fig. 6 along with experimental values measured for the cells studied. The data for the Zn–Cd system are seen to approach regular behavior closely, while the agreement is not as good for the Zn–In alloys.

A regular solution also can be shown to follow the relation

$$RT \ln \gamma_2 = BN_1^2 \quad (14)$$

Some departure from this relation is seen in Fig. 7, as the experimental points deviate from linearity.

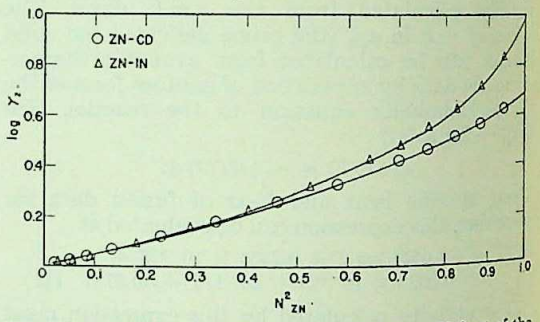

Fig. 7.—Variation of the log of the activity coefficient of the solute with the square of the atom fraction of Zn.

When the volume fraction rather than atom fraction is used, as Hildebrand has suggested, the agreement with the theoretical curve is much improved, as shown in Fig. 8. It is not unexpected that the volume fraction is of considerable importance in the properties of solutions, since the relative volumes greatly affect the degree of packing and the action of interatomic forces. Data for the molar volumes of the pure metals were taken from the density

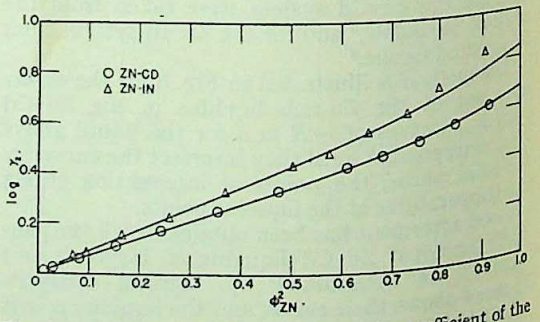

Fig. 8.—Variation of the log of the activity coefficient of the solute with the square of the volume fraction of Zn.

data of Hogness[18] and Williams and Miller.[19] The value of the constant in the volume expression was evaluated at 470° as 2290 and 2810 cal./g. atom for the Zn–Cd and Zn–In systems, resp.

It might be argued that the regular solution concept is unrealistic (Lumsdem[20]), but an alternative approach to solution behavior based on a statistical model is so empirical at present that it is impossible to make any predictions of solution behavior from constituent properties. Until the state of statistical theory advances beyond the present empirical state, the concept of regular solutions appears justified.

Reaction of Mercury(II) with Halides in Glacial Acetic Acid

BY ORLAND W. KOLLING

RECEIVED JANUARY 28, 1957

The reaction between mercury(II) acetate and potassium halides in glacial acetic acid yields HgX_2 as the predominant species. The stoichiometry of the reaction was determined by potentiometric titrations with the glass and calomel electrodes, in which the glass electrode responds to changing acetate concentration. Potential difference measurements as a function of concentration of solution were made for reactants and products, and demonstrated the order of increasing acidity to be $Hg(OAc)_2 < KCl < KBr < KI$ for these weak acids in glacial acetic acid.

As a result of covalent bonding, mercury(II) chloride, bromide and iodide are soluble in a number of organic solvents, and form non-ionic aqueous solutions. In aqueous solutions containing excess halide, mercury(II) forms tetrahedral complexes of the type $HgX_4^=$, through (sp^3) hybridization. Analogous molecular and ionic species might be expected for glacial acetic acid solutions of mercury(II) halides, for it has been demonstrated that mercury(II) acetate reacts with amine hydrohalides, liberating the amine, quantitatively.[1] The present study confirms that the predominant species present in glacial acetic acid solutions of mercury(II) chloride, bromide and iodide is HgX_2, and that such solutions are essentially non-ionic.

The stoichiometry of the reaction between mercury(II) acetate and the potassium halides was established by potentiometric titrations. The covalent nature of the mercury–halide bond in glacial acetic acid solution was shown by potentiometric measurements, using the method of Higuchi, Danguilan and Cooper.[2] Curves representing the potential difference between the glass and calomel electrodes as a function of solution concentration were determined for the reactants and products, as well as for reference salts.

Experimental Details

All chemicals in these experiments were analytical reagent grade and were used without additional purification. Solution concentrations were restricted to the hundredth formal level by the limited solubility of alkali halide salts in glacial acetic acid.

Preparation of Standard Solutions.—Standard solutions of perchloric acid and hydrochloric acid were prepared by adding suitable amounts of the concentrated aqueous acids to glacial acetic acid and adding sufficient acetic anhydride to consume the water present from the concentrated acids. Each acid solution was allowed to stand for one week, then standardized potentiometrically against potassium acid phthalate (primary standard grade, dried two hours at 120°). The glacial acetic acid solution of hydrochloric acid was 0.00343 *F* and the perchloric acid was 0.0414 *F*, with an uncertainty of ±2 p.p.t.

The 0.0100 *F* solutions of potassium chloride, bromide, iodide, acetate and acid phthalate, and mercury(II) acetate and chloride, in glacial acetic acid were prepared from accurately weighed portions of finely ground and dried samples of the salts. All stock solutions and dilutions from these were carefully thermostated at 25.0 ± 0.1°. The somewhat rapid release of triiodide from glacial acetic acid solutions of potassium iodide necessitated immediate measurements on freshly prepared solutions for this salt.

Malachite green indicator solution was 0.001 *F* prepared by dissolving the solid (as the hydrochloride) in glacial acetic acid.

Volumetric Methods.—Indirect titrations of mercury(II) acetate were made by adding to aliquots of the mercury(II) solution known excesses of the potassium halide salt solution, and the equivalent potassium acetate released was titrated with standard perchloric acid. The end-points in these acid–base titrations were determined both potentiometrically with the glass–calomel electrode pair and with malachite green as a visual indicator, using 0.20 ml. of the latter solution per 30-ml. sample solution being titrated.

Direct titrations of 2.00-ml. aliquots of mercury(II) acetate solution with hydrochloric acid and the potassium halide solutions were made in a total solution volume of 15 ml., and the titration curves were determined from potentiometric measurements.

Potential Difference. Dilution Measurements.—The method employed for the determination of the potential difference as a function of concentration was that of Higuchi, Danguilan and Cooper.[2] In all potentiometric measurements a Beckman Model H-2 *p*H meter, equipped with the usual glass and calomel electrodes, was used. The reference solution was 0.100 *F* sodium salicylate in glacial acetic acid, and the reported values are differences in absolute magnitude between the e.m.f. for the sodium salicylate solution and that for the unknown solution. The e.m.f. for the reference solution was checked before and after each unknown solution. The experimental uncertainty in these potential measurements is ±1 millivolt.

Results

Titrations.—To establish the mole ratio in which the halide reacts with mercury(II) acetate, a number of direct and indirect titrations were performed.

First, to a fixed amount of mercury(II) acetate, known amounts of potassium halide were added, and in accordance with equation 1 the released

potassium acetate was titrated with perchloric acid.

$$Hg(OAc)_2 + yKX = HgX_y + yK(OAc) \quad (1)$$

The ratio of $Hg(OAc)_2$:KX was varied in the range 4:1 to 1:10, and for all ratios it was observed that the potassium acetate released was equivalent to the amount of halide consumed. These results, as shown in Fig. 1, indicate the ratio of X:Hg(II) to be 2:1 in the product.

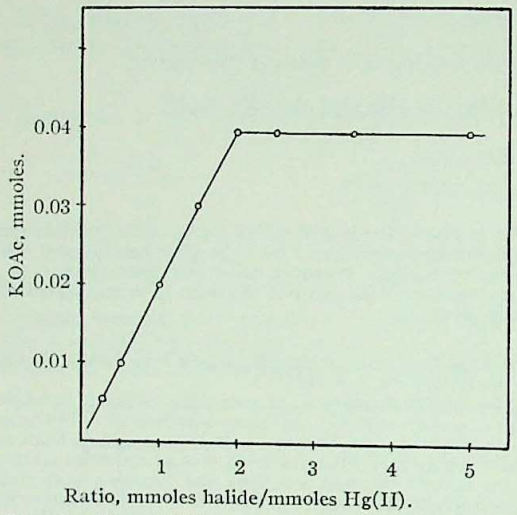

Fig. 1.—The stoichiometry of the reaction between Hg(II) acetate and chloride, bromide and iodide in glacial acetic acid.

Secondly, direct titrations of known amounts of mercury(II) acetate were made, using hydrochloric acid as titrant. The potentiometric titration curve in Fig. 2 may be compared with the compar-

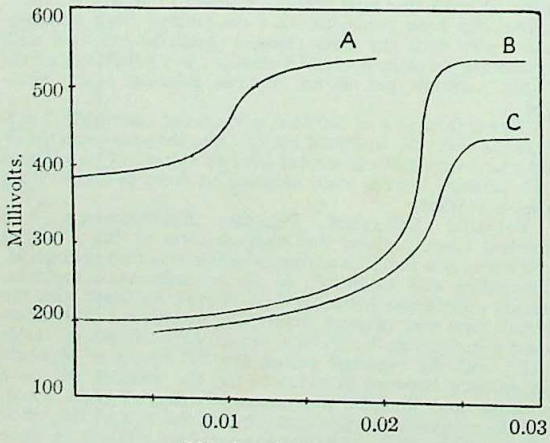

Fig. 2.—Potentiometric titration curves for: (A) potassium acid phthalate with HCl; (B) mercury(II) acetate with HCl; and (C) mercury(II) acetate with KBr.

able curve for the neutralization of hydrochloric acid (a moderately strong acid) with potassium acid phthalate (a moderately strong base). Also, it was observed that mercury(II) acetate could be titrated directly with potassium chloride, bromide and iodide. A typical curve for this direct titration is plotted in Fig. 2. For all direct titrations, the reaction is that given in equation 1, and the product is HgX_2, as was noted above. It is interesting that the curves are not symmetrical in shape, but beyond the break in the curve a nearly constant e.m.f. is obtained (except for the iodide where the magnitude of the e.m.f. becomes greater as triiodide is released from the excess titrant).

Potential Difference *vs.* Concentration.—In Fig. 3 the potential difference between the glass–calomel electrode pair is plotted as a function of concentration of solution in glacial acetic acid for potassium acetate, potassium acid phthalate, the

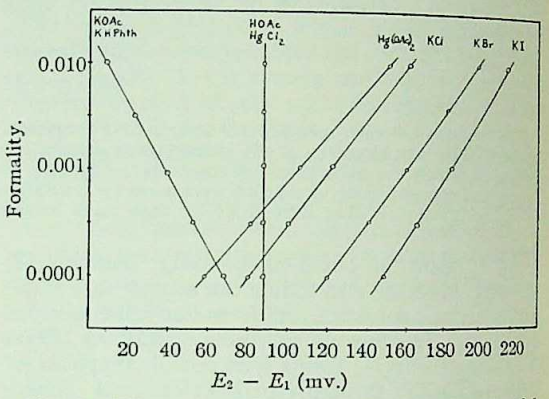

Fig. 3.—Effect of solution concentration on potential difference between the glass–calomel electrode pair in glacial acetic acid. E_1 is the e.m.f. for the reference solution and E_2 is that for the unknown solution.

potassium halides, mercury(II) acetate and mercury(II) chloride. For all compounds, a linear plot is obtained, and, with the exception of the plot for mercury(II) chloride, the slopes correspond closely to 0.0591/2 volts per tenfold change in concentration. The dilution curves for potassium acetate and potassium acid phthalate are coincident, and that for mercury(II) chloride is indistinguishable from that for the solvent alone.

The dilution curves indicate that the order of decreasing acidity is $I^- > Br^- > Cl^-$ for the potassium salts. This is consistent with the results of Kolthoff and Willman.[3] Mercury(II) acetate is more weakly acidic than the potassium halide salts, sufficiently so that a considerable excess of the former may be present with amines without competing in the quantitative reaction between the bases and perchloric acid. The very weak basicity assigned to mercury(II) acetate by Kolthoff and Willman[3] would suggest that this compound is among the most nearly "neutral salts" in glacial acetic acid. The dilution curve for mercury(II) chloride shows the compound to be a complete non-electrolyte in glacial acetic acid. Potassium acetate and potassium acid phthalate appear to be bases of equal strength.

Discussion and Conclusions

It is apparent that the reaction between mercury(II) acetate and the potassium halides is one between moderately strong electrolytes to produce

[3] Kolthoff and Willman, THIS JOURNAL, 56, 1014 (1934).

Digitized by Arya Samaj Foundation Chennai and eGangotri

one non-ionized product and a strong base. In the unsymmetrical titration curves for this reaction it is significant that beyond the break in the curve the e.m.f. increases much less than would be expected from the dilution curves on the potassium halides. This would suggest that the excess titrant undergoes interaction with mercury(II) chloride, probably through ion-pair or ion-multiple formation, or through coördination of halide by mercury(II) to give products of the type K_nHgX_{2+n} (where n = 1, 2, . . .). However, the nature of the product of this interaction cannot be determined by the present experimental approach. It appears certain that the predominant product of the reaction between mercury(II) and halide in glacial acetic acid is molecular HgX_2.

Although it would be expected that the course of the reaction between mercury(II) acetate and a halogen acid could be followed with the glass electrode, it was not anticipated that this indicator electrode would be suitable for the titrations with the potassium halides. Experimentally, it is easily demonstrated that mercury(II) acetate undergoes no detectable neutralization reaction with perchloric acid nor with potassium acid phthalate, when titrated potentiometrically with the glass–calomel electrode pair. Likewise, it is notable that the magnitude of the break in the titration curve for potassium acid phthalate (a strong base) with hydrochloric acid (a moderately strong acid) is significantly smaller than that for the reaction between mercury(II) acetate and the same acid or the potassium halide. It is evident that the mercury(II) acetate–potassium halide reaction cannot be considered as a neutralization reaction involving a direct or indirect proton transfer mechanism. The glass electrode appears to respond as the indicator electrode toward changes in acetate concentration during the titration involving a nearly neutral acetate and the release of a strongly basic acetate. It has been suggested by Higuchi, Feldman and Rehm,[4] that measurements of acidity and basicity in glacial acetic acid with the glass electrode may be expressed in terms of acetate concentrations. Such an interpretation appears to be experimentally valid.

Principles of Phosphorus Chemistry. III. Structure Proofs by Nuclear Magnetic Resonance[1]

BY C. F. CALLIS, J. R. VAN WAZER, J. N. SHOOLERY[2] AND W. A. ANDERSON[2]

RECEIVED NOVEMBER 12, 1956

Structure proofs based on nuclear magnetic resonance measurements are given for some oxyacids of phosphorus and several other phosphorus compounds. Indirect spin–spin coupling shows that essentially all of the primary and secondary phosphite esters, as well as the free acid and its salts, are present in the form in which one hydrogen is attached directly to the phosphorus. Structure proofs are given for the hypophosphate, isohypophosphate and diphosphite molecule-anions, as well as for P_2S_3 and $P_4O_6S_4$. Indirect spin–spin splitting in the tripoly- and tetrapolyphosphate anions shows that the P-O-P linkages are basically covalent; and all of the data indicate that the often postulated P^{+5} ion does not exist in the phosphates and related compounds.

Gutowsky, McCall and Slichter[3] have already shown that indirect spin–spin splitting of nuclear magnetic resonance peaks is a powerful tool for proving structures in the chemistry of phosphorus. Thus, these authors were able to demonstrate that the hydrogen and fluorine atoms are attached directly to the phosphorus by primarily covalent bonds in the following structures: PH_3, PF_3, $(CH_3O)PF_2$, $OPClF_2$, $OPCl_2F$ and the $F_2PO_2^-$, $H_2PO_2^-$, $HPO_3^=$ and PF_6^- ions. In this paper, structure proofs based on both indirect spin–spin splitting and chemical shifts will be presented along with a discussion of bonding in phosphorus compounds. The experimental procedure and the raw data are given in Paper II of this series. Unless otherwise designated, the data are P^{31} spectra. The majority of the measurements were made at 7140 gauss and 12.3 Mc. The chemical shifts relative to 85% orthophosphoric acid are defined as

$$\delta = \frac{H_{\text{sample}} - H_{H_3PO_4}}{H_{H_3PO_4}} \times 10^6$$

where H is the resonance field strength. The splittings given in cycles per second (c.p.s.) can be converted to parts per million (p.p.m.) of the applied field by dividing by the frequency of the rf probe in Mc., or to field units in gauss by multiplying the p.p.m. value by the field strength (times 10^{-6}) in gauss.

The simplest method of differentiating between chemical shifts and indirect spin–spin splittings is to make measurements at different field strengths. Thus, the separation between resonance peaks attributable to differently situated phosphorus atoms in a molecule or molecule-ion (the chemical shift) is found to be invariant with field strength when measured in p.p m. of the field. In other words, the separation divided by the field strength is a constant. On the other hand, the separation between multiplet peaks due to indirect spin–spin

coupling between a specific phosphorus atom and some other atom having nuclear spin is the same value in gauss or frequency units at any field. This method of determining whether a given set of lines is due to chemical shifts or spin–spin coupling was used in this study whenever there was some doubt in the matter.

Splitting by Directly Attached Atoms

Organic Phosphites.—Tertiary esters of phosphorous acid are quite universally represented with three atoms attached to the phosphorus, as shown by the formula $(RO)_3P$. However, the primary and secondary esters are depicted with either three or four atoms attached directly to the phosphorus.[4] This comes about by a shift of the hydrogen atom, as shown below for the secondary ester.

$$(RO)_2P(OH) = (RO)_2P(H)O \qquad (1)$$

The question of which of these two forms predominates has been argued for many years in the literature. However, Kosolapoff[4] and others have indicated recently that, because of hydrogen bonding between the phosphorus of one anion and the oxygen of another, both forms are simultaneously present, and the old question of which form predominates is simply semantics.

Nuclear magnetic resonance has shown that the question is not a semantic one. Indirect spin–spin splitting by the hydrogen attached directly to the phosphorus and the absence of other detectable peaks at field strengths where resonance is observed for the trisubstituted phosphites proves that approximately 95% or more of the primary and secondary esters, as well as the free acid, are present in the form in which one hydrogen is attached directly to the phosphorus. In other words, equation 1 is shifted far to the right. This means that the primary and secondary phosphites are more closely related[5] in structure to the phosphonates than they are to the tertiary esters, which can be considered as completely substituted phosphine derivatives. Whatever hydrogen bonding is present probably consists of a strong bond between the phosphorus and the hydrogen and a much weaker, secondary bond between the hydrogen and the oxygen atoms of neighboring molecules. The nuclear magnetic resonance data show that the hydrogen on the phosphorus atom is not readily exchanged whereas other experience[1,6] has shown that there should be considerable exchange of hydrogens on a given oxygen atom.

Substituted Phosphines.—Gutowsky has shown that phosphine, PH_3, gives the expected four peaks of relative areas 1–3–3–1, with a splitting between adjacent peaks of 170 c.p.s. Monomethyl- and dimethylphosphine give 1–2–1 and 1–1 patterns, respectively, with splittings of 205 c.p.s. Trimethylphosphine, as expected, gives only one peak (no splitting). In measuring these substituted phosphines, a relatively large field gradient of 0.05 gauss per cm. was used so that spin–spin splitting due to interaction of the phosphorus with the hydrogens on the methyl groups was not visible.

Ethyldifluorophosphine, $(C_2H_5)PF_2$, ethylchlorofluorophosphine, $(C_2H_5)(Cl)PF$, and ethylisopropoxyfluorophosphine, $(C_2H_5)(F)P(OC_3H_7)$ gave three, two and two peaks, respectively, with splitting in satisfactory agreement with that previously reported[3] for fluorine.

Splitting by Atoms Attached Directly and through an Intermediate Atom

Oxyacids Containing Two P Atoms.—The historically known salts of the oxyacids of phosphorus containing two phosphorus atoms per anion are the (1) pyrophosphate, (2) hypophosphate and (3) pyrophosphite. Blaser[7] has described two more anions which he has called (4) "isohypophosphate" and (5) "diphosphite." The structures of the anions of these five acids—as determined from chemical evidence—are

(1) $\left[\begin{smallmatrix} O & O \\ OPOPO \\ O & O \end{smallmatrix}\right]^{=}$ (2) $\left[\begin{smallmatrix} O & O \\ OP—PO \\ O & O \end{smallmatrix}\right]^{=}$

(3) $\left[\begin{smallmatrix} O & O \\ OPOPO \\ H & H \end{smallmatrix}\right]^{-}$ (4) $\left[\begin{smallmatrix} O & O \\ OPOPO \\ O & H \end{smallmatrix}\right]^{=}$ (5) $\left[\begin{smallmatrix} O & O \\ OP—PO \\ O & H \end{smallmatrix}\right]^{-}$

The P^{31} magnetic resonance spectra of the pyrophosphate (1) and hypophosphate (2) anions each show only one resonance peak. This proves that the structures, assuming two phosphorus atoms, are symmetrical and that no hydrogens are attached directly to the phosphorus. Up to now, the proof that the hypophosphate ion is symmetrical was weak, being based on crystal symmetry[8] from X-ray diffraction without assignment of atom positions. Interpretation of chemical data both for and against the symmetrical structure has appeared in the literature over the past century; of these, the most convincing[9] supports the incorrect isohypophosphate formula for the hypophosphate ion.

The chemical shift of the pyrophosphate anion, obtained from measurements on a solution of tetrasodium pyrophosphate in water, is +6 p.p.m. of the applied field (7140 gauss) relative to 85% orthophosphoric acid. The chemical shift of the hypophosphate anion obtained in the same way from an aqueous solution of disodium dihydrogen hypophosphate, is −9 p.p.m.

The pyrophosphite (3) anion exhibits two equal peaks, with the center of the two peaks shifted +5 p.p.m. of the applied field relative to 85% orthophosphoric acid. The separation of these peaks was found to be 630 c.p.s. at a field of 7140 gauss and 685 c.p.s. at a field of 9850 gauss. Since the difference between these two values is of the order of the experimental error involved, the two peaks undoubtedly arise from indirect spin–spin

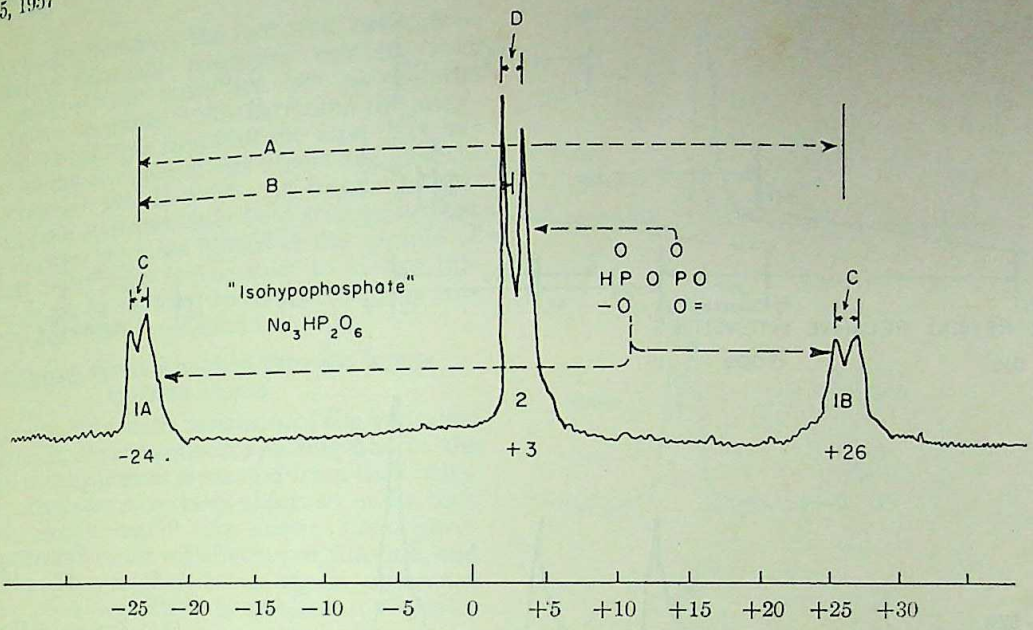

Fig. 1.—P^{31} magnetic resonance spectrum of the isohypophosphate anion at 7140 gauss and 12.3 Mc.: A = 620 c.p.s.; B = 27 p.p.m. or 328 c.p.s.; C = 17 c.p.s.; D = 17 c.p.s.

coupling. This means that the structure is symmetrical, with one hydrogen attached to each phosphorus atom.

The spectrum of the isohypophosphate (4) anion is shown in Fig. 1. This anion gives a splitting of 620 c.p.s. for the hydrogen attached directly to one of the phosphorus atoms. The magnitude of this splitting (to give Peaks 1A and 1B) is approximately equal to that of the phosphite anion (590–690 c.p.s.), and of the dialkyl phosphites (670–700 c.p.s.). The area of peak 2 equals the area of Peaks 1A plus 1B as would be expected for the assignment of peak 2 to the phosphorus atom to which no hydrogen is attached. All three peaks show a splitting of 17 c.p.s. due to interaction of the two chemically different phosphorus atoms through the bridging oxygen. This amount of splitting is approximately equal to the splitting found for the interaction of end and middle groups in the phosphates (see Fig. 3). The observed spectrum is in agreement with the theoretical treatment of the system containing three coupled nuclei discussed in the following paragraph, if the reasonable assumptions are made that the coupling of the hydrogen to the adjacent phosphorus is much greater than the coupling of the hydrogen to the other phosphorus and also much greater than the coupling of the two phosphorus atoms. Thus, the structure proposed by Blaser on the basis of chemical evidence has been proven correct by this physical method.

The phosphorus spectrum of the diphosphite (5) anion is shown in Fig. 2b. This spectrum corroborates the mathematical treatment of a system consisting of three coupled nuclei of spin $1/2$. The Zeeman levels shown in the schematic diagram, Fig. 2a, were calculated from the following Hamiltonian[10] representing the total energy of the system, assuming that the spin-coupling of the hydrogen and either phosphorus is small compared to the chemical shift between the hydrogen and either phosphorus

$$\mathcal{H} = -\hbar\{\omega_H I_H^0 + \omega_{P1} I_{P1}^0 + \omega_{P2} I_{P2}^0 + J_{HP1} I_H^0 I_{P1}^0 + J_{HP2} I_H^0 I_{P2}^0 + J_{P1P2}[I_{P1}^0 I_{P2}^0 + 1/2(I_{P1}^+ I_{P2}^- + I_{P1}^- I_{P2}^+)]\} \quad (2)$$

where $\mathcal{H}$ is the Hamiltonian operator, $\hbar$ the quantum of action divided by 2π, ω the unperturbed resonance frequency, I^0 the z-component of the spin operator chosen in the direction of the applied magnetic field, J the spin-coupling constant, and $I^{\pm}$ the complex spin operator in the plane perpendicular to the field. The subscripts H, P1 and P2 refer to the hydrogen nucleus, the phosphorus adjacent to the hydrogen, and the other phosphorus, nucleus respectively. The resonance frequencies of the phosphorus nuclei derived from equation 2 are

$$\omega_1 = \omega_{P2} + 1/2\delta + 1/2(J' + J_{P1P2}) + 1/2\sqrt{(\delta + J'')^2 + J_{P1P2}^2} \quad (3)$$

$$\omega_2 = \omega_{P2} + 1/2\delta + 1/2(J' - J_{P1P2}) + 1/2\sqrt{(\delta + J'')^2 + J_{P1P2}^2} \quad (4)$$

$$\omega_5 = \omega_{P2} + 1/2\delta - 1/2(J' - J_{P1P2}) + 1/2\sqrt{(\delta - J'')^2 + J_{P1P2}^2} \quad (5)$$

$$\omega_6 = \omega_{P2} + 1/2\delta - 1/2(J' + J_{P1P2}) + 1/2\sqrt{(\delta - J'')^2 + J_{P1P2}^2} \quad (6)$$

$$\omega_3 = \omega_{P2} + 1/2\delta + 1/2(J' + J_{P1P2}) - 1/2\sqrt{(\delta + J'')^2 + J_{P1P2}^2} \quad (7)$$

$$\omega_4 = \omega_{P2} + 1/2\delta + 1/2(J' - J_{P1P2}) - 1/2\sqrt{(\delta + J'')^2 + J_{P1P2}^2} \quad (8)$$

$$\omega_7 = \omega_{P2} + 1/2\delta - 1/2(J' - J_{P1P2}) - 1/2\sqrt{(\delta - J'')^2 + J_{P1P2}^2} \quad (9)$$

$$\omega_8 = \omega_{P2} + 1/2\delta - 1/2(J' + J_{P1P2}) - 1/2\sqrt{(\delta - J'')^2 + J_{P1P2}^2} \quad (10)$$

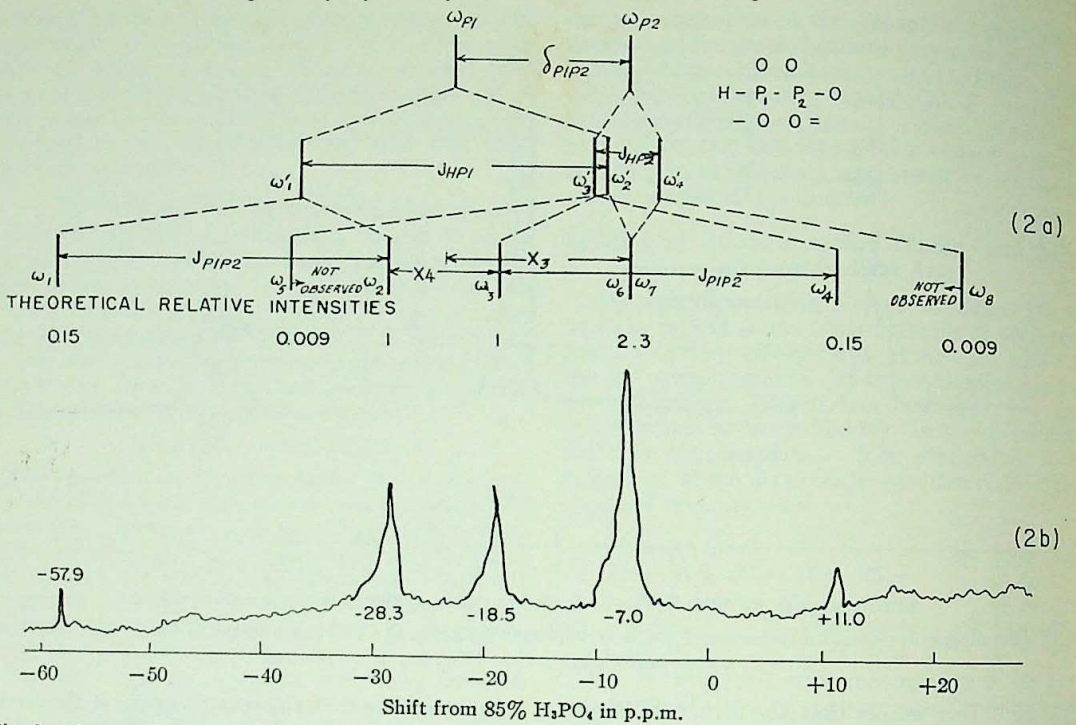

Fig. 2.—Zeeman levels and observed phosphorus spectrum for the diphosphite anion at a field of 9440 gauss. Because of saturation effects at the high rf field used to show up the small peaks, the peak areas are not strictly proportional to their predicted values. The measured values of X_3 and X_4 are 16.4 and 9.8 p.p.m. of the applied field as compared to the calculated values of 16.2 and 9.6 p.p.m., respectively. At the 7140 gauss field, the observed values of X_3 and X_4 are 21.9 and 9.5 p.p.m. compared to the calculated values of 21.6 and 10 p.p.m., respectively.

where δ is the chemical shift between the phosphorus nuclei, and

$$J' = {}^1/_2(J_{HP1} + J_{HP2}) \quad (11)$$

$$J'' = {}^1/_2(J_{HP1} - J_{HP2}) \quad (12)$$

Examination of the phosphorus spectrum does not yield sufficient information to compute the chemical shift of the phosphorus nuclei and all of the spin-coupling constants. Consequently, it was necessary to examine the hydrogen spectrum of the diphosphite anion dissolved in D_2O in order to obtain the phosphorus–hydrogen spin-coupling constants. Four lines were observed in the hydrogen spectrum (one masked by HDO resonance), which means that the hydrogen is strongly coupled to both of the phosphorus nuclei. Measurements of line spacings on these hydrogen spectra, and on the phosphorus spectra reproduced in Fig. 2b at two different fields permit the calculation of the quantities summarized in Table I. In these computations it was assumed that the resonance frequencies, ω_6 and ω_7, form an unresolved doublet.

The line intensities of the satellite lines, ω_1, ω_5, ω_4, and ω_8, relative to the parent line intensities are given by the ratios $[\sqrt{(\delta \pm J'')^2 + J^2_{P1P2}} - J_{P1P2}]/[\sqrt{(\delta \pm J'')^2 + J^2_{P1P2}} + J_{P1P2}]$. These relative values are included in Fig. 2a just below the schematic diagram. Two of the satellite lines, ω_1 and ω_4, were observed only under conditions of high rf power (some saturation) and their resonance frequencies are in agreement with those predicted from the mathematical treatment.

The theoretical splitting of the phosphorus lines resulting in resonance frequencies ω_1', ω_2', ω_3' and ω_4' can be obtained from equations 3–10 inclusive by setting J_{P1P2} equal to zero. It is interesting to note that the observed splitting of these lines is not symmetrical, and that the more asymmetric the split of the line, the greater the difference in relative line intensities—with the more intense line near the center of the pattern.

TABLE I

NUCLEAR MAGNETIC RESONANCE CONSTANTS OF THE DIPHOSPHITE ANION

Notation	Spin-spin couplings: Cycles[a] per sec.	Value: Gauss (spectrum)	P,P-Chemical shift in P spectrum: Value (p.p.m.) Between nuclei	Shift of P2 relative to 85% H_3PO_4	Field (gauss)
J_{P1P2}	480 ± 10	0.28 (phosphorus)	15.4	−7.0	7140
J_{HP1}	444	.26 (phosphorus)	15.8		9440

phorous acid. However, the fact that the hydrogen nuclear resonance spectrum exhibits four peaks indicates that there are two phosphorus atoms in the structure. Furthermore, the magnitude of the splitting supports the idea that hydrogen and the two phosphorus atoms are directly bonded together, *viz.*, H–P–P. All in all, the nuclear magnetic resonance data lend strong support to the structure given by Blaser[7] if the sample of trisodium diphosphite (amorphous to X-ray diffraction) which he supplied to us represents a reasonably pure (> 95%) compound.

Splitting by Atoms Attached through Intermediate Atoms

In the case of magnetic resonance of the hydrogen nucleus in organic compounds, splitting due to the interaction of hydrogens separated from each other by two carbon atoms has been observed under high resolution conditions.[10,12] As shown here, phosphorus also can interact with hydrogen, fluorine, and chemically different phosphorus atoms separated from the phosphorus atom in question by one or two other atoms.

Polyphosphates.—The spectra of the pyro-, tripoly- and tetrapolyphosphate[13] anions are shown in Fig. 3. As previously described,[14] isolated (orthophosphate), end, and middle PO_4-groups resonate at measurably different external fields, with the end- and middle-group shifts being 5–10 and 18–21 p.p.m. with respect to 85% H_3PO_4, which contains the isolated PO_4-groups. In Fig. 3, the end-group resonance peaks are denoted by E, and the middle-group resonance peaks by M. Since the two phosphorus nuclei in the pyrophosphate ion are indistinguishable, internally and externally, *i.e.*, they are chemically equivalent, the indirect spin–spin coupling does not show up as observable splitting, although this coupling ought to be approximately equal to the coupling of the end and middle phosphorus atoms in the tripolyphosphate anion (J_{P1P2} in the pyrophosphate $\approx J_{P1P2} = J_{P2P3}$ in the tripolyphosphate). For the tripolyphosphate anion, the area under peak M is half the area under peak E, and the M peak is split into three parts, of approximate relative areas 1–2–1, whereas the E peak is split into two parts of equal area. Since the middle-group phosphorus is attached to two chemically different phosphorus atoms (in the two end groups), spin–spin splitting into a 1–2–1 triplet is to be expected. Likewise, attachment of the two end-group phosphorus atoms to the lone middle group gives spin–spin splitting into a 1–1 doublet. Measurements of the spectrum of tripolyphosphate at a higher field (9,850 gauss) offer additional verification of the accepted structure. The ratio of the separations, ($\delta_1/\delta_2 = 1.3$), of the pairs of multiplets at the two fields is in acceptable agreement with the ratio of the two fields ($H^6/H_2 = 9850/7140 = 1.4$), as expected for non-equivalent nuclei. The splitting

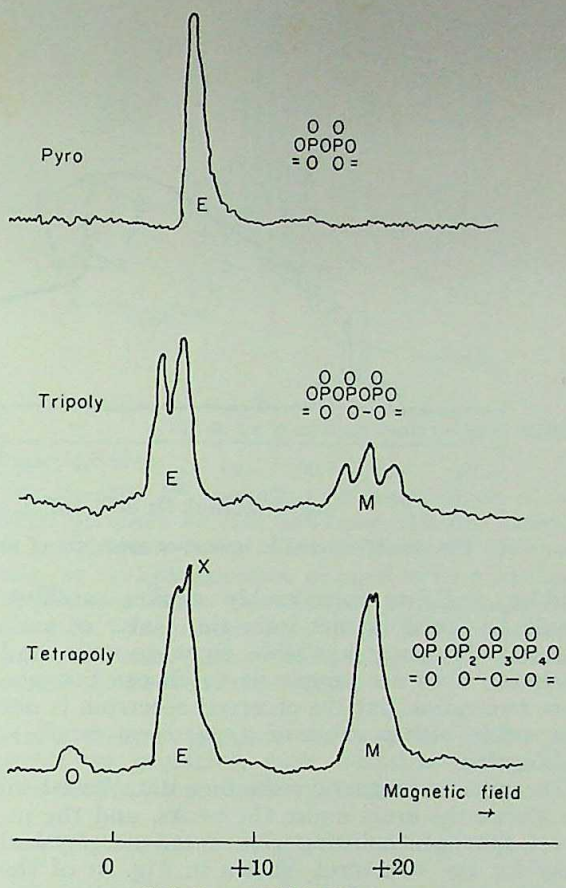

Fig. 3.—P^{31} magnetic resonance spectra of chain-phosphate anions at 7140 gauss and 12.3 Mc. as adjusted to the same scale. The end-group peaks are denoted by E, and the middle-group peaks by M. Orthophosphate impurity is denoted by O, and the extra height of the peak marked "X" is due to some pyrophosphate impurity.

in the multiplets (17 c.p.s.) is independent of field strength as was confirmed earlier[3] for several cases of multiplet splittings.

For the tetrapolyphosphate anion, the E and M peaks are of approximately equal area (after correction for pyrophosphate, a known impurity), and are both split into doublets of intensity 1–1. Such a picture is in accord with the published analysis[15] for the case of four coupled nuclei in a molecule with a plane of symmetry and two pairs of non-equivalent nuclei.[16] If we let $J_{P1P2} = J_{P3P4}$ be the spin coupling between adjacent end and middle phosphorus nuclei, and J_{P2P3} be the spin coupling between the central nuclei, a similar analysis can be made for various values of the ratio of $J_{P2P3}/J_{P1P2} = J_{P3P4}$. For this ratio equal to zero, a simple doublet with spacing $J_{P1P2} = J_{P3P4}$ is predicted for each phosphorus group. For the above ratio equal to one, two lines with spacing $J_{P1P2} = J_{P3P4}$ are still predicted for each phosphorus group, but in addition two slightly weaker lines are predicted closer to the center of each

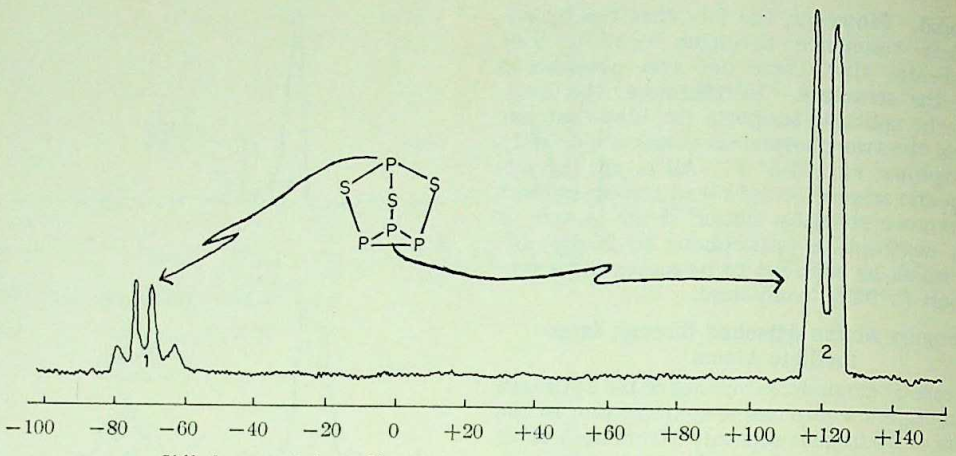

Fig. 4.—P^{31} magnetic resonance spectrum of phosphorus sesquisulfide at 7140 gauss and 12.3 Mc.

doublet, and two considerably weaker satellites should be found farther from the center of each doublet. Presently available signal-to-noise and resolution does not permit us to choose between these two ratios, but the observed spectrum is not compatible with a value of $J_{P2P3}/J_{P1P2} = J_{P3P4}$ greater than *ca.* 1.2.

The nuclear magnetic resonance data based on the shifts, the areas under the peaks, and the indirect spin–spin splitting give a unique physical proof for the structures (shown in Fig. 3) of the tripoly- and tetrapolyphosphates, for which only chemical structure proofs have heretofore been available.[17]

Phosphorus Sulfides.—The most interesting member of this class of compounds which we have studied is phosphorus sesquisulfide, P_4S_3, the nuclear magnetic spectrum of which is shown in Fig. 4. In accord with the structure of this compound as determined by X-ray diffraction[18] and shown in Fig. 4, there are two major peaks. Peak 1, which is a 1–3–3–1 quadruplet, corresponds to the phosphorus atom connected through three sulfur atoms to the other three, chemically different phosphorus atoms. Peak 2, a 1–1 doublet exhibiting a total area which is three times that of peak 1, is attributable to the three phosphorus atoms in a ring. Splitting of this peak is due to interaction with the lone phosphorus atom. Presumably, the relatively large splitting (86 c.p.s.) in the case of this sulfide as compared to the splitting (17 c.p.s.) in compounds in which the chemically different phosphorus atoms are separated by oxygens is attributable to the fact that the phosphorus atoms are triply connected[19] in the sulfide (also bent bonds) and is not due to a difference between oxygen and sulfur in transmitting the interaction between the phosphorus atoms.

The existence of one peak in the spectrum of phosphorus sulfoxide, $P_4O_6S_4$, is in agreement with a symmetrical structure[20] in which the four phosphorus atoms are identical.

Splitting by Hydrogen and Fluorine Atoms.—Hydrogen and fluorine interacting with phosphorus through an intermediate atom or atoms cause spin–spin splitting as well as do phosphorus atoms which are chemically different. An example of such behavior is found in dichlorofluoromethyl-tris-(dimethylamido)-phosphonium chloride, $[Cl_2FCP(N(CH_3)_2)_3]^+ Cl^-$, in which the fluorine attached to the carbon atom causes a splitting of 85 c.p.s. of the phosphorus peak.

Splitting is not recorded in the Appendix of Paper II for the compounds containing P–C linkages (such as the phosphonates) because the spectra of these compounds were observed with insufficient resolution to show up splitting of the order of magnitude of *ca.* 20 c.p.s. However, a recent spectrum of trimethylphosphite, $P(OCH_3)_3$, has been taken under conditions of extremely high resolution and shows spin–spin splitting due to the hydrogens acting on the phosphorus through the carbon *and* oxygen atoms. This spectrum, shown in Fig. 5, clearly exhibits eight of the ten peaks (two of which are too small to show over the background) for the 1–9–36–84–126–126–84–36–9–1 splitting expected for coupling with nine other atoms—the nine hydrogens in the molecule. In comparison, it was found that at the same resolution no fine structure showed up in the peak observed for triphenyl phosphite. Presumably this lack of fine structure is due to the fact that in the triphenyl phosphite the nearest hydrogen is separated from the phosphorus by three intermediate atoms (–C–C–O–) as compared to the two intermediate atoms (–C–O–) in the trimethyl compound.

Dimethyl phosphite shows two major peaks, with a splitting of 710 c.p.s., because of the hydrogen atom directly attached to the phosphorus. Under super high resolution conditions, both of these

(17) The previously available structure proofs for these two anions have been (1) proximate analysis, (2) *p*H titration, (3) cryoscopy in $Na_2SO_4 \cdot 10H_2O$, (4) paper chromatography, and (5) interpretation of hydrolysis data.

(18) O. Hassel and A. Pettersen, *Tid. Kem. Berg. Met.*, **1**, 57 (1941).

(19) J. R. Parks, This Journal, **79**, 757 (1957), has shown that the chemical shift of triply connected phosphorus compounds can be related to the electronegativity of the ligands and the bond angles. This reference gives a more quantitative picture of the idea presented here.

(20) A. Stock, *Ber.*, **72**, 1130 (1939).

Digitized by Arya Samaj Foundation Chennai and eGangotri

major peaks are split into seven subpeaks of relative heights 1–6–15–20–15–6–1 by the six hydrogens attached to the carbon atoms. This secondary splitting corresponds to *ca.* 14 c.p.s.

When the spectrum of orthophosphoric acid was run at the same resolution as was used in showing the fine structure of trimethyl phosphite in Fig. 5, there was no sign of fine structure due to interaction of the weakly acidic hydrogens through the oxygen atoms on the phosphorus. This means that the average frequency of the exchange process of the weakly acidic hydrogen from one phosphate to another or from phosphate to water and *vice versa* must exceed the splitting frequency, and thus collapse the spin–spin coupling to a single resonance line. As was noted in Paper II of this series, removal of the third, extremely weakly acidic hydrogen from the orthophosphate ion causes a slight negative shift which probably indicates covalent bonding of this hydrogen, with concomitant rapid exchange.

Structures from Chemical Shifts

By utilizing shift contributions, as described in Paper II, an approximation can be made to the positions of resonance peaks to be found for phosphorus atoms attached to various given atoms. Likewise, a good estimation can be made of the amount of spin–spin splitting to be observed. Examples of this type of structure analysis are found for the isohypophosphate anion and phosphorus sesquisulfide in this paper and for ethyl "metaphosphate" in Paper II.

Estimation of the average number of phosphorus atoms in a mixture of chain phosphates also exemplifies the use of chemical shifts to determine structures. It is found that the relative areas of the end-group (A_E) and middle-group (A_M) peaks for a solution of a vitreous sodium phosphate gives the number average chain length, $\bar{n}$, as expected from the equation $\bar{n} = 2(A_E + A_M)/A_E$.

As shown in Fig. 2 of Paper II in this series, attachment of phenyl groups to a phosphate moiety causes a significant positive shift—with a shift of +5 p.p.m. (with respect to 85% H_3PO_4) for one phenyl group and +12 p.p.m. for two phenyl groups in a 7140 gauss field. Therefore, if pentaphenyl bis-(diethylene glycol) triorthophosphate and hexaphenyl tris-(diethylene glycol) tetraorthophosphate exhibit structures in which isolated PO_4-groups are separated by organic radicals so that two phenyl groups are attached to the PO_4-groups at the end of the resulting chains and one phenyl group is attached to the PO_4-group(s) away from the ends, they will have peaks at the positions found for the corresponding monomers. Moreover, the hexaphenyl compound should exhibit two peaks of equal area and the pentaphenyl compound a peak at +5 p.p.m., which is half the size of the peak at +12 p.p.m. The observed spectra showed two equal sized peaks at +7.5 and +12.5 p.p.m. for the hexaphenyl compound and one peak at +7.0 p.p.m. and another twice as large at +13 p.p.m. for the pentaphenyl compound. These results demonstrate that the organic chemist who synthesized these compounds most probably attributed the proper structure to them. At least

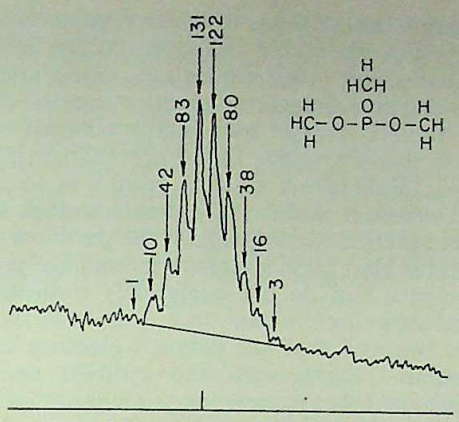

Fig. 5.—The P^{31} magnetic resonance spectrum of trimethyl phosphite at 7140 gauss and 12.3 Mc. showing the fine structure due to spin–spin splitting of the phosphorus by the hydrogen atoms on the three methyl groups. The measured heights are listed (on a relative basis) over each peak. The random-noise height is somewhat less than *ca.* ±4 units. Theoretical splitting for nine attached atoms is 1-9-36-84-126-126-84-36-9-1.

the compounds give nuclear magnetic resonance spectra as predicted from his structures. The structure for the pentaphenyl compound is thus

$$\begin{array}{ccccc} & O & & O & \\ C_6H_5OPOC_2H_4OC_2H_4OPOC_2H_4OC_2H_4OPOC_6H_5 & & & & \\ & O & & O & \\ & C_6H_5 & & C_6H_5 & \end{array}$$

Discussion

During the first half of the Twentieth Century, much of the discussion of the structure of oxyacids in the chemical and mineralogical literature was in terms of completely ionized atoms. According to this picture, a solid sodium phosphate would be made up of P^{+5}, $O^{=}$ and Na^{+} ions, so arranged as to give close packing of spheres (the ions) with alternation of positive and negative charges in such a manner as to result in electroneutrality over even relatively short distances within the array. Application of this idea was usually confined to solids, although one would have to infer that, for example, condensed phosphate molecule-ions in solution were merely aggregates of P^{+5} and $O^{=}$ ions. The existence of spin–spin splitting in the tripoly- and tetrapolyphosphates indicates that this ionic picture is false and that a better picture consists of covalently bonded phosphorus and oxygen atoms making up the phosphate molecule-anions, the negative charges of which are balanced by the counter ions, *e.g.*, Na^{+}, some of which may be tightly affixed to the oxygens of the molecule-anions. If these condensed phosphate anions were merely a collection of ionized atoms, the rate of exchange (say, between the oxygens of the P–O–P linkages and the water) would be so rapid that no indirect spin–spin coupling could be observed.

Although complete X-ray structure analyses[21]

in which detailed electron density projections are employed do show that the atoms in the anions of phosphates and other similar oxyacids share electrons, occasional reports[22] purporting to demonstrate the existence of such highly charged ions as P^{+5} occasionally appear in the crystallographic literature. Publication of such results is to be deplored unless it is definitely demonstrated that a covalent picture cannot explain the data[23] or unless it is stated that ionic structure factors are used for convenience and do not necessarily indicate that the real structure is ionic.

It is believed that the detailed electron density projections[21] along with the indirect spin–spin splitting and other nuclear magnetic resonance data reported here and in Paper II of this series demonstrate that an ionic representation[24] of phosphorus in its compounds must be considered absurd unless one is equally ready to represent carbon in organic compounds as being ionized, *e.g.*, C^{+4} in CCl_4 or C^{-4} in CH_4.

The Molecular Structure of $B_{10}H_{12}I_2$[1]

BY RILEY SCHAEFFER

RECEIVED FEBRUARY 4, 1957

The structure of $B_{10}H_{12}I_2$, obtained from $B_{10}H_{14}$ by treatment with I_2, has been determined by X-ray diffraction techniques. The unique space group D_{2h}^{10}Pccn and the presence of four molecules per unit cell requires the molecule to possess a twofold axis and makes possible the unambiguous determination of the intramolecular iodine–iodine distance. This observed distance is in agreement with that expected if substitution has occurred at the apices of the two pentagonal pyramids which share a common edge in the $B_{10}H_{14}$ structure.

Introduction

Although substituted diboranes ($B_2H_2R_4$) and borines (HBR_2) have been known for many years and present few structural problems, only two substitution derivatives of higher boranes have been described. Both $B_{10}H_{12}I_2$ and $B_{10}H_{12}Br_2$ were prepared by Stock by direct action of the halogen on $B_{10}H_{14}$.[2] Although many isomeric dihalides of decaborane are possible, the nature of the products obtained by Stock indicates that a single isomer was obtained at least in large part. Apparently, effects are operative in determining the mechanism of substitution which have not as yet been adequately assessed and it was consequently of considerable interest to determine which of the isomers was formed.

Experimental

A sample of $B_{10}H_{12}I_2$ crystallized from benzene as flat plates was available. Several crystals were selected, mounted, coated with Krylon and examined by X-ray diffraction. The crystals were not well formed but one showed only a small amount of extraneous scattering, which did not interfere with indexing, and was used for further study. Weissenberg and rotation photographs taken with filtered Cu radiation and precession photographs taken with filtered Mo radiation showed orthorhombic symmetry and gave the following unit cell dimensions: $a = 13.13$, $b = 7.26$, $c = 12.00$ Å.

Comparison of the unit cell dimensions with those of the disordered unit of $B_{10}H_{14}$ strongly suggested that only four molecules were present per unit cell. Indexing of the reflections on the basis of this unit cell led to the criteria for systematic extinction

$$hkl \text{ present in all orders} \quad (1)$$

$$0kl \text{ present only for } l = 2n \quad (2)$$

$$hk0 \text{ present only for } h + k = 2n \quad (3)$$

$$h0l \text{ present only for } l = 2n \quad (4)$$

The space group was thus uniquely established as D_{2h}^{10}-Pccn.

Sets of precession pictures of varying intensity were obtained by timed exposures of the $h0l$ and $hk0$ zones and the intensities of individual spots estimated visually with the aid of a standard scale prepared from the same crystal. Values of F_{hkl}^2 (on an arbitrary scale) were calculated from the observed intensities by application of the Lorentz and polarization factors.

Iodine positions were located readily by analytical interpretation of the Patterson function. Since the general positions of the space group are eightfold and only four molecules are present, the molecules must possess a center of symmetry or lie on a twofold axis. If the molecule is structurally derived from $B_{10}H_{14}$ it cannot possess a center of symmetry and must consequently have iodines substituted in one of the five sets of positions equivalent under twofold rotation (see Fig. 1). The intramolecular iodine–iodine distance could then be determined readily from the $hk0$ projection of the iodine

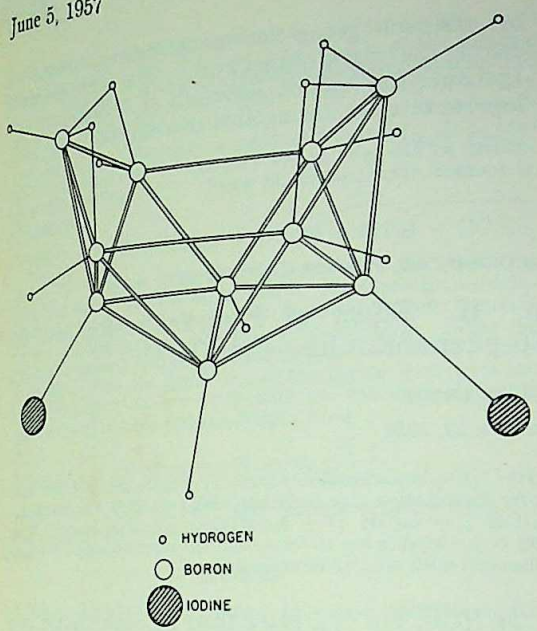

Fig. 1.—The molecular structure of $B_{10}H_{12}I_2$.

positions since they were required by the space group to lie in a plane perpendicular to the *C*-axis; this distance was found to be 6.25 Å. Using 2.20 Å. as a close approximation to the expected B–I bond distance (the sum of the covalent radii of the atoms), the iodine–iodine distance was calculated for each of the pairs of positions related by the twofold axis by an analytical extension of the B–H bond in the decaborane unit cell using the coördinates of Kasper, Lucht and Harker.[3] It was immediately apparent that position 5 need not be considered since the sum of the bond distances is only 6.12 Å. and the B–H angle is about 120°. It was also necessary to consider only one of the sets 1 and 4 since they would lead to identical I–I distances. Iodine–iodine distances calculated for substitution on positions 1, 2 and 3 were 7.28, 5.92 and 7.56 Å., respectively.[4] In view of the fact that Kasper, *et al.*, were not able to determine the hydrogen positions with high precision, agreement between the observed value (6.25 Å.) and that calculated for position 2 (5.92 Å.) may be considered good. A further refinement of the $B_{10}H_{14}$ structure by Moore and Lipscomb leads to the following somewhat different parameters of interest[5]

	x	$y - 1/4$	z
B_1	0.034	0.080	0.000
B_2	.100	.023	.168
B_3	.116	.028	− .131
H_1	.041	.138	.000
H_2	.164	.026	.320
H_3	.195	.042	− .220

Recalculation of the expected I–I distances for substitution on position 1, 2 and 3 leads to values of 7.88, 6.21 and 7.60, respectively. The agreement between the calculated distance for position 2 and the observed is now better than one has any right to expect when one considers the accuracy with which the hydrogen positions in $B_{10}H_{14}$ are known and possible variation in the B–I bond distance from that assumed.

Structure factors calculated for the crystal based on the assumption that only iodine was present in the cell were in moderately good agreement with the observed values; the usual index of reliability $R = ||F_{obsd}| - |F_{calcd}^{1}|/|F_{obsd}|$ was 0.18 for the $hk0$ zone and 0.20 for the $h0l$ zone after application of a temperature factor correction of the usual form with $B = 4.42$ and adjustment of the scale of F_{obsd} to provide the best fit to F_{calcd}. Fourier syntheses were calculated for both $hk0$ and $h0l$ zones using the largest observed structure factors and assigning to them the signs calculated from the iodine positions. No direct indication of molecular shape was present in the $hk0$ projection since two molecules overlap. However the $h0l$ projection shown in Fig. 2 distinctly suggests a cup shaped boron arrangement with the iodine near the closed surface and thus bonded to either position 2 or 5. As noted above, the latter position is not suitable on the basis of I–I distance.

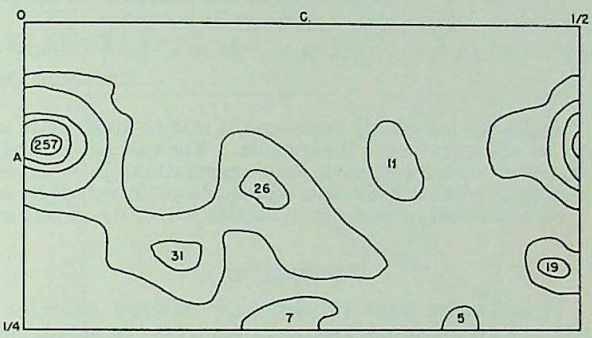

Fig. 2.—$h0l$ Fourier projection of $B_{10}H_{12}I_2$.

Both the $hk0$ and $h0l$ projections suggested parameters for two of the borons (well defined election density maxima) and corrections of structure factors were made for these. A difference synthesis for each zone suggested positions for the remaining boron atoms and second difference syntheses, which included contributions of these borons in F_{calcd}, suggested only slight shifts in parameters for all atoms in the cell. On the basis of the final positions located by the difference synthesis, R values of 0.103 were calculated for both the $hk0$ and $h0l$ zones. The low R values obtained make it apparent that further refinement will be difficult since agreement already is nearly as good as expected experimental error in estimating intensities will permit. Although the R values for each zone are surprisingly sensitive to the boron locations, values of the parameters common to both zones differ by as much as 0.020. Furthermore, attempts to obtain boron positions in the $0kl$ projection (where only data obtained with Cu radiation were available) were unsuccessful. Since the isomer problem had already been adequately resolved, further refinement with the diiodide seemed unprofitable. The partial refinement that was possible with the iodine compound makes it seem quite likely that accurate boron positions could be obtained for $B_{10}H_{12}Br_2$ and study of this compound has been initiated.

Discussion

The dipole moment of $B_{10}H_{14}$ is 3.52 ± 0.02 debye units according to Laubengayer and Bottei.[6] Calculations of Eberhardt, Crawford and Lipscomb[7] show that considerable negative charge should be located on the borons at positions 2. The fact that these atoms are the site of the iodines in $B_{10}H_{12}I_2$ strongly suggests that the mechanism of iodination of the borane is similar to that of an aromatic hydrocarbon in which attack of a positive halogen species occurs at the site of localized negative charge within the substrate molecule. Experiments carried out in this Laboratory by Mr. Gerald Brennan using ICl and N-bromosuccinimide tend to support this mechanism for halogenation and will

Kinetics of 1,10-Phenanthroline Chelation. II. Effect of Hydroxide Ion on the Dissociation Rate of Tris-(1,10-phenanthroline)-iron(II)[1,2]

BY D. W. MARGERUM

RECEIVED DECEMBER 10, 1956

Hydroxide ion greatly increases the rate of dissociation of tris-(1,10-phenanthroline)-iron(II) despite the fact that there are no acidic protons in the complex. The value of k_0, first-order dissociation rate constant with respect to the complex, is dependent on the hydroxide ion concentration: $k_0 = k_d + k_1[OH^-] + k_2[OH^-]^2 + k_3[OH^-]^3$. The kinetics may be explained by an SN2 mechanism with nucleophilic attack by water or hydroxide ion to form reaction intermediates, which are in turn attacked by water or hydroxide ion, or by an SN1 mechanism with similar intermediates.

Introduction

It is known that the brightly colored complex, tris-(1,10-phenanthroline)-iron(II), is stable in aqueous solution in the pH range 2–9.[3] Outside this pH range there is noticeable dissociation of the complex. Although the rate of dissociation of tris-(1,10-phenanthroline)-iron(II) (hereafter abbreviated $FePh_3^{++}$) has been studied by a number of workers,[4–6] all of these studies have been performed in acidic solutions. Under the conditions of these studies, the rate of dissociation of the complex is first order with respect to the concentration of $FePh_3^{++}$ and independent of acidity. The acidities examined were from 0.005 to 0.50 M H_2SO_4. The kinetics of the over-all iron(II)-1,10-phenanthroline system are summarized as follows,[4] omitting the coördinated water molecules

$$\left.\begin{aligned} Fe^{++} + Ph &\rightleftharpoons FePh^{++} \\ FePh^{++} + Ph &\rightleftharpoons FePh_2^{++} \end{aligned}\right\} \text{Fast}$$

$$FePh_2^{++} + Ph \underset{k_d}{\rightleftharpoons} FePh_3^{++} \quad \text{Slow}$$

where $k_d = 0.0045$ min.$^{-1}$. Only the addition or removal of the third 1,10-phenanthroline molecule to iron(II) proceeds at a measurable rate. Because of the stability of the mono and tris complexes, the bis-(1,10-phenanthroline)-iron(II) ion, $FePh_2^{++}$, does not exist in any appreciable concentration in solutions of varying iron(II) and 1,10-phenanthroline concentration.[7]

Tris-(1,10-phenanthroline)-iron(II) has been resolved into its optical isomers and the rate of its racemization has been studied.[6] The racemization rate is also independent of acidity (from 0.1 to 1.0 M HCl), but is greater than the dissociation rate. It has been suggested that racemization of $FePh_3^{++}$ proceeds both by a dissociation mechanism and by an intramolecular racemization mechanism.

Much more work has been done on the mechanism of substitution reactions with cobalt(III) complexes than with other coördination compounds. When weak nucleophilic groups react with cobalt(III) complexes, the reactions proceed by SN1 kinetics. More powerful nucleophilic substitutions may be interpreted as SN2[8] or SN1CB[9,10] reactions. The SN1CB reaction is one where the conjugate base of the complex is formed prior to a slow first-order step in the reaction mechanism. In support of the SN1CB kinetics it has been pointed out that "complexes containing no acidic protons release their replaceable ligands at a rate independent of the pH of the solution."[10] This generalization may be applicable to the cobalt(III) complexes but it does not fit all complexes. Tris-(1,10-phenanthroline)-iron(II) contains no acidic protons but its dissociation rate in basic solution is highly dependent upon the pH of the solution. This paper is concerned with the nature and significance of the hydroxide ion effect on the rate of dissociation of $FePh_3^{++}$.

Experimental

A stock solution of $FePh_3^{++}$ was prepared using a slight excess of 1,10-phenanthroline so that the concentration of $FePh_3^{++}$ was 4.87×10^{-4} M and the excess 1,10-phenanthroline was 2.55×10^{-4} M. Ten-ml. aliquots of this solution were diluted to 100 ml. volumes in solutions containing KCl, NaOH and slight amounts of ethylenediaminetetraacetic acid. The latter was added to help displace the equilibrium by reacting with Fe(II) and to prevent the precipitation of iron hydroxides. The KCl was used to maintain constant ionic strength. The dissociation rates were followed at 510 mμ with a thermostated (25.0°) Beckman DU spectrophotometer. All measurements were started 1 to 3 minutes after mixing the reagents and readings were taken every 30 or 60 seconds for 10 to 20 minutes.

Hydroxide ion concentrations were calculated either from the amount of NaOH added or from the pH of the solution using a Beckman Model G pH meter equipped with an E-2 (high alkalinity) electrode. Since some NaOH will react with the added ethylenediaminetetraacetic acid (abbreviated H_4Y), the following calculation was used. It is possible to assume that all the H_4Y added, Y_T, will be present as either HY^{-3} or Y^{-4}. Then from the charge balance in the solution

$$[OH^-] = [\text{NaOH added}] + [Na^+]_0 - 3[Y_T] - [Y^{-4}]$$

where $[Na^+]_0$ is the original concentration of Na^+ resulting from the use of the disodium salt of ethylenediaminetetraacetic acid. The $[Y^{-4}]$ can be estimated from titration curves and the approximate pH of the solution. Since the $[Y_T]$ was maintained between 0.002 and 0.010 M, these corrections were not significant at the higher hydroxide ion concentrations. At low hydroxide ion concentrations pH was also used to calculate the $[OH^-]$ from

$$\log m_{OH} = p\text{H} + \log \frac{K_w}{f_{NaOH}}$$

where $K_w = 1.008 \times 10^{-14}$ and f_{NaOH} was taken from the ionic strength of the solution.[11]

Results

When $FePh_3^{++}$ is placed in basic solutions, its rate of dissociation is much faster than when it is in acidic solutions. The half-life of the bright red complex in sulfuric acid solutions is 2.5 hours while in strong base the colored complex may completely disappear in only ten minutes. Spectrophotometric evidence indicates none of the blue, oxidized state of the complex $FePh_3^{+++}$ is formed during the disappearance of $FePh_3^{++}$. Two additional tests show that oxidation is not responsible for the rapid disappearance of the red complex in strong base. First, the reaction is just as fast in the presence of a reducing agent such as sodium hydrosulfite ($Na_2S_2O_4$). Second, when the solid blue iron(III) complex, $FePh_3(ClO_4)_3$, is dissolved in water and strong base is added, the blue solution immediately turns red due to the formation of the iron(II) complex. Although the 1,10-phenanthroline molecule does not decompose readily, it is also conceivable that hydroxide ion could attack the 1,10-phenanthroline molecule in the iron(II) complex. In order to test for decomposition of 1,10-phenanthroline, a solution of $FePh_3^{++}$ was allowed to dissociate completely in 0.72 M NaOH in the absence of ethylenediaminetetraacetic acid. On neutralization of the solution, the bright red complex, identical with the original solution, re-formed. (It was necessary to add more Fe(II) or else hydroxylamine to re-form all the complex, as the original Fe(II) released from the $FePh_3^{++}$ rapidly formed iron(III) hydroxide in the strong base.) From these tests it is apparent that the 1,10-phenanthroline itself is not decomposed and it can be assumed that the disappearance of the red color is, in fact, due only to the dissociation of the original complex.

The hydroxide ion concentration is either in large excess of the $[FePh_3^{++}]$ or else it is well buffered by the ethylenediaminetetraacetic acid. Hence, during any given kinetic run the $[OH^-]$ is a constant. The presence of excess hydroxide ion and of ethylenediaminetetraacetic acid also displaces the equilibrium so far that the reverse reaction, *i.e.*, the formation of $FePh_3^{++}$, is in all cases negligible over the time the reaction was followed kinetically. Therefore, the dissociation of $FePh_3^{++}$ appears to be first order

$$\frac{-\,d[FePh_3^{++}]}{dt} = k_0[FePh_3^{++}] \qquad (1)$$

where k_0 is a function of $[OH^-]$, ionic strength and temperature. A variation in the $[Y^{-4}]$ from 0.001 to 0.010 M at constant $[OH^-]$ and constant ionic strength indicated that for the concentration range used in these experiments Y^{-4} had no appreciable effect on the dissociation rate.

The rates of dissociation are highly dependent on the $[OH^-]$ as shown in Fig. 1, where three typical first-order plots are given. As the hydroxide ion concentration is increased, the value of k_0 becomes larger and larger. Figures 2 and 3 illustrate the effect of $[OH^-]$ on k_0 with three different series of constant ionic strength runs. Increased ionic strength decreases the effect of $[OH^-]$ on k_0, but k_0 still increases rapidly with $[OH^-]$ even at $\mu = 4.5$. The experimental data are summarized in Table I.

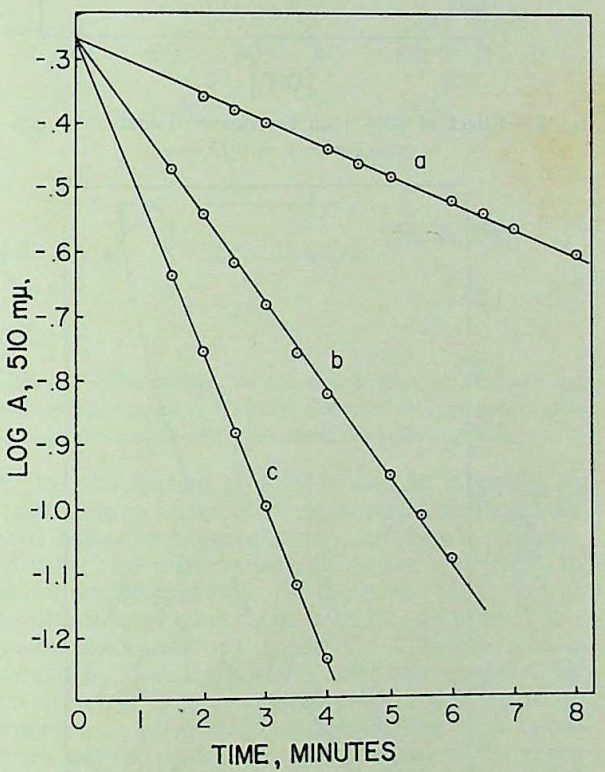

Fig. 1.—First-order plot of dissociation of $FePh_3^{++}$ at various $[OH^-]$: a is 0.098 M $[OH^-]$; b is 0.496 M $[OH^-]$; and c is 0.997 M $[OH^-]$.

At low $[OH^-]$, k_0 can be expressed as $k_d + k_1[OH^-]$, where k_d is the intercept in Figs. 2 and 3 and k_1 is the slope of the straight line near the intercept. The constant, k_d, is merely k_0 in neutral (or acid) solutions and experimental values for k_d at various ionic strengths are summarized in Table II. These values are in agreement with the previously determined values in acidic solutions except that previously the effect of ionic strength was not taken into account.

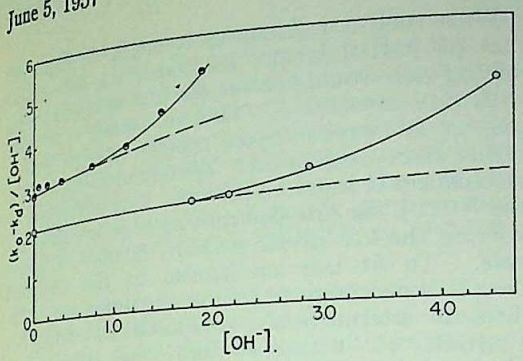

Fig. 5.—Dependence of k_0 on eq. 3: ⊖, for $\mu = 2.01$; O, for $\mu = 4.56$.

it was useful to assume that their logarithms *versus* $\sqrt{\mu}$ would appear as smooth curves. The values of k_3 are only estimates, especially at low ionic strengths. Increased ionic strength consistently suppresses the size of the rate constants even at very high ionic strengths. There is no apparent inversion of the k_1 or k_2 values above one molar KCl that can account for the rapid increase in k_1 at high $[OH^-]$. Equation 4 and the k values in Table II can be used to accurately predict the dissociation rate of $FePh_3^{++}$ at any concentration of hydroxide ion.

Discussion

It has previously been shown that only the loss of the first Ph molecule from $FePh_3^{++}$ is a kinetically important step in the dissociation of the complex. The present study has borne this out as in all cases the kinetics appear first order with respect to $FePh_3^{++}$ and independent of Ph concentration. Therefore, any mechanism involving the formation of kinetically significant bis-(1,10-phenanthroline)-iron(II) complexes, such as that below, would be ruled out.

$$FePh_3^{++} \rightleftharpoons \left\{ \begin{matrix} FePh_2(H_2O)_2^{++} + Ph \\ FePh_2(OH)(H_2O)^{+} + Ph \\ FePh_2(OH)_2 + Ph \end{matrix} \right\} \longrightarrow \text{Products}$$

This mechanism is not possible because the varying concentration of Ph during a reaction would alter the kinetics from those observed.

If the $FePh_3^{++}$ complex is compared to the cobalt(III) complexes, the question arises whether or not the iron(II) complex is subject to nucleophilic attack by water or hydroxide ion. Two sets of mechanisms can be considered, one assuming water and hydroxide ion attack and the other assuming hydroxide ion catalysis. The nucleophilic mechanism is discussed first.

1. **Nucleophilic Attack.**—If it is assumed that hydroxide ion is capable of nucleophilic attack on $FePh_3^{++}$, it would be consistent to assume that the water molecule behaves similarly so that in neutral solutions the dissociation of $FePh_3^{++}$ proceeds by attack of water. The observed kinetics show that k_0 has greater than a first-order dependence on hydroxide ion. Since a combination of attack by water and hydroxide ions to give bi-, tri- and tetramolecular reactions is unreasonable, it is necessary to assume some type of unstable reaction intermediate where H_2O or OH^- is associated with $FePh_3^{++}$. Although this intermediate might be pictured as some type of complex with a coördination number of seven, it is more convenient to represent it as having one singly-bonded 1,10-phenanthroline molecule. The latter is assumed in Fig. 6. Since two nitrogen–iron bonds must be broken

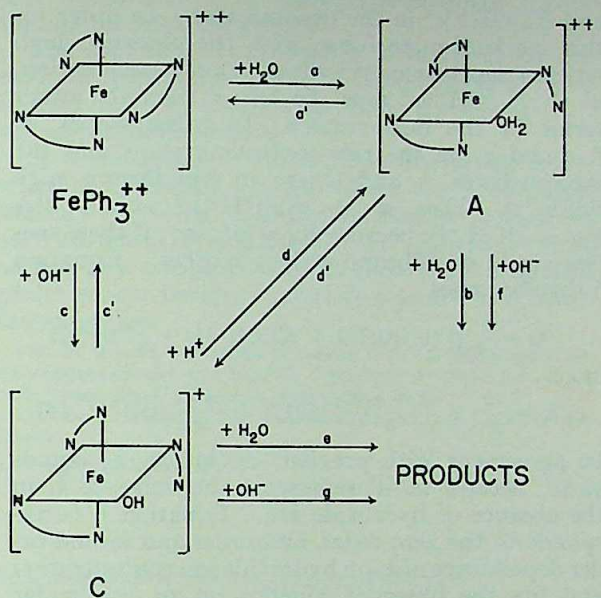

Fig. 6.—Mechanism for the dissociation of $FePh_3^{++}$ by nucleophilic attack of H_2O and OH^-: N–N represents 1,10-phenanthroline; A and C are unstable intermediates.

in the dissociation of a Ph molecule, it would be reasonable to expect that under nucleophilic attack both bonds would not react and break simultaneously. In other words, a four centered reaction would not be expected. If the bonds do not break simultaneously then there must be an intermediate species such as A or C in Fig. 6. The species A is formed by the attack of H_2O and the species C by the attack of OH^-. Once A is formed it would be expected to come to rapid equilibrium with C because only a proton transfer is involved in going from one intermediate to the other. The intermediates, A or C, may revert back to $FePh_3^{++}$ by unimolecular reactions or they may lose the activated Ph molecule by subsequent nucleophilic attack by another H_2O or OH^-.

Let

$$K_d = \frac{d'}{dK_w} = \frac{[C]}{[OH^-][A]}$$

and use the steady-state approximations to assume that $d[A]/dt + d[C]dt = 0$. From Fig. 6

$$\frac{-d[FePh_3^{++}]}{dt} = k_0[FePh_3^{++}] = (a + c[OH^-])\,[FePh_3^{++}] - a'[A] - c'[C]$$

and assuming no reversible reaction from the products

$$[A] = \frac{a + c[OH^-]}{a' + b + f[OH^-] + K_d[OH^-](c' + e + g[OH^-])}\,[FePh_3^{++}]$$

and

$$[C] = K_d[OH^-][A]$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Therefore, the rate constant[12] is

$$k_0 = (a + c[OH^-]) \frac{b + f[OH^-] + K_d[OH^-](e + g[OH^-])}{a' + b + f[OH^-] + K_d[OH^-](c' + e + g[OH^-])} \quad (5)$$

In eq. 5, the numerator and denominator of the part in the brackets are identical except for a' and $K_d[OH^-]c'$ in the denominator. In order for this mechanism to agree with the observed high order of dependence of hydroxide ion concentration, $a' + K_d[OH^-]c'$ must be larger than the other terms in the denominator. In other words, b, f, e and g are the rate-controlling steps and the intermediates A and C are in equilibrium with $FePh_3^{++}$. Then $a' + K_d[OH^-]c'$ equals $a'/a(a + c[OH^-])$, because $K_d = a'c/ac'$, if these species are in equilibrium with each other. Equation 5 then becomes

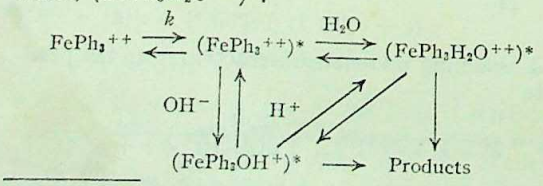
$$k_0 = \frac{a}{a'} \{b + f[OH^-] + K_d[OH^-](e + g[OH^-])\}$$

or

$$k_0 = \frac{ab}{a'} + \frac{af + aeK_d}{a'}[OH^-] + \frac{agK_d}{a'}[OH^-]^2 \quad (6)$$

In agreement with previous definition, k_d equals ab/a', because ab/a' represents the value of k_0 in the absence of hydroxide ion. Equation 6 corresponds to the zero-order, first-order and second-order dependence of k_0 on hydroxide ion concentration and fits the observed kinetics up to one molar $[OH^-]$. The introduction of a $[OH^-]^3$ term above one molar hydroxide ion concentration may be due to several factors. At such high ionic strengths it is possible that specific salt effects, characteristic of NaOH as opposed to KCl, might change the activity coefficients. This would be equivalent to having a high concentration of NaOH cause an increase in the values of k_d, k_1 and k_2, something which is not observed with KCl. Another explanation of the $[OH^-]^3$ term can be derived by extending the kinetic picture of Fig. 6. A second Ph molecule in intermediate C can be activated to form another intermediate, D, with two singly bonded phenanthroline molecules. If D then goes to product by OH^- attack, the system would have a $[OH^-]^3$ term.

2. Hydroxide Ion Catalysis.—An alternative explanation to nucleophilic attack may be postulated by assuming that $FePh_3^{++}$ spontaneously forms an intermediate, $(FePh_3^{++})^*$, where one Ph molecule is only partially bonded to Fe(III). This intermediate might rapidly accept a water molecule or hydroxide ion prior to the complete dissociation of the Ph molecule from the Fe(II). The intermediate with a hydroxide ion, $(FePh_3OH^+)^*$, would lose the partially bonded Ph molecule more readily than the intermediate formed with water, $(FePh_3H_2O^{++})^*$.



With such a mechanism it might be expected that as $[OH^-]$ greatly increased, the rate-determining step would become the first activation step with rate constant k. This, of course, is not the case as k_0 increases more rapidly at high $[OH^-]$ rather than leveling off. Therefore, to apply this mechanism it must be assumed that regardless of the $[OH^-]$, the rate-determining steps are those involving the loss of the partially bonded Ph molecule. To fit this mechanism to the observed data it is necessary to assume the formation of additional intermediates, $(FePh_3(OH)_2^0)^*$ and $(FePh_3(OH)_3^-)^*$, with two and three one-bonded phenanthroline molecules, respectively. If nucleophilic attack is not allowed, then each of these intermediates must be preceded by their corresponding activated species with which OH^- equilibrates.

Another mechanism should be mentioned in addition to the two already considered, both of which change the bonding to Fe(II). Ion pair formation between $FePh_3^{++}$ and OH^- could conceivably lead to intermediates with one or more OH^-, which would dissociate at different rates. However, other ions such as Cl^-, F^-, NO_3^- and ClO_4^- might be expected to form ion pairs as readily as OH^-, but none of these ions increase the dissociation rate. In fact, as noted earlier, increased ionic strength decreases the dissociation rate rather than increasing it. Hence, an ion pair type mechanism is not possible unless OH^- forms some unique species with $FePh_3^{++}$, in which case it would essentially be bonded to Fe(II) and no longer a mere ion pair.

The dissociation of $FePh_3^{++}$ is not the only phenanthroline reaction where it has been necessary to postulate reaction intermediates to explain the kinetics. The dissociation and formation rates of mono-(1,10-phenanthroline)-nickel(II) are affected by acidity in such a way as to necessitate the assumption of a partially bonded intermediate.[2] Other studies on the racemization of $FePh_3^{++}$ have shown an intramolecular racemization in addition to the dissociation racemization.[6] The intramolecular racemization can be explained readily from the point of view of a partially bonded intermediate. It is possible to predict that the racemization reaction should proceed faster in basic solutions.

The exact nature of the reaction intermediates with 1,10-phenanthroline complexes is not clear. The intermediate might be considered as having opened a chelate ring and coördinated another nucleophilic group to the central ion shown in Fig. 6. However, the fact that the nitrogen atoms in 1,10-phenanthroline are only 2.5 Å. apart and that the 1,10-phenanthroline molecule is a fixed planar structure has been used as steric arguments against any tendency for 1,10-phenanthroline to behave as a monodentate group.[6] On the other hand, optical isomers of 4,5-disubstituted phenanthrenes have been obtained.[13] These compounds have a structure similar to 1,10-phenanthroline and optical isomers can exist only by steric repulsion causing nonplanarity of the molecule. Hence, it is not impos-

(12) Equation 5 may also be derived by first assuming only that $d[A]/dt = 0$, and $d[C]/dt = 0$ and then simplifying the resulting expression by assuming that d' and c' are very small.

sible to have a reaction intermediate with a broken chelate ring. The alternative explanation is a reaction intermediate with a seven coördinated iron(II) ion. Such a coördination intermediate would presumably necessitate changes in electron configuration of the complex, which would account for the slowness of its formation. Somewhere in the dissociation reaction the electronic configuration for iron(II) changes from $d^2d^2d^2D^2SP^3$ to $d^2d^1d^1d^1d^1SP^2D^2$.

It is not possible from this work to definitely establish whether the hydroxide ion effect on $FePh_3^{++}$ is due to an SN1 or an SN2 mechanism. Both mechanisms involve partially dissociated species and neither mechanism accounts for the observed $[OH^-]^3$ term without the introduction of several intermediates. However, the SN2 mechanism is the simpler of the two. It has fewer intermediates and gives a $[OH^-]^2$ dependence at low hydroxide ion concentrations without the necessity of assuming an intermediate with two activated Ph molecules. The hydroxide ion is not the only nucleophilic ion which can accelerate the dissociation of $FePh_3^{++}$. Cyanide ion and thiocyanate ion both cause faster dissociation of $FePh_3^{++}$.[14] The cyanide ion kinetics with $FePh_3^{++}$ resemble the hydroxide ion kinetics, with a reaction intermediate likely. The aqueous cyanide ion causes faster dissociation than the hydroxide ion. All of these factors contribute to the feasibility of an SN2 mechanism with reaction intermediates containing nucleophilic groups.

The fact that it is possible to bring about the rapid dissociation of $FePh_3^{++}$ should prove of value in analytical separations involving the use of 1,10-phenanthroline kinetics.[15]

It is naturally of considerable interest to know whether hydroxide ion will affect the dissociation kinetics of other 1,10-phenanthroline complexes such as nickel(II) and cobalt(III). These systems, as well as a comparison of the effect of other nucleophilic groups besides hydroxide ion, are now under investigation.

Tridentate Chelate Compounds. I

BY FRANCIS LIONS AND KENNETH V. MARTIN[1]

RECEIVED DECEMBER 10, 1956

New tridentate chelate compounds containing three donor nitrogen atoms and possessing structural features resembling those of terpyridine have been prepared and shown to form coördination compounds readily. Some polymers possessing recurring tridentate chelate groups also have been prepared and their capacity to combine with metal salts demonstrated. Some of the iron containing polymers have unusual magnetic properties.

2,6-Bis-(α-pyridyl)-pyridine (I), better known by its trivial name "terpyridine," is a most important tridentate chelate compound which has been extensively studied. However, it is relatively inaccessible. In 1953 one of the authors and his co-workers[2] reported briefly on the preparation and use of 8-(α-pyridylmethyleneamino)-quinoline (II) as a tridentate chelate compound with constitutional features similar to those of I and showed that it coördinated with iron(II) salts similarly to I. The present paper describes a number of new tridentate chelate compounds, each containing three donor nitrogen atoms and some possessing details of molecular structure similar to I.

2-Aminomethylpyridine (III) is available from the reduction with zinc dust and acetic acid of pyridine-2-aldoxime.[3] We have also found that it can be synthesized from the 2-chloromethylpyridine of Matsumura[4] by condensation with potassium phthalimide using Bolhofer and Shea-han's[5] modification of the Gabriel reaction, and hydrolysis of the 2-phthalimidomethylpyridine so obtained. However, the over-all yield is small and the method of Craig and Hixon is preferable.

III reacts readily with pyridine-2-aldehyde to give the Schiff base 2-(α-pyridylmethyleneaminomethyl)-pyridine (IV) as a pale yellow oil. IV might well be expected to function as a tridentate chelate compound with all three nitrogen atoms acting as donors and attaching the tridentate residue to a metal atom in two coplanar 5-membered ring "chelate loops."[6] The molecules of both I and IV possess the same sequence of atoms and bonds, *viz.*, –N=C–C=N–C–C=N–, in the donor chain, so that at least some of the possibilities which exist for double bonding and resonance must be similar for the molecules of both substances.

Addition of iron(II) sulfate to an aqueous suspension of II results in formation of an intensely red-colored solution from which bis-(2-(α-pyridylmethyleneaminomethyl) - pyridine) - iron(II) perchlorate (V) can be precipitated. This salt is diamagnetic and must apparently be an octahedral iron(II) complex salt with lower level ($3d^24s4p^3$) covalent bonds. Its complex cation must be very similar structurally to that of the bis-terpyridine iron(II) salts, each tridentate residue lying in one

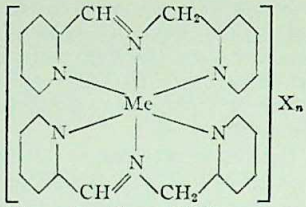
or other of two equatorial planes at right angles to each other, the metal atom being in both planes



V, Me = Fe, X = (ClO_4), $n = 2$
VI, Me = Co, X = (ClO_4), $n = 2$
VII, Me = Co, X = I, $n = 3$.

(Fig. 1). The complex cation of V should thus exist in enantiomorphous forms.

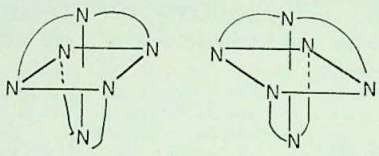


Fig. 1.

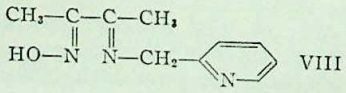
Addition of cobalt(II) chloride to an ethanolic solution of IV leads to development of a deep-blue color and blue bis-(2-(α-pyridylmethyleneaminomethyl)-pyridine)-cobalt(II) perchlorate (VI) can be precipitated. Its magnetic moment of 4·3 Bohr magnetons indicates the use of upper level ($4s4p^34d^2$) covalent bonds. Treatment of the blue ethanolic solution of the complex cobalt(II) chloride corresponding to VI with a mild oxidising agent, such as aqueous hydrogen peroxide, changes the color to brown. After destruction of excess peroxide by boiling, addition of potassium iodide to the cooled solution leads to precipitation of diamagnetic bis-(2-(α-pyridylmethyleneaminomethyl)-pyridine)-cobalt(III) iodide (VII). Structurally, the complex cations of VI and VII must be constituted similarly to those of V.

Interaction of III and diacetyl monoxime in hot ethanol leads to formation of colorless crystalline 2-oximino-3-methyl-4-aza-5-α-pyridyl-Δ^3-pentene (VIII). VIII coördinates readily with iron(II) and cobalt salts. Thus, solid VIII readily dissolves in aqueous iron(II) sulfate solutions with development of an intense red color and diamagnetic bis-(2-oximino-3-methyl-4-aza-5-α-pyridyl-Δ^3-pentene)-iron(II) iodide (IX) readily can be precipitated by addition of a soluble iodide.

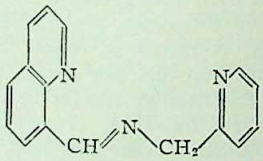


VIII

Interaction of VIII with cobalt(II) chloride in aqueous ethanol followed by oxidation with cerium(IV) nitrate leads to formation of the complex bis-(2-oximino-3-methyl-4-aza-5-α-pyridyl-Δ^3-pentene) cobalt(III) salt and the diamagnetic iodide X can be precipitated. Heating of the reaction mixture during the preparation leads to decomposition and liberation of diacetyl. In each of the complex salts IX and X the two residues of VIII function as tridentates without proton loss from the oximino group, each tridentate residue forming two coplanar 5-membered ring chelate loops with the metal atom, the structural pattern being similar to that of Fig. 1.

We have again prepared 8-(α-pyridylmethyleneamino)-quinoline[2] (II) and have found that it combines readily with cobalt(II) salts to give complex cobalt(II) salts which can be oxidized to the cobalt(III) state. Thus, bis-(8-(α-pyridylmethyleneamino)-quinoline)-cobalt(III) perchlorate can be obtained as a diamagnetic crystalline solid. The relative ease of synthesis of II and similar compounds suggests commencement of a study of the coördinating capacity of substituted derivatives of XI. It has already been amply demonstrated that substituents in the 2,2′-bipyridine or the 1,10-phenanthroline molecule can affect the chelating power, whether because of steric or electron-attracting or -repelling effects.[7] We have condensed pyridine-2-aldehyde with 8-aminoquinaldine[8] to obtain the Schiff base 8-(α-pyridylmethyleneamino)-2-methylquinoline (XII) and have found that XII coördinates readily with iron(II) salts to give diamagnetic intensely-green bis-(8-(α-pyridylmethyleneamino)-2-methylquinoline)-iron(II) salts. The intensity of the color is indistinguishable from that obtained with XI and it seems reasonable to infer that the single substituent methyl group in the quinoline nucleus does not materially affect the chelating capacity, despite its proximity to one of the donor nitrogen atoms. This is in marked contrast to the effect on the chelating power of 2,2′-bipyridine or of 1,10-phenanthroline of methyl groups similarly introduced into positions adjacent to the donor nitrogen atoms.

Quinoline-8-aldehyde[9] condenses readily with 2-aminomethylpyridine (III) to give 2-(8′-quinolylmethyleneaminomethyl)-pyridine (XVI), which coördinates readily as a tridentate chelate compound with iron(II) sulfate in aqueous solution. From the resulting intensely-green solution can be isolated green crystalline diamagnetic bis-(2-(8′-quinolylmethyleneaminomethyl) - pyridine) - iron(II) iodide (XVII). It is worth noting that of the two chelate loops formed by a molecule of XVI when it coördinates with a metal atom, one is a five-membered ring whilst the other is six-membered.



XVI

In any consideration of design of new tridentate chelate compounds related to I cognizance must be taken of the recent availability of pyridine-2,6-dialdehyde (XVIII). XVIII will condense with primary amines (2 mols.) to give Schiff bases of the general formula XIX in which there is the same sequence of donor atoms and bonds as

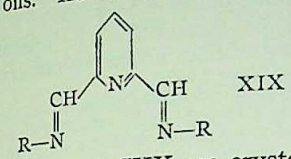
in I. When R is methyl or ethyl in XIX these bases are oils. However, when R is phenyl or



XIX

benzyl the compounds XIX are crystalline solids. These coördinate readily with metal salts as tridentate chelates. Thus, it is quite easy to prepare the red diamagnetic bis-(2,6-pyridylene-dimethyleneaniline)-iron(II)[10] perchlorate (XX) and bis-(2,6-pyridylene-dimethylenebenzylamine)-iron(II) bromide (XXI), typical octahedral iron(II) complex salts with lower level ($3d^2 4s 4p^3$) covalent bonding. Structurally, the planar tridentate residues in a molecule of one of them must be situated in two planes at right angles, and since these residues are symmetrical, the complex ion must be identical with its mirror image so that the salts are not resolvable (Fig. 2).

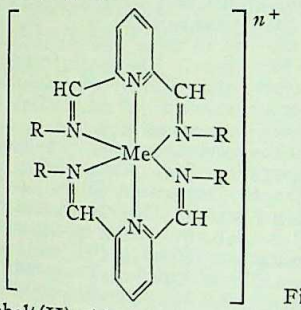


Fig. 2.

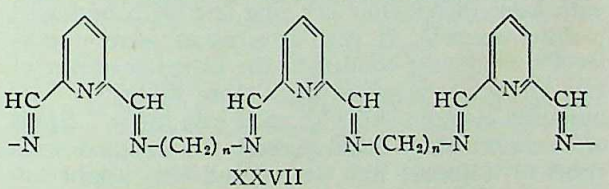
From cobalt(II) chloride and XIX (R = $-CH_2C_6H_5$) in aqueous ethanol can be obtained in solution bis-(2,6-pyridylene-dimethylenebenzylamine)-cobalt(II) chloride. The corresponding iodide XXII, which crystallizes in dark brown needles, is paramagnetic with a magnetic moment of 3.8 Bohr magnetons. The chloride can be oxidized in solution with chlorine and, eventually, diamagnetic bis-(2,6-pyridylene-dimethylenebenzylamine)-cobalt(III) iodide can be isolated. This oxidation cannot be effected with any rapidity with cerium(IV) nitrate in nitric acid solution, almost pure complex cobalt(II) salt being recoverable.

When copper(II) chloride is allowed to react with XIX (R = $-CH_2C_6H_5$) in ethanol a bright green color develops and a solid separates. Addition of more base results in re-solution of the solid and change of color to grey-green. From this solution perchloric acid precipitates bis-(2,6-pyridylene-dimethylenebenzylamine)-copper(II) perchlorate (XXIII). We consider this salt to be an octahedral copper(II) complex salt with $4s 4p^3 4d^2$ upper level covalent bonds. Six-covalent copper(II) complexes are not novel.[11]

Pyridine-2,6-dialdoxime (XXIV) appears to function as a tridentate chelate compound. Thus, when it is treated in aqueous ethanol solution with iron(II) sulfate and then sodium acetate, a deep-red crystalline solid $C_{14}H_{11}N_6O_4FeNa$ (XXV) is obtained. This is a binary electrolyte with the coördinated iron atom in the anion. However, further consideration of its structure is reserved for a later paper.

Reduction of XXIV with zinc dust and acetic acid leads to formation in good yield of 2,6-bis-aminomethylpyridine (XXVI), a colorless oil which absorbs carbon dioxide from the air but which can be characterized by its crystalline bis-salicylidene or its bis-piperonylidene derivative. XXVI reacts readily with iron(II) sulfate in aqueous solution to give deep green bis-(2,6-di-(aminomethyl)-pyridine)-iron(II) sulfate, and then addition of potassium iodide causes precipitation of the corresponding iodide, a paramagnetic salt with a magnetic moment of 5.2 Bohr magnetons, indicative of upper level covalent bonding. Exposure of this salt to moisture and air leads to breakdown and liberation of iron(III) hydroxide. XXVI also reacts readily with nickel(II) salts and bis-[2,6-di-(aminomethyl)-pyridine]-nickel(II) bromide was isolated as deep mauve-colored needles.

Among the condensation products obtainable from XVIII and primary amines are the linear polymers derivable from diamines. We have condensed XVIII with ethylenediamine, 1,6-diaminohexane and benzidine and have obtained solid infusible polymers from each condensation. The molecules of each of them contain potential tridentate chelate groups, a section of the polymer chain occurring in the molecules of each of the former two being capable of formulation as in XXVII. It would therefore seem reasonable to ex-



XXVII

pect them to be able to absorb certain kinds of metal salt from solution through the ability of the recurring tridentate groups to coördinate with the metal atoms. The polymer derived from benzidine apparently possesses very little capacity for coördination with ions such as iron(II) which favor an octahedral environment. However it will combine with salts such as copper(II) chloride. The polymers from ethylenediamine and hexamethylenediamine do readily combine with salts such as iron(II) sulfate, rapidly acquiring a purplish-blue color when suspended in aqueous solutions of it.

Consideration of the spatial requirements of the various atoms in the molecule of the polymer derived from hexamethylenediamine shows that it should be possible for two successive tridentate residues in the chain to coördinate with the same six-covalent metal atom, the two planar tridentate residues becoming disposed in two planes at right angles to each other. If this process were to occur regularly along the chain the resulting giant molecule might be looked on as containing a series of sexadentate chelate residues regularly spaced along a linear molecule and each coördinated through six nitrogen atoms to a metal atom. However, it

(10) The bivalent radical C_5H_4N is named pyridylene by analogy with phenylene.

Digitized by Arya Samaj Foundation Chennai and eGangotri

is quite unlikely that such regularity could occur. Thus, if in a series of five successive three-nitrogen-atom groups along the chain the first and second became bonded to a metal atom (as a sexadentate) and the fourth and fifth did also, then the third group—now an isolated tridentate group—might function by bonding to a metal atom to produce cross-linking of neighboring polymer chains. It might also remain unattached. Such a process of forming recurring sexadentate coördinated ions along the chain of the polymer would involve very complicated twining and twisting and it hardly seems probable that a polymer molecule, once formed, could undergo this process.

In fact, suspension of the powdered water-insoluble 1:1 polymer obtained by condensing XVIII with hexamethylenediamine in an aqueous solution containing excess iron(II) sulfate, followed by boiling, leads to the taking up of one molecule of iron(II) sulfate for each two residues of XVIII. The suspended solid acquires a deep reddish-blue color. This iron-containing solid is insoluble in any of the common solvents and does not melt below 300°. The analytical results suggest that in its molecules each iron atom is probably bonded to the six nitrogen atoms from two tridentate residues, the results agreeing with an empirical formula $C_{26}H_{34}N_6FeSO_4 \cdot 6H_2O$. The magnetic behavior was quite unusual, the solid being ferromagnetic with a molar susceptibility (ψ_m) of $155{,}000 \times 10^{-6}$ c.g.s. unit. It is difficult, without much more evidence, to draw conclusions concerning the molecular structure. Ferromagnetism is usually observed in lattices of magnetic particles with loose interatomic bonding and with unpaired parallel spins.[12] If each iron atom were upper-level convalently bonded to the nitrogen atoms of two tridentate residues then there would be four unpaired electron spins for each iron atom. Spins of one iron atom could possibly be coupled with spins of adjacent iron atoms and this might account for the observed ferromagnetism.

When an ethanolic solution of XVIII is added to a solution of hexamethylenediamine and iron(II) sulfate in aqueous ethanol (polymer preparation in the presence of iron(II) sulfate) a small amount of an insoluble solid separates from the solution. Addition of a soluble perchlorate to the red filtrate then causes precipitation of a diamagnetic red complex iron(II) perchlorate. From its elementary composition it would appear that in this salt two iron(II) atoms are bound for every seven tridentate residues in the polymer molecule. Since the material is diamagnetic it seems probable that the immediate environment of each iron atom contains six bound nitrogen atoms (from two tridentate residues), and the solubility of the sulfate in water suggests that these are derived from successive residues in the same polymer chain and that there is no cross-linking.

Suspension of the finely ground pre-formed 1:1 polymer in an alcoholic solution of cobalt(II) chloride followed by boiling, leads to the taking up of one molecule of cobalt(II) chloride for each residue of XVIII, the polymer being converted into a brown solid. This was found to be paramagnetic (3.7 Bohr magnetons). Without further prolonged studies it is only possible to guess at its structure, but it could be that there are present chlorine bridges linking cobalt atoms in structures of the type shown in Fig. 3.

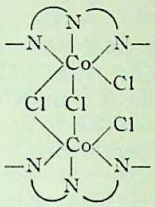

Fig. 3.

These preliminary studies with polymers are being continued.

Experimental

2-Aminomethylpyridine.—The base, best prepared by the method of Craig and Hixon,[3] was a colorless oil, b.p. 104° (20 mm.). It also was prepared as follows. 2-Picoline-N-oxide (4 g.) was added to a solution of *p*-toluenesulfonyl chloride (7 g.) in dry benzene (20 ml.). After 4 hours the benzene was removed *in vacuo* and the residue heated at 170° (oil-bath) for 1 hour. The residual thick dark oil was washed with ether, then treated with saturated aqueous sodium bicarbonate solution (20 ml.). Three extractions with ether (50 ml.) were then made and the combined extracts dried and the solvent removed. The remaining crude 2-chloromethylpyridine (3 g., picrate had m.p. 144°) was dissolved in dimethylformamide (20 ml.) and potassium phthalimide (5 g.) added. The stirred mixture was then heated at 100° for 6 hours. After cooling, aqueous potassium hydroxide solution (50 ml. of 10%) was added and two ether extractions (25 ml.) made. The combined ether extracts were washed with 5% potassium hydroxide solution, dried over solid potassium hydroxide and then the ether removed. After many recrystallizations from ethanol **2-phthalimidomethylpyridine** (0.5 g.) was obtained in colorless plates, m.p. 125°.

Anal. Calcd. for $C_{14}H_{10}N_2O_2$: C, 70.6; H, 4.2; Found: C, 70.5; H, 4.4.

Hydrolysis of this compound to 2-aminomethylpyridine was effected by the method of Ing and Manske.

Bis-[2-(α-pyridylmethyleneaminomethyl)-pyridine]-iron(II) Perchlorate Monohydrate (V).—Admixture of equimolecular proportions of freshly distilled pyridine-2-aldehyde and III caused immediate reaction and rise of temperature to about 60°. The condensation was completed by warming at 100° for 15 min. The yellow oily Schiff base IV could not be induced to crystallize. Addition of aqueous iron(II) sulfate (0.7 g. of the heptahydrate) to IV (1 g., 2 moles) led to formation of an intensely red solution from which saturated aqueous sodium perchlorate solution precipitated a red salt. Recrystallized from water this formed dark red plates which decomposed at 193°. The salt was diamagnetic.

Anal. Calcd. for $C_{24}H_{22}N_6FeCl_2O_8 \cdot H_2O$: C, 4.38; H, 3.7; Fe, 8.4; Found: C, 44.0; H, 4.0; Fe, 8.3.

Bis-[2-(α-pyridylmethyleneaminomethyl)-pyridine]-cobalt(II) Perchlorate Monohydrate (VI).—A solution of cobalt(II) chloride hexahydrate (0.7 g.) in water (10 ml.) was added to IV (1 g.). An immediate blue color developed and a small amount of solid separated. This was filtered off and saturated aqueous sodium perchlorate solution (5 ml.) added to the filtrate. A deep blue precipitate formed. It was collected, well washed with water and dried *in vacuo*. On exposure to air it gradually changed to a red gum.

Anal. Calcd. for $C_{24}H_{22}N_6CoCl_2O_8 \cdot H_2O$: C, 43.0; H, 3.6; Co, 8.8; Found: C, 43.1; H, 3.9; Co, 8.9.

This complex cobalt(II) salt had a magnetic moment of 4.2 Bohr magnetons at 23°.

2-Oximino-3-methyl-4-aza-5-α-pyridyl-Δ³-pentene(VIII).—2-Aminomethylpyridine (5 g.) was added to a solution of

(12) R. S. Nyholm, *Quart. Revs.*, 7, 377 (1953).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

diacetylmonoxime (5 g.) in ethanol (20 ml.) and the mixture refluxed for 5 minutes. The product (3.5 g., 40%) crystallized on cooling, and was recrystallized from ethanol and thus obtained in colorless needles, m.p. 157°.

Anal. Calcd. for $C_{10}H_{13}N_3O$: C, 62.8; H, 6.8; Found: C, 62.6; H, 6.7.

Bis-(2-oximino-3-methyl-4-aza-5-α-pyridyl-3-pentene)-iron(II) Iodide Dihydrate (IX).—Iron(II) sulfate heptahydrate crystals (0.23 g.) were added to a stirred suspension of VIII (0.45 g.) in water (5 ml.). The solids soon dissolved to a deep red solution. Saturated aqueous potassium iodide solution (5 ml.) was then added. The complex iodide which crystallized was collected and recrystallized from an ethanol–ether mixture, being thus obtained as a diamagnetic micro-crystalline red solid which did not melt below 300°.

Anal. Calcd. for $C_{20}H_{26}N_6O_2FeI_2 \cdot 2H_2O$: C, 33.0; H, 4.1; Fe, 7.7. Found: C, 32.5; H, 4.2; Fe, 7.5.

Bis-(2-oximino-3-methyl-4-aza-5-α-pyridyl-Δ³-pentene)-cobalt(III) Iodide (X).—A solution of cobalt(II) chloride hexahydrate (0.2 g.) in water (5 ml.) was added to a solution of VIII (0.3 g.) in ethanol (10 ml.). A solution of cerium(IV) ammonium nitrate (0.2 g.) in nitric acid (10 ml. of *N*) was then added to the brown solution, followed eventually by saturated aqueous potassium iodide solution (3 ml.). The diamagnetic complex cobalt(III) iodide crystallized and was collected and dried *in vacuo*. Heating of the reaction mixture during the preparation led to liberation of diacetyl.

Anal. Calcd. for $C_{20}H_{26}N_6O_2CoI_3$: C, 29.2; H, 3.2; Co, 7.2. Found: C, 28.7; H, 3.1; Co, 7.0.

Bis-[8-(α-pyridylmethyleneamino)-quinoline]-cobalt(III) Perchlorate.—8-(α-Pyridylmethyleneamino)-quinoline[2] (XI) was prepared precisely as follows. Freshly redistilled pyridine-2-aldehyde (5.35 g.) was added to a solution of recrystallized 8-aminoquinoline (7 g.) in ethanol (6 ml.) and the mixture warmed at 100° for 1 minute. It was then cooled and dry ether (15 ml.) added. Vigorous scratching induced crystallization of the Schiff base in yellow needles which were collected and washed with dry ether, m.p. 139–140°. Recrystallization from ethanol, as previously reported, leads to some decomposition.

Anal. Calcd. for $C_{15}H_{11}N_3$: C, 77.2; H, 4.8; Found: C, 76.2; H, 5.1.

A solution of cobalt(II) acetate tetrahydrate (0.55 g.) in methanol (15 ml.) was added to a solution of XI (0.95 g.) in ethanol (5 ml.). Hydrogen peroxide solution (5 ml. of 3%) was then added and the solution evaporated to a volume of approximately 5 ml. Addition of saturated aqueous sodium perchlorate solution (5 ml.) caused precipitation of the diamagnetic brown cobalt(III) perchlorate which was collected, washed and dried *in vacuo*. It decomposed above 265°.

Anal. Calcd. for $C_{30}H_{22}N_6CoCl_3O_{12}$: C, 43.7; H, 2.7; Co, 7.2. Found: C, 43.5; H, 2.8; Co, 7.2.

Bis-[8-(α-pyridylmethyleneamino)-quinaldine]-iron(II) Iodide Dihydrate.—Solutions of 8-aminoquinaldine (3.06 g.) in ethanol (5 ml.) and pyridine-2-aldehyde (2.14 g.) in ethanol (5 ml.) were mixed and gently refluxed for 5 min. After cooling, a solution of iron(II) sulfate heptahydrate (2.4 g.) in water (10 ml.) was added. An intense green color developed. Saturated aqueous potassium iodide solution (5 ml.) was added. The complex iron(II) salt which separated was collected and recrystallized from aqueous ethanol. It was obtained in black prisms which decomposed above 250°.

Anal. Calcd. for $C_{32}H_{26}N_6FeI_2 \cdot 2H_2O$: C, 46.7; H, 3.7; Fe, 6.8. Found: C, 46.3; H, 3.4; Fe, 6.6.

Bis-(8-quinolylmethylene-α-aminomethylpyridine)-iron(II) Iodide Trihydrate (XVII).—Admixture of hot solutions of quinoline-8-aldehyde[9] (0.8 g.) in ethanol (3 ml.) and 2-aminomethylpyridine (0.55 g.) in ethanol (2 ml.) gave an orange solution. Addition of a solution of iron(II) sulfate heptahydrate (0.6 g.) in water (5 ml.) gave an intense green solution from which saturated aqueous potassium iodide solution precipitated the dimagnetic complex iron(II) salt.

Anal. Calcd. for $C_{32}H_{26}N_6FeI_2 \cdot 3H_2O$: C, 44.6; H, 3.7; Fe, 6.5. Found: C, 44.5; H, 3.5; Fe, 6.5.

2,6-Pyridylene-bis-methyleneaniline (XIX, R = C_6H_5).—Freshly distilled aniline (8 g.) was added to a solution of pyridine-2,6-dialdehyde (5.8 g.) in ethanol (30 ml.) and the solution boiled under reflux for 30 minutes. On cooling, the Schiff base crystallized. Recrystallized from ethanol it formed colorless needles, m.p. 98°.

Anal. Calcd. for $C_{19}H_{15}N_3$: C, 80.0; H, 5.3; Found: C, 79.6; H, 5.5.

Bis-[2,6-pyridylene-bis-methyleneaniline]-iron(II) Perchlorate Dihydrate.—A solution of iron(II) sulfate heptahydrate (1 g.) in water (10 ml.) was added to a solution of XIX (R = C_6H_5) (2 g.) in ethanol (10 ml.). An intensely red solution resulted. Ethanol was removed by evaporation from a water-bath and perchloric acid solution (5 ml. of 5%) added. The complex iron(II) perchlorate which precipitated was collected and recrystallized from ethanol and obtained in red plates which decompose violently at 215°.

Anal. Calcd. for $C_{38}H_{30}N_6FeCl_2O_8 \cdot 2H_2O$: C, 52.4; H, 3.9; Fe, 6.5; Found: C, 52.7; H, 4.0; Fe, 6.3.

Boiling of aqueous solutions of this salt caused some decomposition.

2,6-Pyridylene-bis-(methylenebenzylamine) (XIX, R = $-CH_2C_6H_5$).—A solution of benzylamine (4.36 g.) and pyridine-2,6-dialdehyde (2.7 g.) in ethanol (20 ml.) was heated under reflux for 40 minutes. After concentration and cooling a colorless solid (6.2 g.) was deposited. Recrystallized from ethanol it formed colorless tablets, m.p. 80°.

Anal. Calcd. for $C_{21}H_{19}N_3$: C, 80.5; H, 6.1. Found: C, 80.3; H, 6.3.

Bis-(2,6-pyridylene-bis-methylenebenzylamine)-iron(II) Bromide Bi-sesquihydrate (XXI).—Saturated aqueous potassium bromide solution (10 ml.) was added to the intensely red solution obtained by mixing solutions of XIX (R = $CH_2C_6H_5$) (1.25 g.) in ethanol (10 ml.) and iron(II) sulfate heptahydrate (0.55 g.) in water (10 ml.). The precipitate was collected and recrystallized from water. Dark red diamagnetic needles, m.p. 265° (with previous softening at 165°), were thus obtained.

Anal. Calcd. for $C_{42}H_{38}N_6FeBr_2 \cdot 2.5H_2O$: C, 56.9; H, 4.9; Fe, 6.3. Found: C, 56.7; H, 4.8; Fe, 6.2.

Bis-(2,5-pyridylene-bis-methylenebenzylamine)-cobalt(II) Iodide.—Addition of a solution of cobalt(II) chloride tetrahydrate (0.7 g.) in water (10 ml.) to a solution of XIX (R = $CH_2C_6H_5$) (2 g.) in ethanol (10 ml.) caused a yellow solid to separate from the solution. It redissolved on addition of water (10 ml.). Addition of saturated aqueous potassium iodide solution then caused the complex cobalt(II) iodide to separate. It was collected and recrystallized from ethanol, and was thus obtained in dark brown needles, m.p. 251°.

Anal. Calcd. for $C_{42}H_{38}N_6CoI_2$: C, 53.7; H, 4.0; Co, 6.3. Found: C, 53.6; H, 4.0; Co, 6.1.

The molar conductance of this salt in 10 *M* aqueous solution was 255 ohms^{-1}. The salt was paramagnetic with a moment of 3.8 Bohr magnetons.

Bis-(2,6-pyridylene-bis-methylenebenzylamine)-cobalt(III) Iodide Dihydrate.—A solution of cobalt(II) chloride hexahydrate (0.6 g.) in water (20 ml.) was added to a solution of XIX (R = $CH_2C_6H_5$) (1.5 g.) in ethanol (10 ml.). Chlorine was then bubbled through the solution for 10 minutes, the intense red-brown color changing to brown. Eventually, saturated aqueous potassium iodide solution (10 ml.) was added. The solid salt which separated was collected, washed well with water and ethanol and dried *in vacuo*. It was a micro-crystalline, relatively insoluble diamagnetic solid, m.p. 212°.

Anal. Calcd. for $C_{42}H_{38}N_6CoI_3 \cdot 2H_2O$: C, 45.7; H, 3.8; Co, 5.4. Found: C, 45.8; H, 3.7; Co, 5.1.

Bis-(2,6-pyridylene-bis-methylenebenzylamine)-copper(II) Perchlorate.—A solution of the base XIX (R = $CH_2C_6H_5$) (0.63 g.) in ethanol (10 ml.) was added to a solution of copper(II) chloride dihydrate (0.17 g.) in ethanol (10 ml.). A bright green solid separated at once. On warming it dissolved and the color changed to gray-green. Perchloric acid (5 ml. of 5%) was added. The complex copper(II) perchlorate crystallized in grey-green plates which were collected, washed and dried *in vacuo*.

Anal. Calcd. for $C_{42}H_{38}N_6CuCl_2O_8$: C, 86.7; H, 4.3; N, 9.5; Cu, 7.2. Found: C, 56.3; H, 4.4; N, 9.3; Cu,

Pyridine-2,6-dialdoxime was obtained in colorless needles, m.p. 216° (from ethanol).

Anal. Calcd. for $C_7H_7N_3O_2$: C, 50.9; H, 4.2. Found: C, 50.9; H, 4.5.

Addition of an aqueous solution of iron(II) sulfate heptahydrate (0.59 g.) to a solution of this pyridine-2,6-dialdoxime (0.7 g.) in ethanol (10 ml.) caused development of an intense red color. Addition of sodium acetate solution caused a deep red solid to crystallize. It was recrystallized several times from hot water.

Anal. Calcd. for $C_{14}H_{11}N_6O_4FeNa$: C, 41.4; H, 2.7; Fe, 13.8; Found: C, 41.5; H, 3.2; Fe 13.1.

The equivalent conductivity at 23° was 124 ohms^{-1} indicating the salt to be a binary electrolyte.

2,6-Bis-(aminomethyl)-pyridine.—Glacial acetic acid (500 ml.) and zinc dust (400 g.) were added over a period of 2 hours to a stirred solution of pyridine-2,6-dialdoxime (25 g.) in ethanol (100 ml.). After standing overnight the solids were separated by filtration and well washed with ethanol and these washings added to the filtrate which was then evaporated almost to dryness *in vacuo*. A considerable excess of strong potassium hydroxide solution was then added and the oil which separated was taken up in ether (4 lots of 500 ml.). After removal of the ether the residual oil was distilled *in vacuo* and obtained colorless, b.p. 112° (1.2 mm.), (13 g., 63%). It solidified on standing but was difficult to handle because of its tendency to carbonate.

Anal. Calcd. for $C_7H_{11}N_3$: C, 61.3; H, 8.0; Found: C, 60.0; H, 7.9.

For analysis it was much better to prepare derivatives such as 2,6-bis-(piperonylideneaminomethyl)-pyridine colorless needles, from pyridine–ethyl acetate, m.p. 179°.

Anal. Calcd. for $C_{23}H_{19}N_3O_4$: C, 68.8; H, 4.8; Found: C, 68.7; H, 4.9.

2,6-Bis-(salicylideneaminomethyl)-pyridine, almost colorless needles (from ethanol), had m.p. 120°.

Anal. Calcd. for $C_{21}H_{19}N_3O_2$: C, 73.1; H, 5.5; Found: C, 72.9; H, 5.5.

Bis-[2,6-di-(aminomethyl)-pyridine] iron(II) Iodide.—The base XXVI (0.9 g.) was added to a solution of iron(II) sulfate heptahydrate (0.7 g.) in water (10 ml.). After filtration the resulting deep green solution was treated with saturated aqueous potassium iodide solution (5 ml.). The green complex iodide which separated was collected, washed and dried *in vacuo*. It did not melt below 300°.

Anal. Calcd. for $C_{14}H_{22}N_6FeI_2$; C, 28.8; H, 3.8; Fe, 9.6. Found: C, 28.6; H, 3.8; Fe, 9.6.

Allowing aqueous solutions of this salt to stand in air leads to decomposition and iron(III) hydroxide is deposited. The salt has a magnetic moment of 5.24 Bohr magnetons (23°).

Bis-(2,6-(diaminomethyl)-pyridine)-nickel(II) Bromide. (XXVI).—(0.6 g.) was added to a solution of nickel(II) sulfate sexahydrate (0.5 g.) in water (10 ml.). Addition of saturated aqueous potassium bromide solution (5 ml.) to the resulting deep mauve solution caused the complex nickel(II) bromide to separate. It crystallized from hot water in mauve needles which did not melt below 300°.

Anal. Calcd. for $C_{14}H_{22}N_6NiBr_2$: C, 34.1; H, 4.5; Ni, 12.0; Found: C, 33.8; H, 4.6; Ni, 11.7.

Condensation of Pyridine-2,6-dialdehyde with 1,6-Diaminohexane.—The following experiment was typical. A hot solution of pyridine-2,6-dialdehyde (3.5 g., 1 mole) in ethanol (20 ml.) was added to a hot solution of 1,6-diaminohexane (3 g., 1 mole) in ethanol (20 ml.) and the mixture boiled. Within 20 sec. a white solid had separated from the hot solution. It was collected and washed with hot ethanol. It was insoluble in most solvents but did dissolve on warming in dimethylformamide. However, this solution soon redeposited solid, probably because of molecular weight increase due to further condensation. The solid did not melt but decomposed when very strongly heated.

Anal. Calcd. for $(C_{13}H_{17}N_3)_n$: C, 72.6; H, 7.9; Found: C, 72.0; H, 7.9.

Addition of this dried, finely ground white polymer (0.65 g.) to a boiling solution of iron(II) sulfate heptahydrate (1.8 g., excess) in water (25 ml.) caused its transformation to a deep red powder. This was collected and well washed with water. It was insoluble in any of the common solvents.

Anal. Calcd. for $(C_{13}H_{17}N_3)_2 \cdot FeSO_4 \cdot 6H_2O$; C, 45.2; H, 6.7; Fe, 8.1. Found: C, 45.6; H, 6.5; Fe, 8.1.

This solid was found to be ferromagnetic with a molar susceptibility at 24° of 155,000 × 10^{-6} c.g.s. unit.

The finely ground polymer (0.5 g.) was suspended in ethanol (15 ml.) and a solution of cobalt(II) chloride sexahydrate in ethanol (50 ml.) added. The liquid was then gently refluxed. The white polymer gradually changed in color to deep brown but the solution was still a blue color after one hour. The solid polymer was again ground and reheated with the solution which eventually became colorless. The solid was then collected, well washed with ethanol and dried *in vacuo*.

Anal. Calcd. for $C_{13}H_{17}N_3CoCl_2$; C, 45.2; H, 5.0; Co, 14.2. Found: C, 44.9; H, 5.4; Co, 13.8.

The authors gratefully acknowledge their indebtedness to Miss B. Stevenson for all the C, H and N micro-analyses recorded in this paper.

Vinyl Derivatives of the Metals. IV. The Preparation of Vinylgermanium Compounds by the Grignard Method[1]

BY DIETMAR SEYFERTH

RECEIVED JANUARY 17, 1957

The addition of germanium(IV) chloride to vinylmagnesium bromide in tetrahydrofuran solution results in moderate yields of hexavinyldigermane in addition to tetravinylgermane. Diethyldivinylgermane and ethyltrivinylgermane have also been prepared. Hexavinyldigermane is cleaved by bromine and by iodine to give trivinylgermanium bromide and iodide, respectively.

The use of the vinyl Grignard reagent in tetrahydrofuran solution for the preparation of vinyltin compounds[2] and vinylsilanes[3] has been reported recently. In the examples where tin(IV) chloride and tetrachlorosilane were vinylated only tetravinyltin and tetravinylsilane, respectively, were isolated.

We have now investigated the reaction of vinylmagnesium bromide[4] in tetrahydrofuran solution

with germanium(IV) chloride and some ethylgermanium chlorides. Addition of germanium(IV) chloride to a slight excess of this Grignard reagent gave a 26% yield of hexavinyldigermane in addition to a 35% yield of the expected tetravinylgermane. Identification of the former compound was made on the basis of analysis, determination of molecular weight, molar refraction and its conversion to trivinylgermanium iodide by iodine cleavage and trivinylgermanium bromide by means of bromine cleavage

$$(CH_2{=}CH)_3GeGe(CH{=}CH_2)_3 + X_2 \longrightarrow 2(CH_2{=}CH)_3GeX$$

Johnson and Harris[5] have reported that hexaphenyldigermane is similarly obtained in the reaction of an excess of phenylmagnesium bromide with germanium(IV) chloride is an ether–toluene solvent system. No such reductive alkylation of germanium(IV) chloride has been observed with aliphatic Grignard reagents. Johnson and Harris made no attempt to explain their observed reaction, but it is noteworthy that they demonstrated that the phenylation of germanium(IV) chloride can be forced to give tetraphenylgermane exclusively by completely removing the ether and operating at the temperature of the refluxing toluene solution.

In the few years that have elapsed since the work of Johnson and Harris it has become increasingly apparent that the chemistry of germanium presents some anomalies, and that in some cases the reactions of certain germanium compounds do not parallel those of the corresponding silicon and tin compounds. For example, organogermanium halides can be reduced to the hydrides by zinc and hydrochloric acid[6]; this reaction is not observed with the corresponding chlorides of silicon and tin. Also, as Gilman and his co-workers have shown, the reaction of triphenylgermane with alkyllithium compounds results in the formation of triphenylgermyllithium,[7] while triphenylsilane[8] and triphenyltin hydride[9] are alkylated by alkyllithium compounds. These and other differences in the reactions of germanium compounds on one hand, and of silicon and tin compounds on the other, were explained by these and other workers[10] on the basis of a higher electronegativity of germanium, new experimental verification of which has now been provided in this Laboratory by Allred and Rochow.[11] It is interesting to note that such "reductive coupling" as described by Johnson and Harris and by the author of the present study has not been observed in the Grignard alkylation of tetrachlorosilane and tin(IV) chloride with phenylmagnesium and vinylmagnesium bromides, and it is possible that these results similarly could be a direct consequence of the high electronegativity of germanium, and that the reaction proceeds *via* an unstable or poorly stable intermediate containing a Ge–Mg bond. Work in this Laboratory[12] has shown that a germanium Grignard reagent of the type $(CH_3)_3GeMgCl$ does not form when trimethylgermanium chloride is treated with magnesium in diethyl or dibutyl ether in the presence or absence of a catalyst. Other workers[7] have shown that triphenylgermane does not exchange with a Grignard reagent. However, these observations do not preclude the possibility of an unstable $(CH_2{=}CH)_3GeMgBr$ or $(C_6H_5)_3GeMgBr$ intermediate in the "reductive coupling" reaction. Such an intermediate could possibly be formed in an exchange reaction between trivinylgermanium halide and vinylmagnesium bromide, but we consider it more likely that formation of such an intermediate would occur *via* primary reduction of $GeCl_4$ to $GeCl_2$ by the Grignard reagent, followed by vinylation to give divinylgermane(II). The latter could then add vinylmagnesium bromide

$$GeCl_4 + 2CH_2{=}CHMgBr \longrightarrow GeCl_2 + CH_2{=}CH{-}CH{=}CH_2 + MgCl_2 + MgBr_2$$

$$GeCl_2 + 2CH_2{=}CHMgBr \longrightarrow (CH_2{=}CH)_2Ge + MgCl_2 + MgBr_2$$

$$(CH_2{=}CH)_2Ge + CH_2{=}CHMgBr \longrightarrow (CH_2{=}CH)_3GeMgBr$$

$$(CH_2{=}CH)_3GeMgBr + (CH_2{=}CH)_3GeCl \longrightarrow (CH_2{=}CH)_3GeGe(CH{=}CH_2)_3 + {}^1/_2MgCl_2 + {}^1/_2MgBr_2$$

Both the reduction of metal halides to a lower oxidation state by Grignard reagents[13] and the addition of active organometallic reagents to diorganogermane(II) compounds[14] have been reported previously.

The vinylmonogermanes prepared in this study are much more stable with respect to cleavage reactions than are the corresponding vinyltin compounds.[1,15] Thus mercuric chloride in refluxing ether solution caused no cleavage of the vinylgermanium bond and no redistribution reaction was observed on refluxing a mixture of tetravinylgermane and germanium(IV) chloride. These indications that the Ge–C mean bond energy is considerably greater than that of the Sn–C bond in analogous organotin compounds are further borne out by the recently described successful side-chain chlorination of ethylgermanium trichloride.[16] Attempted side-chain chlorination of ethyltin trichloride resulted in Sn–C bond cleavage.[17] Hexavinyldigermane appears to be moderately stable in air, turning from colorless to light yellow in color over a period of several weeks.

Experimental

1. **Diethyldivinylgermane.**—To 0.5 mole of vinylmagnesium bromide in 200 ml. of tetrahydrofuran[18] was added 18 g. (0.089 mole) of diethylgermanium dichloride, dissolved in an equal volume of tetrahydrofuran, at such a rate that a gentle reflux was maintained. The reaction mixture was refluxed for about 20 hours, then was cooled and hydrolyzed with 75 ml. of a saturated aqueous solution of ammonium chloride. The organic layer was decanted and the residual salts were washed with diethyl ether, the washings being added to the decanted liquid. Distillation of the solvents followed by fractional distillation of the residue gave 11.5 g. (70%) of diethyldivinylgermane, b.p. 59–60° at 28.5 mm., $n^{25}D$ 1.4540.

Anal. Calcd. for $C_8H_{16}Ge$: C, 51.99; H, 8.73. Found: C, 52.16; H, 8.80.

2. **Ethyltrivinylgermane.**—A similar procedure was followed in the reaction of 1.0 mole of vinylmagnesium bromide in 300 ml. of tetrahydrofuran with 35.3 g. (0.17 mole) of ethylgermanium trichloride. A 50% yield (15.5 g.) of ethyltrivinylgermane, b.p. 55–57° at 28 mm., $n^{25}D$ 1.4605, was obtained.

Anal. Calcd. for $C_8H_{14}Ge$: C, 52.56; H, 7.72. Found: C, 52.55; H, 7.62.

3. **Tetravinylgermane and Hexavinyldigermane.**—To a solution of 2.0 mole of vinylmagnesium bromide in 800 ml. of tetrahydrofuran was added 95.5 g. (0.445 mole) of germanium(IV) chloride at such a rate that a gentle reflux was maintained. The reaction mixture was then refluxed for about 20 hours. After it had cooled to room temperature the mixture was hydrolyzed with 300 ml. of a saturated aqueous solution of ammonium chloride. The orange organic layer was decanted and the residual salts were washed with ether, the washings being combined with the organic layer. After the solvents had been removed by distillation the brownish liquid residue was fractionally distilled to give: (a) **tetravinylgermane**, b.p. 52–54° at 27 mm., $n^{25}D$ 1.4676, d^{25}_4 1.040; 28.5 g., a yield of 35.4%. *Anal.* Calcd. for $C_8H_{12}Ge$: C, 53.15; H, 6.69. Found: C, 53.00; H, 6.96; (b) a small middle run, boiling from 65° at 23 mm. to 89° at 4.2 mm., which turned grape red on standing in air; (c) **hexavinyldigermane**, b.p. 55° at 0.35 to 0.25 mm., $n^{25}D$ 1.5217, d^{25}_4 1.171; 17.8 g., a yield of 26.1%. *Anal.* Calcd. for $C_{12}H_{18}Ge_2$: Ge, 47.23; C, 46.87; H, 5.90; mol. wt., 307.5. Found: Ge, 47.02; C, 47.00; H, 6.19; mol. wt. (Rast), 318.

The product from another run gave: C, 47.06; H, 6.14. The molar refractions calculated from the data did not check those calculated for any of the other possible higher boiling products such as $(Vi_3Ge)_2O$, Vi_3GeBr, Vi_3GeOH, Vi_3GeBr_3, Vi_2GeCl_2, $(Vi_2GeO)_n$ and others. No direct check was possible since the bond refraction of the Ge–Ge bond is not known. Using the refractive index and density listed above we calculate a value of 6.6 for the Ge–Ge bond refraction, which as expected, lies between the values of the Si–Si and Sn–Sn bond refractions.

4. **Trivinylgermanium Iodide.**—To a solution of 7.2 g. (0.023 mole) of hexavinyldigermane in 30 ml. of diethyl ether were added a few crystals of iodine. The iodine color was not discharged on refluxing the solution for one hour. When most of the ether had been replaced by chloroform the iodine was used up slowly on further heating. The rest of the iodine (5.94 g. total, 0.023 mole) was then added and the solution was refluxed for four hours. The solution at the end of this time was dark in color, but this did not appear to be due to free iodine. The chloroform was boiled off at atmospheric pressure and the dark residue was fractionally distilled to give 6 g. (45.6%) of trivinylgermanium iodide, b.p. 71–74° at 12 mm., and about 1 g. of unreacted digermane. Trivinylgermanium iodide is extremely sensitive to light; the initially colorless distillate rapidly turned reddish pink and darkened further on standing.

Anal. Calcd. for C_6H_9IGe: C, 25.68; H, 3.23; I, 45.22. Found: C, 26.20; H, 3.46; I, 44.84.

5. **Trivinylgermanium Bromide.**—To 10 g. (0.0325 mole) of hexavinyldigermane in chloroform solution was added dropwise a solution of 5.2 g. (0.0325 mole) of bromine in chloroform. The bromine was decolorized immediately in a very vigorous reaction and the solution soon began to reflux. After the addition was completed the solvent was boiled off and the residue was fractionally distilled to give 3.5 g. (23%) of trivinylgermanium bromide, b.p. 58° at 10 mm., $n^{25}D$ 1.5057.

Anal. Calcd. for C_6H_9BrGe: C, 30.84; H, 3.88; Br, 34.21. Found: C, 30.79; H, 3.99; Br, 34.23.

In addition, an unidentified high-boiling fraction distilled continuously from 75° at 6.0 mm. to 93° at 1.4 mm.

Trivinylgermanium bromide had the sharp smell and lachrymatory action normally associated with trialkyltin halides.

6. Analyses were performed by the Schwarzkopf Microanalytical Laboratories, Woodside 77, New York.

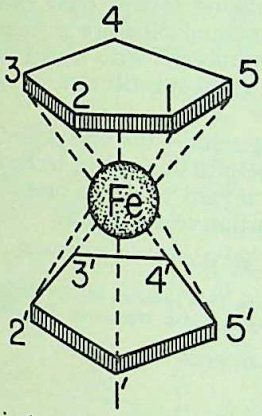
The Dipole Moment of Bis-(*p*-chlorophenylcyclopentadienyl)-iron

BY DOROTHY A. SEMENOW AND JOHN D. ROBERTS[1]

RECEIVED JULY 23, 1956

The dipole moment (3.12 *D*) found for bis-(*p*-chlorophenylcyclopentadienyl)-iron indicates a molecular configuration having the *p*-chlorophenyl groups in rather close proximity to one another.

The sandwich structure[2] for ferrocene[3] is supported by X-ray[3,4-7] and electron[3,8] diffraction, diamagnetic moment,[2] infrared absorption spectrum,[2] dipole moment[2] and chemical properties.[2] In the crystal, the rings occupy fairly fixed positions best described by the antiprismatic sandwich structure (I).[3,4-7] The apparent spreading of the carbon atoms along the circumference of the rings is regarded as being due to a fairly large amplitude of thermal vibration and hindered rotation.[3]



Free rotation is, however, suggested by electron diffraction patterns for ferrocene vapor,[3,8] as well as chemical[2,3] and dipole moment studies[9] of bis-(acetylcyclopentadienyl)-iron and molecular orbital treatments of the ferrocene molecule.[10,11] The dipole moment of a bis-(*p*-chlorophenylcyclopentadienyl)-iron measured in the present investigation provides evidence that, even though the rings may rotate freely, not all possible orientations of a bis-substituted ferrocene are equally probable.

Experimental and Results

The bis-(*p*-chlorophenylcyclopentadienyl)-iron, kindly supplied by Dr. V. Weinmayr of the Jackson Laboratory, E. I. du Pont de Nemours and Co., was prepared by treatment of the ferricinium ion $[Fe(C_5H_5)_2]^{\oplus}$ with *p*-chlorophenyldiazonium ion.[12] The purity of the compound was established by analysis.[12] Assignment of the *p*-chlorophenyl substituents to different rings is supported by the infrared spectrum (of carbon tetrachloride and carbon disulfide solutions) which showed no bands at 9.0 and 9.95 μ characteristic of unsubstituted ferrocenylcyclopentadienyl rings.[3,13,14]

The dipole moment of bis-(*p*-chlorophenylcyclopentadienyl)-iron was measured in benzene solution as described previously[15,16] and evaluated by linear extrapolation of the dielectric constant to zero concentration[17,18] (method I) to be 3.12 ± 0.03 *D*. A value of 2.96 ± 0.13 *D* was obtained by linear extrapolation of molar polarization to zero concentration[19] (method II). Method I is considered to be more reliable because the extrapolated function is linear at low concentrations whereas this is not true for method II.[17,18] The data used for method I are summarized in Table I.

TABLE I

DIPOLE MOMENT DATA FOR BIS-(*p*-CHLOROPHENYLCYCLOPENTADIENYL)-IRON IN BENZENE AT 24.90°

Wt. fract. (w_2)	Sp. vol. (V)	ϵ	$n^{24.9}D$

.030856	1.13171	2.36243	1.50052

$\alpha = \Delta\epsilon/\Delta w_2 = 2.92727$ $\beta = \Delta V/\Delta w_2 = -0.45203$

$MR_D = 109.5 \pm 0.7$ $\mu = 3.12 \pm 0.03$ D.

Discussion of Results

The dipole moments expected for non-freely rotating bis-(*p*-chlorophenyl)-ferrocene structures (see I) and for a freely rotating model were calculated using the following assumptions. (1) Only the C–Cl moments make important contributions to the dipole moment of the molecule—*i.e.*, phenylferrocene would have a very low or zero dipole moment. This assumption is supported by the close agreement between the dipole moments of acetophenone (2.97 *D*)[20] and monoacetylferrocene (3.02 *D*)[9] and the near identity of the first acid ionization constant of ferrocenedicarboxylic acid with that of benzoic acid.[21] These data indicate that the ferro-

cenyl and phenyl groups have comparable electronegativities. (2) The C–Cl axes lie in the planes of the cyclopentadienyl rings to which the *p*-chlorophenyl groups are attached. This orientation of the C–Cl bond is expected if the cyclopentadienyl carbon atoms form the usual aromatic-type sp^2-bonds to substituents. The calculated distance between the cyclopentadienyl rings, 3.6 Å.,[22] is probably large enough to preclude distortion by steric repulsions between substituents on different rings. The vector moment of each C–Cl bond was taken as 1.56 *D*.[23]

The dipole moment for the freely rotating model was calculated using the equation for freely rotating angular groups[9,24] where α and β are the angles ($\alpha = \beta = 90°$) which the moment vectors of the *p*-chlorophenyl groups make with the axes about which they rotate and θ (180°) is the angle between these axes; a and b ($a = b = 1.56$) are the electric moment vectors.

$$\mu = \sqrt{a^2 + b^2 + 2ab \cos \alpha \cos \beta \cos \theta}$$

The dipole moments calculated for the various possible structures of the bis-(*p*-chlorophenyl)-ferrocene are summarized in Table II.

The experimental moment of 3.12 ± 0.03 *D* eliminates a freely rotating model (calculated $\mu = 2.20$ *D*) and is in closest agreement with the moment expected for the 1,1′, prismatic (method I) or 1,1′-antiprismatic (method II) structure. Configurations like these with angles of only 0–36° between the two C–Cl dipole vectors would not be expected to be favored on the basis of dipole–dipole repulsions. However, the tendency for molecules to exist in "*cis*-like" configurations irrespective of such repulsions has been noted in other cases. Thus, the *cis*-configuration of disalicylide is apparently most stable and this has been attributed to resonance involving the lactone bridge.[25] An analogous preference for a *cis*-like "boat" configuration as the most stable form of 1,6-dichloro-1,5-cycloöctadiene has been explained by operation of secondary valence forces,[26] possibly dispersion forces. Such valence forces may also account for why bis-di-(*p*-chlorophenyl)-ferrocene appears to exist in a configuration with the *p*-chlorophenyl groups quite close to one another. A similar conclusion was reached by Hampson and Weissburger[27] with regard to the orientations of the *ortho*-substituents in *o,o*′-dichlorobiphenyl.

TABLE II

DIPOLE MOMENTS CALCULATED FOR DI-(*p*-CHLOROPHENYL)-FERROCENE STRUCTURES

Structure (see I)	Dipole moment, *D*
1,1′, prismatic	3.12
1,1′, antiprismatic	2.97
1,2′, antiprismatic	1.83
1,3′, antiprismatic	0
Freely rotating cyclopentadienyl rings	2.20

Acknowledgment.—We are pleased to acknowledge several helpful suggestions by Prof. Myron Rosenblum with regard to dipole moment calculations and interpretation of the results.

(22) The value of 3.6 Å. is obtained using a value of 1.4 Å. for the C–C ring distance and 2.0 Å. for the C–Fe distance.[5,6,7]

Studies in the Ferrocene Series. I. Some Reactions of Compounds Related to Monobenzoylferrocene[1]

BY NORMAN WELIKY AND EDWIN S. GOULD

RECEIVED OCTOBER 24, 1956

The ketones benzoylferrocene (I) and anisoylferrocene and several diketones have been made from ferrocene (dicyclopentadienyliron) by Friedel–Crafts acylations. Benzoylferrocene is reduced to the pinacol, 1,2-diphenyl,1,2-diferrocenylethanediol (IV), with methylmagnesium bromide in the presence of cobalt chloride; the same ketone is reduced to phenylferrocenylmethanol (II) with lithium aluminum hydride, to phenylferrocenylmethane (X) with zinc, sodium or aluminum and to still another carbinol, probably phenyldiferrocenylmethanol (IX), with sodium amalgam in benzene. The pinacol rearranges with extraordinary ease, with migration of the ferrocene moiety, and is surprisingly easily oxidized to the parent ketone by atmospheric oxygen. The secondary alcohol, phenylferrocenylmethanol, forms ethers under exceptionally mild conditions and behaves somewhat like a tertiary alcohol. These reactions suggest that a carbonium ion obtained by removal of an –OH group alpha to the ferrocene system is subject to special stabilization, possibly by dispersal of the positive charge through partial shift of *d*-electron density from the iron atom into the ring. The oxime of benzoylferrocene (VII) rearranges, through its tosylate, to the anilide of ferrocenecarboxylic acid (VIII).

The easy preparation and purification of benzoylferrocene allows the synthesis and study of a number of relatively simple compounds in which the benzene ring and the ferrocene system are attached to a common carbon atom. Chart I summarizes the transformations which we have carried out.

Acylations.—By suitable variations of reaction conditions, the Friedel–Crafts acylation of ferro-

(1) Based on research carried out under Contract No. DA 30-069-ORD-1137, Project No. TB2-0001 (836), between the U. S. Army, Ordnance Department, and the Polytechnic Institute of Brooklyn.

cene may be made to yield either mono- or diketones as major products.[2] Benzoylferrocene (but no appreciable quantity of dibenzoylferrocene) is obtained from the acylation of ferrocene if equivalent quantities of ferrocene and aluminum halides are used. Since ferrocene reacts with aluminum halides (in a manner which is not yet clear), to form colored products, our most successful preparations of benzoylferrocene (I) and anisoylferrocene were carried out by slow addition of a "Perrier complex"[3] of the acid chloride and aluminum halide to ferrocene solutions.

Reductions of Benzoylferrocene.—Six different products resulting from the reduction of benzoylferrocene with various reagents have been characterized; in addition to these, several reduction products remain unidentified. Reduction with lithium aluminum hydride yields the expected secondary alcohol, phenylferrocenylmethanol (II), which is also formed in small yield from reduction with sodium. This carbinol has an unusually labile hydroxyl group since it is converted to its methyl ether (III, R = CH_3) merely on boiling with aqueous methanol. Similarly, the isopropyl ether results from the reduction of benzoylferrocene with aluminum isopropoxide in isopropyl alcohol, a situation bringing to mind the similar behavior of certain α,β-unsaturated ketones.[4]

The usual methods for bimolecular reduction of ketones to pinacols did not work when applied to benzoylferrocene. No reaction occurred when a solution of the ketone in isopropyl alcohol was irradiated in sunlight for a month,[5] whereas reduction with magnesium–magnesium iodide[6] yielded unidentified products. Among the less conventional bimolecular reduction methods attempted, the most successful was that of Kharasch and Lambert[7] using methylmagnesium bromide and cobalt(II) chloride. The pinacol IV thus obtained rearranged with remarkable ease (merely upon passing gaseous HCl over its solution in benzene) to the pinacolone V. The structure of the latter is indicated by its degradation in base to phenyldiferrocenylmethane (VI) and benzoate.

The pinacolone V is also formed as a minor product in the Clemmensen reduction of benzoylferrocene; the pinacol, which would be expected to rearrange immediately under Clemmensen conditions, is probably an intermediate here. The chief product from the Clemmensen reduction is the expected desoxo compound, phenylferrocenylmethane (X).

Reduction with sodium amalgam yields an additional alcohol which may be reduced further with zinc to VI. This evidence, together with its analysis, suggests that the alcohol is phenyldiferrocenylmethanol (IX), although it is difficult to see how such a product would arise from reduction of benzoylferrocene. This alcohol, like phenylferrocenylmethanol (II), is converted to its methyl ether merely on heating with methanol.

The exceptional ease with which carbinols II and IX are converted to their ethers and the very mild conditions under which the pinacol IV rearranges suggest that the presence of the ferrocene system in the position alpha to a hydroxyl group lowers the energy barrier to conversion of the carbinol to the corresponding carbonium ion. It does

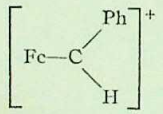
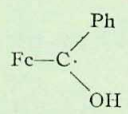
not seem probable that the presence of a single phenyl group and a single ferrocenyl group on a carbon atom would result in enough steric crowding to account for this effect. We suggest rather that a carbonium ion such as XI is stabilized by an unusual ability of the ferrocene system to delocalize the positive charge, possibly through a partial shift of *d*-electron density from the iron atom into the ring.

Equally remarkable is the ease with which the pinacol IV is converted back to benzoylferrocene upon exposure to air. This conversion takes place in polar solvents and in the presence of alumina or silica gel. The pinacol is most stable in the solid state (if protected from air) or in solutions of carbon disulfide or benzene. Very dilute solutions in the latter solvent show a drift in spectra; for a 0.0003 *M* solution, conversion to benzoylferrocene is over 80% complete after 4 days standing. Disproportionation, as is sometimes observed for basic solutions of pinacols,[8] evidently does not occur, for no phenylferrocenylmethanol (II) could be detected in solutions in which the pinacol had been converted to the ketone, even under conditions where the carbinol should survive. Little more can be said about this oxidation[9] on the basis of the present observations, but the possibility that it proceeds through small concentrations of the radical XII (which might be stabilized in much the same manner as carbonium ion XI) cannot, in our opinion, be excluded.



XI



XII

The Beckmann Rearrangement.—The oxime of benzoylferrocene (VII) does not react cleanly under the usual acidic Beckmann rearrangement conditions, but its *p*-toluenesulfonate rearranges in base to ferrocenecarboxanilide (VIII). Although this amide could not be hydrolyzed, either by acid or base, its identity was proved by synthesis from ferrocene and phenyl isocyanate. The structure of the amide indicates either that the phenyl group is *anti*- to the hydroxyl group of the oxime or (less likely) that the oxime is isomerized during the course of the rearrangement. Since the course of both the Beckmann[10] and pinacol[11] rearrangements are thought to be dictated largely by the configurations of the reactants, conclusions about the relative "migratory aptitudes" of the ferrocene system and the benzene ring cannot be drawn.

(9) Similar oxidations of fluorenopinacol and xanthopinacol to the corresponding ketones have been reported by C. R. Masson, V. Boekelheide and W. A. Noyes, Jr., "The Technique of Organic Chemistry," Vol. II, Arnold Weissberger, Editor, Interscience Publishers, Inc., New York, N. Y., 1956, p. 316.

(10) J. Meisenheimer, P. Zimmermann and U. v. Kummer, *Ann.*, **446**, 205 (1926).

(11) The conclusions of Curtin and co-workers, THIS JOURNAL, **73**, 3453 (1951), **74**, 5905 (1952), with regard to pinacolic deaminations and rearrangements of aryl-substituted bromohydrins probably may be applied also to the pinacol rearrangement since the three types of rearrangements are thought to proceed through similar transition states.

Experimental

Benzoylferrocene (I).—A Perrier complex[8] was prepared from 42 g. of benzoyl chloride and 42 g. of anhydrous aluminum chloride. This was dissolved in carbon disulfide and added, over a period of 0.5 hr., to a warm solution of 55 g. of ferrocene in 180 ml. of carbon disulfide. After 20 hr., the mixture was hydrolyzed, worked up in the usual manner and chromatographed on alumina. Red crystals (56 g., 67%) were obtained by crystallization from hexane; m.p. 108–109° (reported[12] 111.5–112.0°).

Anal. Calcd. for $C_{17}H_{14}OFe$: C, 70.35; H, 4.83; Fe, 19.3. Found: C, 70.38; H, 4.92; Fe, 19.0.

The infrared carbonyl band was at 1634 and phenyl absorption at 1458, 1588 and 1605 cm.$^{-1}$. Absorption of an unsubstituted ferrocene ring was at 1108 cm.$^{-1}$. Visible and ultraviolet peaks in alcohol were at 245 (ϵ 14,900), 274 (shoulder, ϵ 7,930), 362 (ϵ 1,230) and 478 mμ (ϵ 696).

Anisoylferrocene.—To 15 g. of anhydrous aluminum bromide in 70 ml. of carbon disulfide at 0° was added slowly 9.3 g. of anisoyl chloride. The resulting mixture was added slowly, with cooling, to 10 g. of ferrocene in 50 ml. of carbon disulfide. After 4 hr., the mixture was hydrolyzed and worked up in the usual manner. Chromatography on alumina yielded 4.5 g. (26%) of blood-red crystals. The product was purified further by sublimation at reduced pressure, a second chromatographic separation and, finally, crystallization from methanol–water. The yield of pure product (m.p. 82–83°) was 4.0 g. (23%).

Anal. Calcd. for $C_{18}H_{16}O_2Fe$: C, 67.50; H, 5.00. Found: C, 67.48; H, 4.97.

The infrared spectrum showed carbonyl absorption at 1612, phenyl absorption at 1515 and 1578 and absorption of unsubstituted ferrocene rings at 1110 cm.$^{-1}$.

Visible and ultraviolet absorption maxima were at 223, 284 and 477 mμ.

Anisic acid did not react with ferrocene in anhydrous hydrogen fluoride.

Benzoylferrocene oxime (VII) was prepared in pyridine[13] from 2.0 g. of benzoylferrocene. The heating period was only 2 hr. The residue was extracted with benzene and crystallization induced by adding hexane. One gram of dark red-brown crystals (48%) was obtained, m.p. 164–169° dec. A portion chromatographed on alumina and crystallized from benzene–hexane yielded orange-red needles, m.p. 158–159° (foamed), reported[12] 160° dec.

Anal. Calcd. for $C_{17}H_{15}ONFe$: C, 66.89; H, 4.91; N, 4.59. Found: C, 67.13; H, 4.82; N, 4.57.

The infrared spectrum indicated the absence of carbonyl groups. Hydroxyl absorption was at 3190, phenyl absorption at 1498, 1580 and 1600 and absorption of unsubstituted ferrocene rings at 1106 cm.$^{-1}$.

Beckmann Rearrangement of Monobenzoylferrocene Oxime.—Monobenzoylferrocene oxime (1 g.) was rearranged through its benzenesulfonyl ester by the method of Brown, Van Gulick and Schmid.[14] A benzene solution of the products was chromatographed on alumina, yielding 0.23 g. of cotton-like yellow needles, m.p. 208–210°.

Anal. Calcd. for $C_{17}H_{15}ONFe$: C, 66.89; H, 4.91; N, 4.59. Found: C, 67.81; H, 4.88; N, 4.58.[15]

The infrared amide bands were at 3280 (N–H), 1643, 1526 cm.$^{-1}$. Phenyl absorption was at 1500 and 1600 and unsubstituted ferrocene ring absorption at 1106 cm.$^{-1}$. The infrared spectrum of this amide was found to be identical to the infrared spectrum of the amide obtained from the reaction of phenyl isocyanate with ferrocene. Visible and ultraviolet maxima were at 245, 271 and 447 mμ in alcohol and chloroform.

Anilide of Ferrocenecarboxylic Acid.—To 5.0 g. of ferrocene and 2.9 g. of phenyl isocyanate in 100 ml. of carbon di-

sulfide, 3.7 g. of anhydrous aluminum chloride was added in portions, while agitating the solution. The mixture was stirred 1 hr., refluxed 1 hr., then left overnight. The carbon disulfide was decanted. The oily residue and the carbon disulfide solution were hydrolyzed and acidified separately and the carbon disulfide removed by evaporation. The solid residues were washed with water and extracted with hexane to remove unreacted ferrocene. The residues were then extracted, first with benzene, then with chloroform. A yield of 2.1 g. (25% over-all, 60% based on ferrocene not recovered) of yellow-brown needles was obtained by crystallization of the extracted material from benzene. By repeated crystallization from isopropyl alcohol, cotton-like yellow needles were obtained, m.p. 205–207°.

The infrared spectrum of this substance was identical to the spectrum of the Beckmann rearrangement product of benzoylferrocene oxime. Evaporation of the hexane left 2.8 g. (57%) of ferrocene.

1,2-Diphenyl-1,2-diferrocenyl-ethanediol.[7]—Methylmagnesium bromide was prepared by passing methyl bromide through a mixture of 0.65 g. of magnesium and 10 ml. of anhydrous ether. Under an atmosphere of nitrogen, 70 mg. of anhydrous powdered cobalt(II) chloride was added to the solution at 0°. Then 2 g. of monobenzoylferrocene in 15 ml. of benzene was added dropwise. The mixture was stirred for 1.5 hr., refluxed 2.5 hr. and stirred 0.75 hr. While a nitrogen atmosphere was maintained, 30 ml. of a saturated aqueous solution of ammonium chloride was added dropwise. The mixture was transferred to a separatory funnel, washing the reaction flask with water and a minimum of ether. The remaining solid and organic layer were extracted with portions of ammonium chloride solution till almost all the dark suspended material changed to a pale yellow solid floating at the lower interface of the organic layer. The yellow solid was washed with water, dried in the air and recrystallized from benzene under nitrogen; yield 0.76 g. (38%), m.p. 125–145° dec.

Anal. Calcd. for $C_{34}H_{30}O_2Fe_2$: C, 70.10; H, 5.15; active H, 0.34. Found: C, 69.61; H, 5.15; active H, 0.36 (lithium aluminum hydride).

The infrared spectrum showed hydroxyl absorption at 3510, phenyl absorption at 1492, 1585 and 1620 and absorption due to unsubstituted ferrocene rings at 1106 cm.$^{-1}$. Carbonyl absorption was absent.

The visible absorption spectrum in benzene showed a maximum near 445 mμ (ε 281). The compound does not dissolve in alcohols or paraffinic solvents.

Solutions of the compound in benzene and carbon disulfide were yellow. In chloroform, dioxane or alcohol–benzene, the solutions rapidly turned red. Chromatography on alumina converted the pinacol to red crystals whose infrared spectrum showed bands characteristic of both the pinacol and benzoylferrocene. Recrystallization yielded a product whose infrared spectrum was identical to that of benzoylferrocene. The same conversion took place very slowly in benzene solution and was studied by measuring the increase in absorption at 362 mμ, the wave length at which benzoylferrocene shows a maximum but the pinacol shows a minimum. At the end of 4 days, a dilute solution of the pinacol in benzene (0.150 g./liter) was 80% converted to benzoylferrocene.

A sample of 20 mg. of the pinacol was dissolved in 5 ml. of benzene. Hydrogen chloride gas was led over the surface for 2 min. The test-tube was stoppered and allowed to stand three days. The benzene was decanted from a green oil and chromatographed on alumina. Development of the chromatogram with hexane yielded 5 mg. of benzoylferrocene and about 4 mg. of orange crystals, m.p. 211° dec. The infrared spectrum of the latter was identical to that of phenylbenzoyldiferrocenylmethane (V).

Phenylbenzoyldiferrocenylmethane (V).—Benzoylferrocene (0.3 g.) was reduced in 1 ml. of absolute alcohol with 0.6 g. of amalgamated zinc.[16] Alcoholic hydrogen chloride (2 ml.) was added over 30 minutes. The solution was heated for 1 hr. at 100° and allowed to stand overnight. The solution was diluted with benzene. Chromatography with benzene–hexane on alumina yielded two solids, the first an unidentified orange substance, m.p. 211° dec., the second the pinacolone V. Of the latter, 100 mg. (33%) was obtained, m.p. 195–198° dec. Infrared carbonyl absorption was at 1680, phenyl absorption at 1492, 1586 and 1600 and absorption of unsubstituted ferrocene rings at 1108 cm.$^{-1}$.

Anal. Calcd. for $C_{34}H_{28}OFe_2$: C, 72.34; H, 4.97. Found: C, 72.16; H, 5.26.

Phenyldiferrocenylmethane (VI).—A 20-mg. sample of the pinacolone V was heated at 100° for 24 hr. in 5% alcoholic potassium hydroxide. The solvent was evaporated to a low volume, extracted with water and filtered. The filtrate was extracted with ether and the ether extracts, in turn, extracted with $NaHCO_3$ solution. The bicarbonate solution was then acidified and re-extracted with ether and the ether then evaporated off. The gray-white solid which remained was sublimed to give a product, m.p. 110–115°. The X-ray powder photograph of this material was identical to that of benzoic acid. The residue from the original basic mixture was dissolved in hexane and chromatographed. In addition to a small amount of the original pinacolone, there was obtained about 10 mg. of phenyldiferrocenylmethane, m.p. 123–124° (from ethanol–water); infrared peaks were at 1106, 1492, 1586 and 1670 cm.$^{-1}$.

Anal. Calcd. for $C_{27}H_{24}Fe_2$: C, 7035; H, 5.22. Found: C, 70.14; H, 5.28.

Phenylferrocenylmethane (X).—To a solution of 0.5 g. of benzoylferrocene in 5 ml. of acetic acid was added 5 g. of zinc dust. The mixture was swirled and became viscous. Three 5-ml. portions of acetic acid were added, and the mixture was allowed to stand. After 3 hr., an additional 17 ml. of acetic acid and 1 ml. of concentrated hydrochloric acid were added. After 18 hr., an additional 5 g. of zinc dust was added, then 10 ml. more of concentrated hydrochloric acid. The red color disappeared from solution. The mixture was diluted with water and filtered, whereupon the major part of the colored material was precipitated on the surface of the zinc dust. The solid was extracted with benzene and the benzene extracts chromatographed on alumina. In addition to an unidentified solid, m.p. 218° dec., and a small amount of pinacolone V, there was obtained 0.13 g. (27%) of the desired hydrocarbon, m.p. 70–74° (from low boiling petroleum ether), λ_{max} at 440 mμ, and infrared peaks at 1105, 1497, 1560, 1588, 2920 and 2980 cm.$^{-1}$.

Anal. Calcd. for $C_{17}H_{16}Fe$: C, 73.91; H, 5.79; mol. wt., 276. Found: C, 74.07; H, 5.36; mol. wt., 277 (isothermal distillation).

Phenylferrocenylmethanol (II).—To a solution of 6 g. of lithium aluminum hydride in 150 ml. of anhydrous ether was added a solution of 10 g. of benzoylferrocene in 600 ml. of anhydrous ether. Stirring was continued for 2 hr. After 20 hr., the mixture was hydrolyzed and the ether decanted from the solids. On evaporation of the ether, a yield of 9.6 g. (96%) of phenylferrocenylcarbinol was obtained, m.p. 81–82° (from low boiling petroleum ether); infrared absorption peaks were at 3470 (OH), 1500, 1560 and 1106 cm.$^{-1}$.

Anal. Calcd. for $C_{17}H_{16}OFe$: C, 69.86; H, 5.48; mol. wt., 291. Found: C, 69.82; H, 5.32; mol. wt., 253 (isothermal distillation).

An attempt to convert this carbinol to the corresponding bromide with PBr_3 led instead to a product believed to be **di-(phenylferrocenylmethyl) ether** (which could be made also by treatment of the carbinol with *p*-toluenesulfonyl chloride). The carbinol (0.7 g.) was dissolved in 2 ml. of dry pyridine, the solution cooled to 0°, 0.2 g. of phosphorus tribromide added dropwise and cooling continued for 1.5 hr. After two days, the solvent was evaporated off and the oil dissolved in chloroform. The white solid was removed by adding benzene, then boiling to a low volume and adding hexane. Chromatography of the filtrate yielded a very small quantity of an unidentified substance, m.p. 110–112°, and about 20 mg. of the *sym*-ether, m.p. 52–56°.

Anal. Calcd. for $C_{34}H_{30}OFe_2$: C, 72.09; H, 5.29; mol. wt., 566. Found: C, 71.72; H, 6.21; mol. wt., (Rast), 508.

The infrared spectrum showed phenyl absorption at 1492, 1588 and 1610, absorption of unsubstituted ferrocene rings at 1104 and a strong ether absorption at 1097 cm.$^{-1}$.

On boiling phenylferrocenylcarbinol in a solution of methanol and water, and crystallization from these solvents, yellow crystals were obtained, m.p. 104–108°. After rechromatographing on alumina in hexane and recrystallizing the first yellow band eluted from methanol–water, the

methyl ether of phenylferrocenylmethanol (III, R = CH_3) was obtained, m.p. 111–112°.

Anal. Calcd. for $C_{18}H_{18}OFe$: C, 70.59; H, 5.88; active H, 0.0. Found: C, 70.26; H, 5.20; active H, 0.0.

The infrared spectrum showed absorption of aliphatic C–H at 2880, 2930 and 2970, phenyl absorption at 1492 and 1559, absorption of unsubstituted ferrocene rings at 1104 and very strong ether absorption at 1063 cm.$^{-1}$.

Isopropyl Ether of Phenylferrocenylmethanol (III, R = *i*-Pr–).—Benzoylferrocene (1 g.) was reduced by the method of Meerwein–Ponndorf–Verley.[17] The hydrolyzed reaction mixture was extracted with benzene, the solvent removed and the mixture extracted with Skellysolve B and chromatographed on alumina with methanol. In addition to a small amount of the methyl ether of phenylferrocenylmethanol, there was isolated 0.35 g. (33%) of yellow crystals of the isopropyl ether, m.p. 74–75°.

Anal. Calcd. for $C_{20}H_{21}OFe$: C, 72.07; H, 6.31. Found: C, 71.24; H, 6.81.

The infrared spectrum showed absorption in the aliphatic C–H region at 2880, 2930 and 2970, phenyl absorption at 1492, 1540 and 1559, absorption of unsubstituted ferrocene rings at 1104 and very strong ether absorption at 1063 cm.$^{-1}$.

Like the carbinol and the methyl ether, the isopropyl ether is soluble in concentrated hydrochloric acid.

Reduction of Monobenzoylferrocene by Sodium.—To 0.25 g. of monobenzoylferrocene in 3 ml. of benzene was added 2.5 g. of 5% sodium amalgam. The mixture was refluxed 2 hr., poured into water and filtered. The organic layer was washed, dried and chromatographed on alumina. Evaporation of solvent from the eluted yellow band, just preceding the large red band of unreacted monobenzoylferrocene, left 35 mg. of orange yellow powder, 150–170° dec. (180–185° red droplets). This substance is believed to be phenyldiferrocenylmethanol (IX). Infrared absorption was found at 3520 (OH), 1492 and 1600 (phenyl) and 1107 cm.$^{-1}$ (ferrocenyl).

Anal. Calcd. for $C_{27}H_{24}OFe_2$: C, 68.05; H, 5.04; active H, 0.21. Found: C, 68.44; H, 5.11; active H, 0.36.

This compound was dissolved in 95% ethanol by refluxing for 15 min. Excess zinc dust was added, then alternately, small amounts of hydrochloric acid and zinc dust till most of the color was gone from the solution. The mixture was filtered, washed, dried, extracted with benzene and the solvent evaporated. The residue was extracted with hexane and chromatographed on alumina in that solvent, yielding a yellow solid with an infrared spectrum identical to that of phenyldiferrocenylmethane (VI).

A 30-mg. sample of the hydroxy compound was refluxed with methanol for 7.5 hr. Evaporation of the methanol yielded crystals which were purified by chromatography on alumina. The resulting product 28 mg., m.p. 158° dec., is presumably the methyl ether of IX. Its infrared spectra showed peaks at 2920, 2820, 1554, 1494, 1106 and a high absorption, indicative of ethers, at 1076 cm.$^{-1}$.

Anal. Calcd. for $C_{28}H_{26}OFe_2$: C, 68.55; H, 5.31. Found: C, 69.41; H, 5.59.

Reductive Cleavage of Ferrocene[1]

BY DANIEL S. TRIFAN AND LOUIS NICHOLAS

RECEIVED JULY 25, 1956

In contrast to the extreme resistance of ferrocene to catalytic reduction, this aromatic ring system is reduced readily by lithium in ethylamine with cleavage of the molecule to metallic iron and cyclopentadiene. The reaction of lithium with ferrocene in ethylamine is very rapid and may be stopped after several minutes with good conversion. Qualitative experiments have ascertained that other metal-amine, ammonia combinations also similarly reduce ferrocene.

No method has yet been described for a mild controlled degradation of the ferrocene ring system (bis-cyclopentadienyl iron, $Fe(C_5H_5)_2$) suitable for structure assignments for isomeric substituted ferrocenes. In this investigation a convenient degradation procedure was sought which would effect cleavage of the ferrocene molecule into its component parts and permit separate examination of each of the resulting 5-carbon rings.

The catalytic hydrogenation route to dearomatization and collapse of the ferrocene molecule appears to be unsuccessful. The resistance of ferrocene to catalytic hydrogenation over platinum has been reported by Woodward, Rosenblum and Whiting.[2] Our own attempts to hydrogenate ferrocene using the more active 5% rhodium-on-alumina in acetic acid for periods up to several weeks have given similar negative results. Under these same conditions benzene is completely hydrogenated in 5 minutes. Fischer[3] also has reported failure to hydrogenate ferrocene with Raney nickel in alcohol at 150° and 150 atmospheres.[4]

As a means of transferring an electron to the ferrocene nucleus to dearomatize the molecule, the use of alkali metals was investigated. Lithium does not attack ferrocene in refluxing ether, benzene or toluene, although attack does occur at *ca.* 200° in mineral oil with formation of metallic iron. In contrast to these slow heterogeneous reactions, however, rapid cleavage of the ferrocene molecule into metallic iron and cyclopentadiene is obtained by use of lithium in ethylamine, the amine functioning as solvent for lithium atoms. This reducing system has been investigated by Benkeser and co-workers in connection with benzenoid aromatic compounds.[5]

June 5, 1957

A series of qualitative experiments summarized in Table I has been carried out to indicate the generality of ferrocene reduction by other alkali and alkaline earth metal-amine, ammonia combinations. The progress of the reaction was followed by the rate of reflux and the appearance of black metallic iron. Rates are substantially lower with sodium than with lithium, and lower in *n*-hexylamine than in ethylamine. Calcium–amine combinations give no reaction. In liquid ammonia, however, reductions with calcium, lithium and sodium are all vigorous. The lithium–ethylamine combination appears to be the most convenient and has therefore been selected for use in quantitative studies.

TABLE I

QUALITATIVE RATES OF REDUCTION OF FERROCENE

Metal	Amine	Description of initial reaction
Li	Ethylamine	Vigorous reaction, black iron
Na	Ethylamine	Gradual appearance of black iron; much slower than Li
Ca	Ethylamine	No reaction
Mg	Ethylamine	No reaction
Li	*n*-Hexylamine	Gradual appearance of black iron; slower than Na–ethylamine
Na	*n*-Hexylamine	Some darkening only after *ca.* 0.5 hr.
Ca	*n*-Hexylamine	No reaction even at b.p.
Li	Liq. NH_3	Vigorous reaction, black iron
Na	Liq. NH_3	Vigorous reaction, black iron
Ca	Liq. NH_3	Very vigorous reaction, black iron
Mg	Liq. NH_3	No reaction

When these results are compared with data on the reaction of sodium with various aromatic hydrocarbons, it may be estimated that in the series of aromatic compounds of increasing electron affinity: benzene << phenanthrene < naphthalene < anthracene, etc.,[6] ferrocene is closer to benzene than to other members of this series, although in view of the very much more rapid reaction of lithium–ethylamine with ferrocene than with benzene it would seem to be higher. Reaction periods of 8–10 hours are employed for the latter[4] while reductions of ferrocene give good conversions in a few minutes.

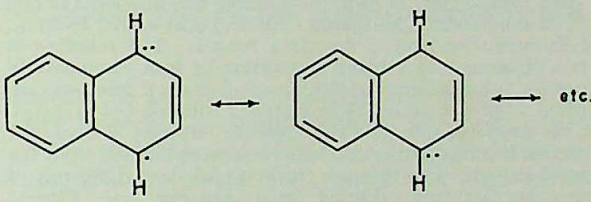
A typical ferrocene reduction using lithium in ethylamine for a period of 4–6 minutes resulted in reduction of 73% of the initial ferrocene. The cyclopentadiene was isolated both by distillation (53%) and by its adduct with maleic anhydride (71%).

A reductive cleavage of ferrocene using the calcium–ammonia reducing system[7] in ether was also carried out for comparison purposes and a 30% yield of cyclopentadiene, corrected for recovered ferrocene, was obtained as the maleic anhydride adduct. This procedure is much less convenient than that using lithium–ethylamine and no attempt was made to improve this yield.

The elemental iron produced in these ferrocene reduction reactions is very finely divided and when allowed to dry in air spontaneously oxidizes to a mixture of oxides. The yield of iron (98%) was therefore determined by solution in dilute sulfuric acid and titration of ferrous ion. In a semi-quantitative run designed to verify the elemental state of the initial iron product, the volume of hydrogen produced from the acidification of the reaction mixture corresponded roughly to that calculated from the amount of ferrocene reduced.[8]

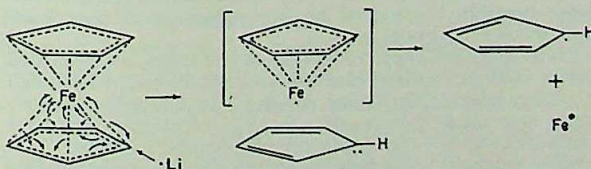
The finely divided iron obtained from a single run with sodium–ethylamine was pyrophoric and more reactive than that from lithium–ethylamine, probably because of a larger amount of adsorbed hydrogen in the former case due to the more rapid rate of hydrogen evolution.

The cleavage reaction proceeds by attack of lithium on carbon with transfer of an electron. Attack on the ferrocene aromatic system has different consequences from the parallel attack on benzenoid aromatic systems. In the latter case the π-electrons are displaced to give resonance-stabilized negative ion free radicals,[5] *e.g.*, I, with no consequent molecular rupture.



I

Similarly, it seems reasonable to suggest that in the analogous instance of the attack of lithium on one of the 5-carbon rings of ferrocene, the π-electrons are displaced to the conjugated double bond orbitals, or more precisely directly to the resonance hybrid orbitals, of the cyclopentadienide ion with resulting detachment from the iron atom. The remaining radical fragment presumably separates into free iron and cyclopentadienyl radical, which in turn may abstract hydrogen from solvent or an electron from lithium.



It is interesting to note that the mass spectrograms of ferrocene[9] and ferrocene derivatives[10] exhibit a very strong peak at mass number 121, corresponding to the C_5H_5Fe fragment, which may be interpreted as evidence of some appreciable degree of stability of this cyclopentadienyl–iron entity.

The instability of the $[(C_5H_5)Fe(C_5H_5)]^-$ anion may be contrasted with the stability of the $[(C_5H_5)Fe(C_5H_5)R]^+$ cation which presumably is an intermediate in the Friedel–Crafts acylation reac-

tion. It may also be mentioned that the $[(C_5H_5)Fe(C_5H_4)]^-$ anion, which readily is obtained[11,12] by exchange reaction with, *e.g.*, *n*-butyllithium, is an obviously stable system since the π-electrons are not involved, and may be utilized in synthesis of corresponding ferrocene derivatives.

This reductive cleavage reaction should prove general for analogous metallocene systems. In addition to degradative structure applications, the reaction also provides a novel approach to the preparation of certain substituted cyclopentadienes from the correspondingly substituted ferrocene derivatives. Some experiments directed toward this end are currently in progress.

Experimental

Ferrocene Reduction with Lithium in Ethylamine.—Ferrocene cleavage runs were conducted in flasks with an 8 mm. bore stopcock at the bottom. Lithium wire (2 mm. diam.) was freshly extruded into the flask containing anhydrous ether which was drained through the stopcock just before the reaction was started. The flask was fitted with stirrer and a large capacity Dry Ice reflux condenser.

In a typical run, 29.39 g. of ferrocene was dissolved in 500 ml. of ethylamine (Matheson cylinder) and added to 21 g. of lithium wire from a dropping funnel. The reaction is very vigorous and a black suspension of iron immediately appears. A minimum addition period of *ca.* 2 min. was required to prevent flooding and after a total of 4–6 minutes, at the end of which time the vigorous refluxing abates, the reaction mixture and ethylamine rinse were drained from the excess lithium wire through the stopcock into 1500 ml. of ice–water mixture, diluted with benzene and filtered through Celite to remove iron. The aqueous phase was separated and extracted with numerous portions of benzene, followed by thorough washing of the benzene phase with water to remove ethylamine. The benzene solution was dried with magnesium sulfate and refluxed with 26.3 g. of maleic anhydride overnight. After the solution was concentrated and evaporated to dryness, the Diels–Alder adduct and excess maleic anhydride were hydrolyzed and extracted from unreduced ferrocene by treatment with portions of hot water. Fractional crystallization of the adduct acid, *endo-cis*-bicyclo[2,2,1]-5-heptene-2,3-dicarboxylic acid, from water yielded 25.78 g. (71% based on ferrocene reduced), m.p. 177.5–179°, lit.[13] 177–179°, mixed m.p. undepressed. A control run using cyclopentadiene and the same extraction and work-up procedure gave no better recovery.

A similar reduction was carried out using a reaction period of 6.5 hours during which time almost all of the lithium wire dissolved. However, only 32.8% (12.19 g.) of the theoretical amount of adduct acid was obtained under these conditions, possibly because of further reduction of the cyclopentadiene initial product.[4]

From a typical rapid reduction of ferrocene, as described above, cyclopentadiene also was isolated directly, although in poorer yield. Ferrocene (37.2 g.) in 300 ml. of ethylamine was allowed to react with 18 g. of lithium strips for 3 minutes and the black mixture was poured into ice. The volatile material was condensed into receivers cooled in Dry Ice at aspirator pressure and distilled. A hydrocarbon layer was separated from ethylamine by addition of water to several combined fractions and dried over $CaSO_4$ (11.2 g. of cyclopentadiene, 53% corrected for 7.4 g. of recovered ferrocene). The cyclopentadiene was identified as the maleic anhydride adduct, a 1.0-g. sample yielding 1.8 g. (72%) of the crude adduct, m.p. 161–163.5° unrecrystallized, lit.[11] 164–165°.

Delayed addition of the ferrocene after the lithium has entirely reacted with the ethylamine results in complete recovery of the ferrocene.

Characterization of Iron from Ferrocene Reductions.—Because of the spontaneous oxidation of the finely divided iron when dry, the yield of iron obtained from a ferrocene reduction was determined by adding the product of a reaction to a mixture of dilute sulfuric acid and ice. Titration of the aqueous phase with 0.1 *N* $KMnO_4$, after extraction with CCl_4 to remove cyclopentadiene, indicated 98% of the theoretical amount of ferrous ion.

The elementary state of the iron was verified by a semi-quantitative determination of hydrogen evolved from acidification of a reaction mixture.[7] The product from a typical reduction was transferred to an empty flask and most of the ethylamine swept out in a stream of helium. Dilute sulfuric acid was then added through a dropping funnel and the hydrogen collected in an inverted graduate, the estimated corrected volume corresponding to *ca.* 90% of the calculated amount.

The finely divided iron can be collected and rinsed with solvent but it immediately begins to oxidize to FeO, Fe_3O_4 and Fe_2O_3, turning from black to brown. Both the moist black and brown materials are characteristically magnetic.

In a single ferrocene cleavage (15 g.) the sodium–ethylamine combination was employed and the slower reaction allowed to continue for 50 minutes. The cyclopentadiene was not isolated, but the iron produced under these conditions was more reactive upon drying and oxidized in air with incandescence. Extreme precautions were required to avoid explosion.

X-Ray diffraction using a North American Philips Geiger-counter spectrometer was employed in the characterization of the iron and iron oxides obtained from this reaction. Freshly prepared iron samples were protected as well as possible from oxygen with either mineral oil (Nujol) or 2% Duco cement in acetone during filtration and measurement but it was still not possible because of the highly active surface to avoid the appearance of peaks corresponding to FeO, Fe_3O_4 and Fe_2O_3, *e.g.*, using Fe K_α radiation, 2θ = 45.9°, 53.5°; 38.1°, 54.9°, 73.6°; 45.2°, 52.2°, respectively. Of those samples most carefully protected the FeO peak at 45.9° was the most prominent oxide peak, while a sample which had been allowed to oxidize as completely as possible in air had its strongest peak at 45.2° (Fe_2O_3).

Although very weak Fe peaks at 57.0°, 85.4° and 102.2° could sometimes be detected with carefully protected samples, the results were not analytically satisfactory and the weak peaks may be due either to amorphous structure or particle size of the iron, where the oxides are either less critically dependent on particle size or have aggregated during oxidation. Finely divided iron similarly prepared by ferric chloride reduction with lithium in ethylamine showed the same weak Fe and various oxide peaks.

Ferrocene Reduction with Calcium in Ammonia.—Several preliminary qualitative tests showed that the reaction of ferrocene with calcium in ammonia was very vigorous and required caution. Ferrocene (30 g.) was dissolved in 500 ml. of anhydrous ether in a flask fitted with a large Dry Ice condenser. Calcium turnings (50 g.) were added and anhydrous ammonia was introduced very slowly with stirring until *ca.* 200–300 ml. of ammonia had been condensed, the addition being interrupted several times when the reaction appeared to increase in rate. Evidence of reaction appeared shortly after introduction of ammonia by the darkening of the calcium and appearance of black iron particles. Additional ether (200 ml.) was added to the cold reaction flask to further dissolve some of the precipitated ferrocene. After 5 hours, during which time a considerable increase in the amount of black suspension had developed, the condenser was filled with ice and the flask was warmed with tap water to allow escape of ammonia.

When the contents were at room temperature, 150 ml. of water was added cautiously from a dropping funnel. The ether phase was decanted from the calcium hydroxide–iron residue and the latter was extracted with numerous portions of benzene until colorless. The combined ether–benzene layer was washed with water to remove ammonia, dried with magnesium sulfate and refluxed with 26.3 g. of maleic anhydride overnight. After the solution was concentrated and evaporated to dryness, the adduct acid was separated from unreduced ferrocene (22.17 g.) by crystallization from water to yield 4.79 g. (30.3%) of recrystallized adduct acid. The presence of iron in the extracted residue was confirmed with a magnet test.

Ferrocene Reduction with Lithium in Mineral Oil.—Lithium sand was prepared by melting 10 g. of lithium in 150 ml. of mineral oil (Nujol) and cooling below the melting

point while stirring at high speed. When the contents were at 100°, 3.0 g. of ferrocene was added and gradual heating resumed, using a protective helium atmosphere. Careful visual examination indicated no appreciable reaction until the temperature had reached *ca.* 190° at which time the lithium surface appeared to darken slightly and the presence of iron particles could be discerned by testing with a magnet. Heating was resumed and the temperature raised to 220° over a 10-minute period and then the mixture was allowed to cool. By this time the lithium particles were very much darker and *ca.* 0.1 g. of magnetic black precipitate had settled to the bottom of the flask. After rinsing with solvent, the Fe-coated lithium sand adhered readily to the magnet. In the absence of lithium at these temperatures and in contact with air, no evidence of degradation could be observed.

Organic Chemistry of Ferrocene. I. The Acetylation of Dialkylferrocenes[1]

BY KENNETH L. RINEHART, JR., KAYE L. MOTZ AND SUNG MOON

RECEIVED DECEMBER 3, 1956

Acetylation of 1,1′-dimethylferrocene gives a 7 to 3 ratio of the 3- or β-acetyldialkylferrocene to the 2- or α-acetyl isomer, while the ratio of the corresponding acetyldiisopropyl isomers obtained from acetylation of 1,1′-diisopropylferrocene is 9 to 2. The isomeric acetyldialkylferrocenes have been isolated, characterized by infrared and ultraviolet spectra and converted by oxidation to the corresponding carboxylic acids and by reduction to the corresponding alkyl derivatives. Dissociation constants of the isomeric dimethylferrocenecarboxylic acids and infrared spectra of the isomeric ethyldimethylferrocenes have been presented and discussed.

Since the initial report in 1951 of the isolation of ferrocene[2,3] and the discovery that the compound is, in many respects, an aromatic system,[4] there have been numerous chemical confirmations of the similarity of its chemistry to that of the classical benzenoid compounds and, indeed, the name ferrocene was chosen to indicate the compound's aromatic character.[4] Thus, for example, ferrocene may be acylated,[4,5] sulfonated,[5,6] metalated[7,8] and arylated by other aromatic nuclei.[7,9–12] On the other hand, in its resistance to alkylation[5,13] and its behavior toward oxidizing media[14] ferrocene shows marked differences from benzene. The present study has been undertaken as part of a general investigation of substituted ferrocenes and to investigate to what extent the normal directive effects of alkyl groups[15] are observed in the ferrocene system.

For this purpose the acylation reaction is particularly well adapted since it has been studied extensively in benzenoid systems and found to be highly selective in substitution at ring positions.[16] Further, acylation of ferrocenes leads to little or no degradation of the ring system and often gives products in high yields.[5,17] Previous investigations of acylations have shown similarities between ferrocene and benzene in that acylation may be accomplished under conditions employed for benzene[4,5] and also in that the presence of one acyl group on the ferrocene nucleus strongly deactivates the substituted ring toward further acylation[4,18] and to a certain extent deactivates the other ring as well.[5,13,18] By contrast, the presence of an alkyl group might be expected to activate somewhat the substituted ring toward acylation.[19]

In the present study the compounds investigated have been the 1,1′-dialkylferrocenes,[20] in which each ring bears a substituent alkyl group. Both 1,1′-dimethyl- (Ia) and 1,1′-diisopropyl-ferrocene (Ib) have been examined in order to observe the differing effects of the methyl and isopropyl substituents and the response of acylation of the system toward increasing steric bulk on the rings.

Acetylation of either of these compounds can give substitution in the 2- or 3- (α- or β-)[21] positions. If care is taken to prevent disubstitution, only two isomers are formed, 2-acetyl- (IIa,b) and 3-acetyl-1,1′-dialkylferrocenes (IIIa,b); measurement of the proportion of the two isomers leads to

(21) The α–β nomenclature commonly employed in heterocyclic and condensed ring aromatic compounds seems preferable to any system based on an *ortho–meta–para* scheme. Confusion arises in the five-membered ring series since electronically there are probably two "para" positions (1 and 4) and one "meta" position (*cf.* below).[14]

an indication of directive influences in the ring.[22]

Influences favoring one or the other of the two isomers may be described as steric or electronic in nature. On purely steric grounds formation of the 3- or β-acetyl isomer is favored, especially from the acetylation of diisopropylferrocene. Electronic effects are more difficultly predictable. The inductive effect of an alkyl substituent should favor the formation of the 2- or α-acetyl isomer since this effect diminishes with increasing distance from the substituent. Hyperconjugative interaction of the alkyl group with the ring might be expected to enhance the reactivity of both positions, however, since acylation transition states of the usual type[23] in which the positive charge is delocalized about the ring may be pictured for substitution at either ring position.[24]

A greater number of such hypothetical delocalized forms may be drawn for hyperconjugation of the acylation transition state at a position alpha to the alkyl group, but, of course, the number of such forms says nothing for the stability or relative contribution of each.[25] From the above discussion no predictions may be made with certainty, but since the various electronic and steric influences are complex and to an extent oppose one another, it might be expected that a mixture of the two isomeric products should be formed in which neither isomer strongly predominates.

Both diisopropyl- and dimethyl-ferrocene were acetylated with acetic anhydride employing an aluminum chloride catalyst. To inhibit the formation of diacetyl products, only one-half mole of anhydride was employed per mole of ferrocene and the anhydride was added slowly to the ferrocene solution. The mixture of products was separated chromatographically, whereby the dialkylferrocene was recovered readily, while the two isomeric acetyldialkylferrocenes were separated with greater difficulty. The relative proportions of the two isomers formed from dimethyl- and diisopropylferrocene are summarized in Table I. These proportions were calculated from the ultraviolet spectra of mixtures of the two compounds and, as a check, for the diisopropylferrocene acetylation, also from the weights of the two isomers obtained from chromatographic fractions; agreement between the two methods is good.

TABLE I

PROPORTIONS OF ISOMERIC ACETYLDIALKYLFERROCENES FORMED

Dialkylferrocene acetylated[a]	Proportion of isomers, % α-[a]	β-[a]
1,1′-Dimethyl-	30[b]	70[b]
1,1′-Diisopropyl-	19[b]	81[b]
1,1′-Diisopropyl-	17[c]	83[c]

[a] α = 2-acetyldialkylferrocene (IIa,b). β- = 3-acetyldialkylferrocene (IIIa,b). [b] Composition estimated from ultraviolet spectra. [c] Composition estimated from weights of chromatographed isomers.

In the acetylation of dimethylferrocene there is little selectivity between the two positions and, while 3-acetyl-1,1′-dimethylferrocene is formed in somewhat greater amount, it nevertheless accounts for only 70% of the product and the 2-acetyl isomer for 30%. There is somewhat greater selectivity in the acetylation of diisopropylferrocene; here the β-isomer is formed in larger amount (82%) than with the methyl analog, while substitution of the α-position, hindered sterically, occurs to the extent only of 18%.

(22) It may be noted that Rosenblum[18] earlier acetylated monoethylferrocene and obtained the expected three isomers, although he did not assign definite structures to the two homoannular compounds. The present 1,1′-dialkyl system has the virtue of simplicity in that it allows the isolation and study of directive effects on substitution in the same ring uncomplicated by those exerted on substitution in the other ring.

(23) J. W. Baker, "Hyperconjugation," Oxford University Press, London, 1952, p. 48.

(24) It is on this basis that the α- and β-positions seem to resemble more closely the *o*- and *p*-positions of benzene, while no true *m*-position exists.

(25) On the basis of an approximate molecular orbital treatment of substituted ferrocenes, Richards has predicted the formation of a somewhat higher proportion of the α-isomer for both electron-donating and electron-withdrawing substituents [J. H. Richards, private com-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

tent of only 18%. This is rather a surprisingly small difference in light of the considerably greater bulk of the isopropyl group.[26] However, the bond angles of the 5-membered ring are much less conducive to steric crowding than those of benzene, as may be seen from Fig. 1, where van der Waals radii[25] have been drawn. Thus there is less interaction between adjacent substituents on the ring. This conclusion is supported by the ultraviolet spectra of the acetyl isomers and the dissociation constants of the corresponding isomeric acids presented below. The formation of the two isomers in similar amounts is consistent with the treatment of competing electronic effects outlined above. In summary, it may be stated that there is little selectivity between acylation at one or the other position of the ferrocene ring and that steric effects are not as important as in the benzene analogs, where acetylation of toluene gives nearly exclusively *p*-substitution,[29] although electronic factors presumably favor *o*-substitution also.[19]

As a further comparison between the ferrocene and benzene systems the physical properties of substituted ferrocenes are of interest. In Table II

TABLE II

ULTRAVIOLET ABSORPTION MAXIMA OF FERROCENYL AND PHENYL KETONES

Ketone	λ_{max}, mμ[a]	ϵ_{max}[a]
Acetylferrocene	226	16,500 (14,600)[b]
	269	6,500 (5,400)[b]
2-Acetyl-1,1′-dimethylferrocene	227	18,600
	271	6,800
3-Acetyl-1,1′-dimethylferrocene	232	15,800
	274	6,600
2-Acetyl-1,1′-diisopropylferrocene	226	18,200
	271	6,700

	273	6,700
Acetophenone	242	12,000 (12,800)[c]
o-Methylacetophenone	243	9,500 (8,850)[c]
m-Methylacetophenone	247	11,300
p-Methylacetophenone	252	15,800 (15,100)[c]

[a] Spectra determined in 95% ethanol. [b] Ref. 18. [c] Ref. 30.

are presented maxima from the ultraviolet spectra of the isomeric acetyl-dialkylferrocenes, together with those of the isomeric methylacetophenones for comparison. Both series of compounds have strong conjugated ketonic absorption; for phenyl ketones this is near 245 mμ, while for ferrocenyl ketones there are two bands, near 230 and 270 mμ. Of particular interest is the striking difference between the effect of alkyl substituents on the spectra of the two systems. Methyl substitution in the *p*-position of acetophenone increases both the wave length of maximum absorption and the

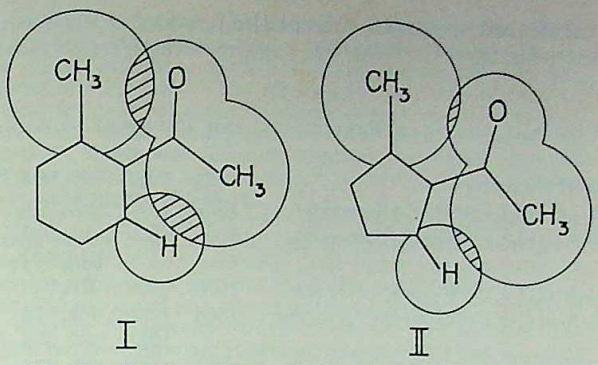

Fig. 1.—Overlap of van der Waals radii between acetyl and adjacent groups in substituted aromatic ketones: I, *o*-methylacetophenone; II, 2-acetyl-1,1′-dimethylferrocene.

extinction coefficient. A *m*-methyl substituent shifts the maximum to somewhat longer wave lengths but has little effect on the extinction coefficient. An *o*-substituent, on the other hand, does not shift the wave length of the peak at all from that of acetophenone but leads to a sharp decrease in the extinction coefficient. This behavior of *o*-methylacetophenone generally has been considered to be due to steric interaction between the acetyl group and the adjacent methyl and hydrogen,[28,30] and Braude has interpreted the effect more specifically as due to a decrease in the population of rotational conformations suitable for transition to the excited state responsible for the 245 mμ maximum.[31]

In the dialkylferrocenyl ketones the β-isomer shows a slight bathochromic shift and an extinction coefficient little different from that of acetylferrocene. In these properties it resembles *m*-methylacetophenone. However, the α-isomer shows strikingly different behavior from that of *o*-methylacetophenone. Although the peak wave length remains the same as that of acetylferrocene, the coefficient is higher than that of the unsubstituted ketone, rather than lower. Thus in these ultraviolet spectra, as in the acylation isomer ratios, steric effects are not so important as in the corresponding benzene compounds (*cf.* Fig. 1). This is further confirmed by the spectra of the diisopropyl ketones, which are nearly identical to those of the corresponding dimethyl isomers.[32]

Stronger absorption by the α-isomer must be due to electronic influences and may be attributed either to a strong inductive effect or to better hyperconjugative stabilization of the excited state in the α-isomer than in the β-analog (*cf.* above). The longer wave length absorption by the β-isomer is due probably to the greater length of the chromophoric system.

(26) An attempt was made to direct acetylation more stereospecifically by employing nitrobenzene as a solvent[27]; however, oxidation to the blue-green, water-soluble ferricinium cation was the predominant reaction under these conditions.

methyl acetophenones for comparison. From this Table it may be seen that the carbonyl stretching band of the ferrocenyl compounds falls near 1665 cm.$^{-1}$ for all isomers, at a somewhat longer wave length than that of the phenyl analogs. However, there are other characteristic bands which differ for α- and β-isomers but which for each positional isomer occur near the same position for both the dimethyl and diisopropyl compounds. Thus, the aromatic ketone band in the 1300–1250 cm.$^{-1}$ region occurs at lower frequency for the α-substituted compounds than for acetylferrocene itself but at higher frequency for the β-isomer. The spectra of corresponding alkyl acetophenones show a similar shift to higher frequencies for *m*- and *p*-substitution, lower for *o*-. In addition to the ketonic bands there are also bands in the 1000–900 cm.$^{-1}$ region, which has been shown to be highly useful for the characterization of isomeric polyalkylferrocenes.[20] In this region, too, both the dimethyl and diisopropyl compounds show similar bands for each of the positional isomers.

Each of the isomeric acetyldimethylferrocenes (IIa, IIIa) was oxidized by the modified iodoform procedure of Weinmayr[5] to the corresponding carboxylic acid (IV, V). Dissociation constants of the two acids and that of ferrocenecarboxylic acid are presented in Table IV, with those of benzoic and the toluic acids for comparison.

TABLE IV

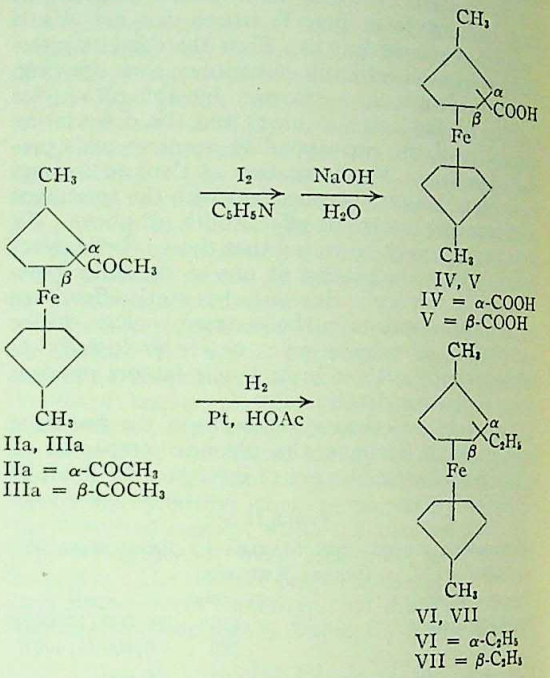
p-Toluic acid	4.34[d]	Water

[a] Determined in *ca.* 3×10^{-3} *M* solution. No correction has been applied for the small effect of ionic strength at this low concentration. Aqueous determinations were effected by back-titration of the potassium salts. [b] Ref. 18. [c] J. F. J. Dippy, *Chem. Revs.*, 25, 151 (1939). [d] G. Briegleb and A. Bieber, *Z. Elektrochem.*, 55, 250 (1951).



Here, as in the ultraviolet spectra of the ketones, the behavior of substituted ferrocenes is considerably different from that of the benzene analogs. While both *m*- and *p*-toluic acids are somewhat weaker acids than benzoic, *o*-toluic acid is stronger than the parent acid (*cf.* Table IV). The anomalous behavior of the *o*-isomer has been attributed by Brown[33] to steric interference toward conjugation between the carboxyl and ring.[34] However, *both* the 2- and 3-methyl-substituted ferrocene acids have lower dissociation constants than the unsubstituted acid, and the α-acid is the weakest of the three. The dissociation constants, then, as the ultraviolet spectra and isomer distribution ratios, support a view of the ferrocene system as being less affected (or at least affected differently) by steric factors than benzene. Electronic factors, either inductive or hyperconjugative, favoring greater electron release by the α-methyl, are probably responsible for the considerably lower dissociation constant of 1,1′-dimethyl-2-ferrocenecarboxylic acid, although an alternative explanation attributing the differences in dissociation constants to decreased solvation of the carboxylate anion[34,35] cannot be ruled out.

(33) H. C. Brown, D. H. McDaniel and O. Häfliger in ref. 31a, p. 603.

(34) Steric interference toward solvation of the carboxylate ion has been discussed by Newman[35] as an opposing effect which serves to lower the dissociation constants of *o*-substituted acids. No attempt is made in the present work to distinguish between the two effects. The principal point to be made is that the ferrocene and the benzene systems sometimes behave differently and that in the present case, the difference is probably due to the steric requirements of the two systems.

Digitized by Arya Samaj Foundation Chennai and eGangotri

The decreased proportion of one isomer formed on acetylation of diisopropylferrocene (as compared to the amount formed on acetylation of dimethylferrocene) argues strongly for the formulation of that as the sterically less favored isomer and thus the α-compound. In addition, the structures assigned to the two isomers have been confirmed by hydrogenation of both acetyldimethylferrocenes (IIa, IIIa) to the corresponding ethyldimethylferrocenes (VI and VII) and comparison of the infrared spectra of the two compounds to those of independently synthesized alkylferrocenes.[20]

The 1000–900 cm.$^{-1}$ region has been shown to contain characteristic bands for the identification of alkyl-substituted ferrocenes.[20] In Table V are

[a] Determined as liquid smears. [b] Ref. 20.

presented bands from that region found in the spectra of the present hydrogenation products and those of two previously known polyalkyl ferrocenes, together with other significant bands useful in distinguishing between the two ethyldimethyl isomers.

Thus, 1,1′-dimethylferrocene has a single band in the 1000–900 cm.$^{-1}$ region, near 925 cm.$^{-1}$, while 2,2′-diethyl-1,1′-dimethylferrocene has two bands, at 965 and 950 cm.$^{-1}$. The 2-ethyl-1,1′-dimethylferrocene obtained on reduction of 2-acetyl-1,1′-dimethylferrocene should, then, have a band near 925 cm.$^{-1}$ characteristic of the monosubstituted ring and bands at 965 and 950 cm.$^{-1}$ characteristic of the α-disubstituted ring. As may be seen from Table V, this is indeed the case. The isomeric 3-ethyl compound has no bands at 965 and 950 cm.$^{-1}$, though it has one at 926 cm.$^{-1}$ for the methyl-substituted ring and bands at 917 and 944 cm.$^{-1}$, apparently characteristic of a 1,3-methylethyl disubstituted ring. Similarly, other bands present in the spectrum of 2-ethyl-1,1′-dimethylferrocene (*e.g.*, at 693, 870 and 1205 cm.$^{-1}$), and absent from that of the 3-ethyl- analog are found in the spectrum of 2,2′-diethyl-1,1′-dimethylferrocene.

Experimental[36]

Acetylation of dimethylferrocene was effected with acetic anhydride and aluminum chloride in the usual Friedel–Crafts manner. A mixture of 20.4 g. of 1,1′-dimethylferrocene[20] and 14.6 g. of aluminum chloride in 300 ml. of methylene chloride was cooled in an ice-bath, and 4.72 ml. of acetic anhydride in 25 ml. of methylene chloride was added during 3 hr. The reaction mixture was allowed to stand for 1 hr. at room temperature and was then poured over ice. After the organic phase had been separated and washed, methylene chloride was removed under reduced pressure and the residue was transferred to an alumina column 25-mm. × 120-cm.

After the column had been developed with benzene, the lower yellow band, containing recovered dimethylferrocene, was eluted with *n*-pentane. The upper orange band of acetylated isomers was eluted rapidly with hexane containing 5% methanol and concentrated to give 9.3 g. (72%) of a mixture of acetyldimethylferrocenes. The oil was distilled rapidly under high vacuum; the distillate had λ_{max} 229 mμ, ϵ_{max} 16,400, ϵ_{227} 16,300. From this spectrum and those of the two pure isomers given below the mixture may be estimated to consist of approximately 70% of the 3-acetyl isomer and 30% of the corresponding 2-acetyl isomer. The infrared spectrum of the distilled mixture was identical with that of the oil before distillation.

The orange oil was re-chromatographed in benzene on the same column to give two major fractions and an intermediate portion. The first fraction was concentrated to a red oil, which could be crystallized from *n*-pentane at Dry Ice–acetone temperatures to red crystals of **2-acetyl-1,1′-dimethylferrocene**, m.p. 15–16°. The ultraviolet spectrum of a distilled sample had λ_{max} 227 mμ, ϵ_{max} 17,600.

Anal. Calcd. for $C_{14}H_{16}FeO$: C, 65.65; H, 6.30; Fe, 21.80.[37] Found: C, 66.30; H, 6.65; Fe, 22.01.

The second fraction on concentration also yielded a red oil, which crystallized on standing to orange needles of **3-acetyl-1,1′-dimethylferrocene**, m.p. 48.4–48.6°. The ultraviolet spectrum had λ_{max} 232 mμ, ϵ_{max} 15,800, ϵ_{227} 15,300.

Anal. Calcd. for $C_{14}H_{16}FeO$: C, 65.65; H, 6.30; Fe, 21.80. Found: C, 65.33; H, 6.35; Fe, 22.13.

1,1′-Dimethylferrocene-2-carboxylic acid was prepared by a modification of the procedure of Weinmayr.[5,38] A mixture of 1.0 g. of 2-acetyl-1,1′-dimethylferrocene, 2 ml. of pyridine and 1.1 g. of iodine was agitated for 12 hr. at room temperature, then for 90 min. in a boiling water-bath. The mixture was diluted with aqueous 0.6 *N* sodium hydroxide and stirred for 24 hr. at room temperature, then for 1 hr. on the steam-bath. The mixture was filtered and acidified with glacial acetic acid to precipitate 185 mg. (18%) of 1,1′-dimethylferrocene-2-carboxylic acid. The crude material was dissolved in ether, filtered free of insoluble impurities, extracted into sodium carbonate solution, reprecipitated with hydrochloric acid and finally recrystallized from ether; m.p. 118–118.5° dec.

Anal. Calcd. for $C_{13}H_{14}FeO_2$: C, 60.49; H, 5.43; Fe, 21.64. Found: C, 60.34; H, 5.39; Fe, 21.68.

Potentiometric titration of the acid showed the apparent molecular weight[39] to be 256 ± 5 (theoretical is 260) and yielded the following dissociation constants: pK_a' 8.15 ± 0.05 (66% dimethylformamide, 34% water), pK_a' 5.4 ± 0.1 (water).

1,1′-Dimethylferrocene-3-carboxylic acid was prepared by the same procedure employed for the corresponding 2-carboxylic acid. The yield of crude acid was 373 mg. (37%), and the recrystallized acid had m.p. 106–106.5° dec., apparent molecular weight 258 ± 15, pK_a' 7.5 ± 0.1 (66% DMF), pK_a' 4.7 ± 0.1 (water).

Anal. Calcd. for $C_{13}H_{14}FeO_2$: C, 60.49; H, 5.43; Fe, 21.64. Found: C, 60.44; H, 5.55; Fe, 21.70.

2-Ethyl-1,1′-dimethylferrocene was prepared by reduction of 2-acetyl-1,1′-dimethylferrocene over platinum oxide

(36) Melting points and boiling points are uncorrected. Fractional distillations were through a 3-ft. Nester whirling band column. Ultraviolet spectra were determined in 95% ethanol in a Beckman model DU spectrophotometer, employing calibrated quartz cells. We are indebted to Mr. Jozsef Nemeth, Mrs. Maria Benassi and Mrs. Ruby Ju for microanalyses and to Mr. James Brader and Mrs. Louise Griffing for infrared spectra. The spectra were obtained for solids in Nujol mulls, for liquids as smears, with a recording Perkin–Elmer infrared spectrophotometer, model 21.

(37) Iron was determined (by J. Nemeth) by the general ashing technique (A. Steyermark, "Quantitative Organic Microanalysis," The Blakiston Co., New York, N. Y., 1951, p. 47), employing sulfuric acid and micro-size samples, ignited to 950°. The ferric oxide residue was weighed to constancy and corrected for surface moisture (previously established for a reliable sample) by deducting 1.5% of its weight.

(38) V. Weinmayr, U. S. Patent 2,683,157 (1954); *C. A.*, **49**, 10364a (1955).

(39) Uncertainty in values of the neutralization equivalents is due to the very small samples available for titration (*e.g.*, sample weight, 2.58 ± 0.05 mg.; volume of titrant, 0.0050 ± 0.0002 ml.).

in a Parr bomb. Hydrogenation, effected in glacial acetic acid under 3.5 atm. pressure, was essentially complete after 24 hr. at room temperature. The product was dissolved in pentane, washed with sodium bicarbonate and separated from ketonic and alcoholic material by chromatography on an alumina column. Concentration of the pentane eluates gave the yellow-brown, liquid 2-ethyl-1,1′-dimethylferrocene.

Anal. Calcd. for $C_{14}H_{18}Fe$: C, 69.44; H, 7.49. Found: C, 69.78; H, 7.79.

3-Ethyl-1,1′-dimethylferrocene was prepared and purified by the procedure described above for the corresponding 2-ethyl isomer.

Anal. Calcd. for $C_{14}H_{18}Fe$: C, 69.44; H, 7.49. Found: C, 69.57; H, 7.76.

Acetylation of 1,1′-diisopropylferrocene was effected by the method described above for acetylation of the corresponding dimethylferrocene. To an ice-cold mixture of 8.75 g. of diisopropylferrocene[39] and 4.86 g. of aluminum chloride in 100 ml. of methylene chloride was added during 1 hr. 1.65 g. of acetic anhydride in 25 ml. of methylene chloride. The resulting mixture was stirred overnight at room temperature and poured over ice. After work-up the concentrated dark brown organic liquid was chromatographed on a 25-mm. × 120-cm. alumina column to give 3.6 g. (41%) of recovered diisopropylferrocene and a total of 4.54 g. (45%) of the isomeric acetyldiisopropylferrocenes, contained in seven fractions. From the weights of the individual fractions it was estimated that the monoacetyl compounds consisted of 17% of the 2-acetyl isomer and 83% of the 3-acetyl analog.

2-Acetyl-1,1′-diisopropylferrocene, obtained from an early chromatography fraction, was purified by distillation and had b.p. 120–125° (0.4 mm.), λ_{max} 226 mμ, ϵ_{max} 18,200, ϵ_{325} 18,000.

Anal. Calcd. for $C_{15}H_{24}FeO$: C, 69.21; H, 7.75. Found: C, 69.53; H, 7.73.

3-Acetyl-1,1′-diisopropylferrocene, obtained from a later chromatographic fraction and purified by distillation, had b.p. 150–155° (1.3 mm.), λ_{max} 231 mμ, ϵ_{max} 15,600, ϵ_{325} 14,300.

Anal. Calcd. for $C_{15}H_{24}FeO$: C, 69.21; H, 7.75. Found: C, 67.58; H, 7.78.

In a second run the above procedure was followed except that the aluminum chloride (1.63 g.) and acetic anhydride (0.572 g.) were added together in 10 ml. of methylene chloride to the diisopropylferrocene (3.0 g.) in 30 ml. of methylene chloride. From the chromatogram 0.65 g. (23%) of diisopropylferrocene was recovered. The acetylated material was removed in one band and distilled to give 0.85 g. (25%) of mixed isomers, b.p. 120–133° (0.8 mm.), λ_{max} 232 mμ, ϵ_{max} 15,500, ϵ_{325} 15,000. From these spectral data and those above for the two pure isomers the proportion of the 2-acetyl compound may be estimated to be 19%, that of the 3-acetyl compound 81%.

Acetylferrocene[40] was prepared by the procedure described above for the acetylation of dimethylferrocene. From 18.6 g. of ferrocene, 14.7 g. of aluminum chloride and 4.73 ml. acetic anhydride there was obtained after chromatography 7.4 g. (65%) of crude acetylferrocene. This material was recrystallized from benzene to give long red needles, m.p. 86–87°, λ_{max} 226 mμ, ϵ_{max} 16,500 (lit. m.p. 85–86°,[5] λ_{max} 225 mμ,[18] ϵ_{max} 14,600[18]).

Ferrocenecarboxylic acid was prepared by the procedure described above for the dimethylferrocenecarboxylic acids, except that the terminal heating of the aqueous sodium hydroxide solution was omitted.[5,38] From 1.0 g. of acetylferrocene there was obtained 0.35 g. (35%) of ferrocenecarboxylic acid, which was recrystallized from chloroform to give crystals which decomposed at 208.5°.[41] Potentiometric titration gave the apparent molecular weight as 250 ± 15 (theoretical is 232) and pK_a' 7.3 ± 0.1 (66% DMF), pK_a' 4.4 ± 0.1 (water) [lit.[18] pK_a' 7.26 (66% ethanol)].

Acetophenone was fractionally distilled; a center cut had b.p. 97–97.5° (14 mm.), $n^{25}D$ 1.5314, λ_{max} 242 mμ, ϵ_{max} 12,000 [lit. b.p. 85.5–86.5° (16 mm.),[30] $n^{20}D$ 1.5338,[41] λ_{max} 242 mμ[30], ϵ_{max} 12,800[30]].

o-**Methylacetophenone**[40] was prepared in 60% yield from the cadmium alkyl reaction from *o*-bromotoluene and acetyl chloride by the method of Cason.[43,44] The fractionally distilled product had b.p. 87–88° (11 mm.), $n^{25}D$ 1.5299, λ_{max} 243 mμ, ϵ_{max} 9,500 [lit. b.p. 93–94° (16 mm.),[30] $n^{20}D$ 1.5320,[42] λ_{max} 243 mμ,[30] ϵ_{max} 8,850[30]].

m-**Methylacetophenone**[40] was prepared from *m*-bromotoluene and acetyl chloride in 45% yield by the same procedure employed for the preparation of *o*-methylacetophenone. The twice fractionally distilled product had b.p. 97–98° (15 mm.), $n^{25}D$ 1.5285, λ_{max} 247 mμ, ϵ_{max} 11,300 [lit.[41] b.p. 109° (12 mm.), $n^{20}D$ 1.5306].

p-**Methylacetophenone** was fractionally redistilled; a center cut had b.p. 99–100° (12 mm.), $n^{25}D$ 1.5317, λ_{max} 252 mμ, ϵ_{max} 15,800 [lit. b.p. 94–95° (12 mm.)[30], $n^{25}D$ 1.5342,[42] λ_{max} 252 mμ[30], ϵ_{max} 15,100[30]].

Acknowledgments.–The authors wish to express their appreciation to the Research Corporation for a generous grant in support of this work. They also wish to thank Mr. Robert C. Reed of Eli Lilly and Co. for the determination of dissociation constants and molecular weights of the carboxylic acids and Dr. E. O. Brimm of Linde Air Products Co. and Dr. A. C. Haven of E. I. du Pont de Nemours and Co. for samples of dimethylferrocene.

URBANA, ILLINOIS

(40) We are indebted to Messrs. P. E. Sokol, K. D. Berlin and J. R. Larson for the preparation of these compounds.

(41) Further purification, either by recrystallization from ether or by dissolving in base and reprecipitating with acid, did not alter the melting point behavior, as the pale orange needles still decomposed below 210° and the decomposition point depended upon the rate of heating. Rosenblum[18] has reported decomposition at 210° and Nesmeyanov[7] over the range 195–205°, while Weinmayr[4] gave m.p. 225–230° for this compound.

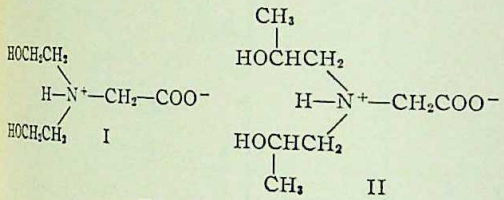
The Preparation and Chelating Properties of N,N-Bis-(2-hydroxypropyl)-glycine

BY ALBERT E. FROST, STANLEY CHABEREK AND NEWELL J. BICKNELL

RECEIVED NOVEMBER 29, 1956

N,N-Bis-(2-hydroxypropyl)-glycine has been synthesized and its acid dissociation constant and metal chelate stability constants with a number of metals determined. Present data indicate that this agent behaves as a tetradentate agent with all metals except copper. Comparison with the corresponding constants of N,N-bis-(2-hydroxyethyl)-glycine indicates a comparable affinity for hydrogen ion and divalent metal ions. However, the behavior with trivalent iron differs considerably from that of N,N-bis-(2-hydroxyethyl)-glycine.

Introduction.—A recent report on the chelating tendencies of the hydroxyethyl substituted glycine derivative N,N-bis-(2-hydroxyethyl)-glycine[1] (I) indicates (1) the association of hydroxyl groups with the metal ions and (2) the appreciable affinity of this derivative for transition metal ions. It, therefore, became of interest to investigate the chelating tendencies of the structurally similar N,N-bis-(2-hydroxypropyl)-glycine (DPG) (II), its homolog.



Experimental

Preparation.—N,N-Bis-(2-hydroxypropyl)-glycine was synthesized by the reaction of N,N-bis-(2-hydroxypropyl)-amine with potassium cyanide and formaldehyde in the molar ratios of 1:1.06:1.05 according to the procedure outlined by Bersworth.[2] The free acid was isolated from the straw-colored aqueous solution of the monopotassium salt by means of the hydrogen form of Dowex-50 on a column process. Elution of the column with distilled water followed by decolorization of the eluate with activated charcoal and concentration to small volume gave a gummy tan solid. Purification was accomplished by dissolution of this solid in a minimum volume of water and precipitation by the addition of a large volume (20 times) of acetone. Two such treatments produced a fine white powder melting at 129–131° (uncor.).

Anal.[3] Calcd. for $C_8H_{17}NO_4$: N, 7.3. Found: N, 7.0.

Method and Apparatus.—The experimental method employed in the study of the acid dissociation and metal chelate stability constants of N,N-bis-(2-hydroxypropyl)-glycine is essentially the same as that described by Chaberek and Martell.[4] The deviations from this procedure were the calibration of the glass electrode against a series of standard buffer solutions and the fact that all runs were made at a temperature of 29.6°. The amino acid concentration used in the several runs ranged from 3.5 to 3.8 × 10^{-3} *M*.

Calculations.—The calculations were carried out in the same manner as described in the above reference.[3] The metal chelate stability constants were calculated by both the algebraic and modified Bjerrum methods. Appreciable overlapping of the successive constants log K_1 and log K_2 made it necessary to correct log *K* values by successive approximations according to the procedure described by Carlson, McReynolds and Verhoek.[5] In the case of copper, the calculation of K_2 from the 1:1 and 2:1 titration data required a modification of the method cited above.[3] The copper–ligand interaction was sufficiently strong to lower the *p*H of the first buffer region to values considerably lower than four. A portion of the unbound ligand would, under these conditions, be converted to the positively charged species through association of a hydrogen ion with the dipolar ion (HA represents N,N-bis-(2-hydroxypropyl)-glycine)

$$HA + H^+ \longrightarrow H_2A^+ \qquad (1)$$

Formation of the positively charged species would decrease appreciably the concentration of (A^-) in this *p*H range. In order to account for the formation of H_2A^+, therefore, it was assumed that this positive ion had the same acid strength as glycine,[6] and the value of the dissociation constant for reaction 2 was taken as 4.5 × 10^{-3}.

$$H_2A^+ \overset{k^1}{\rightleftharpoons} HA + H^+;\ k^1 = (HA)(H^+)/(H_2A^+) \qquad (2)$$

Discussion of Results

1:1 Titration Curves.—The free acid curve of Fig. 1 has one inflection point at "*a*" value of 1 corresponding to formation of the monoalkali metal salt. The curve is typical of a weak monobasic

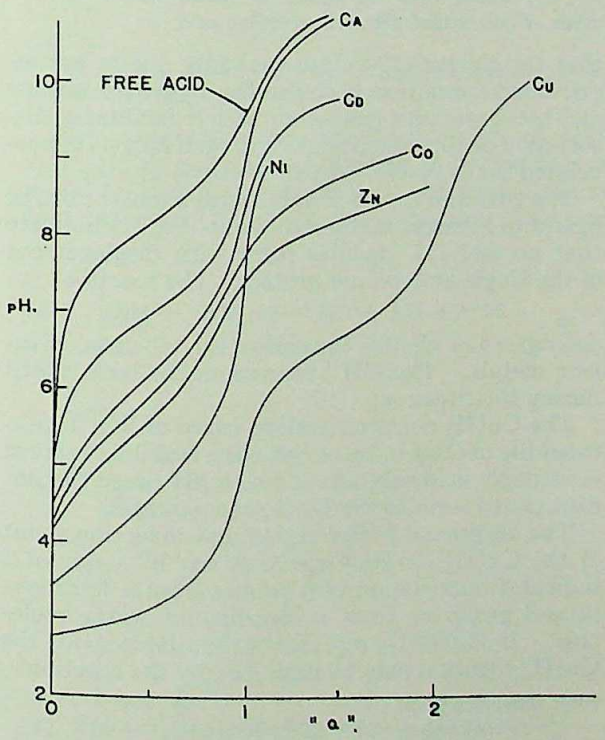


Fig. 1.—Titration of N,N-bis-(2-hydroxypropyl)-glycine (DPG): molar ratio of ligand to metal ion = 1:1; *a* = moles of base added per mole of acid.

Digitized by Arya Samaj Foundation Chennai and eGangotri

acid and exhibits a buffer region about *p*H 8.5. The calculated value of the acid dissociation constant is $10^{-8.13}$. In this respect it is similar to the homologous N,N-bis-(2-hydroxyethyl)-glycine. The greater acidity of the ammonium proton over

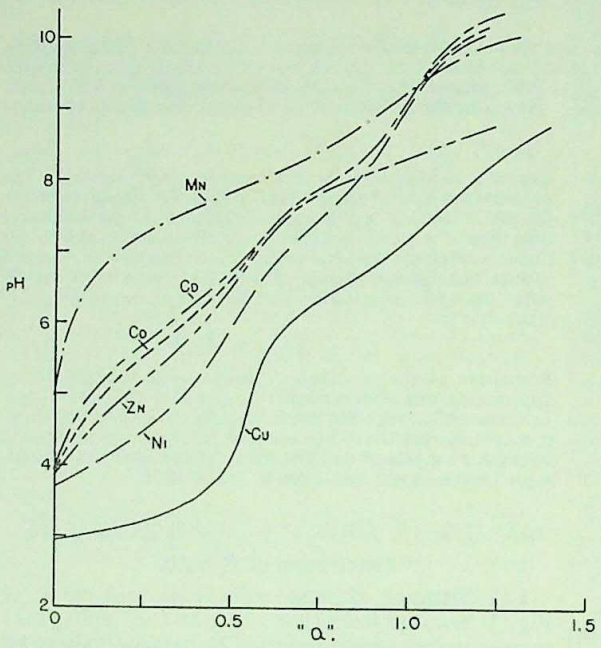

Fig. 2.—Titration of N,N-bis-(2-hydroxypropyl)-glycine (DPG): molar ratio of ligand to metal ion = 2:1; *a* = moles of base added per mole of amino acid.

that for glycine ($10^{-9.78}$) is probably due to hydrogen bond formation between the hydroxyl groups and the basic nitrogen atom which facilitates dissociation of the ammonium hydrogen ions as is postulated for N,N-bis-(2-hydroxyethyl)-glycine.[1]

The titration curves of DPG with a molar ratio of ligand to bivalent metal ion of one (Fig. 1) indicate that normal 1:1 chelates form with displacement of the single ammonium proton. The reaction

$$M^{+2} + HA + OH^- \longrightarrow MA^+ + H_2O \quad (3)$$

describes 1:1 chelate formation for all these bivalent metals. The OH^- represents the base added during the titration.

The Cu(II) chelate titration curve of Fig. 1 indicates the chelate to be of sufficient stability to form in strongly acid solution at which *p*H range the undissociated form of the DPG predominates.

The additional buffer region and inflection point of the Cu(II) titration curve at an "*a*" value of 2 indicates dissociation of a proton from a hydroxypropyl group or from a coördinated water molecule. If $HA(OH)_2$ represents the amino acid, the Cu(II) titration may be described by the reactions

First inflection point

$$HA(OH)_2 + Cu^{+2} \rightleftharpoons CuA(OH)_2^+ + H^+ \quad (4)$$

Second inflection point

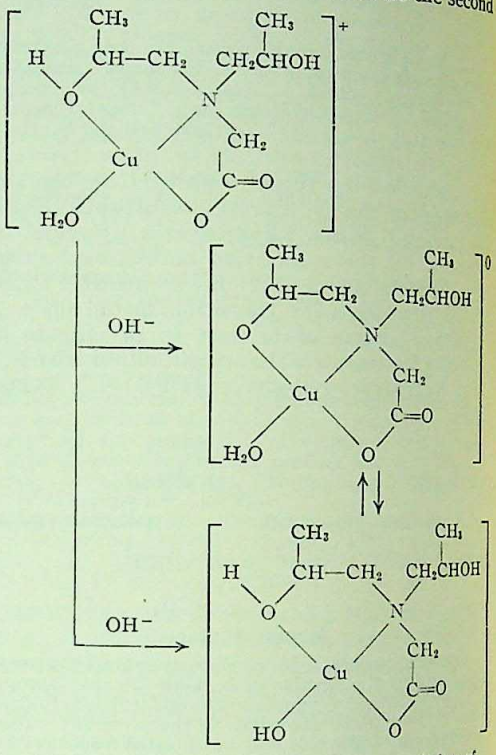
$$CuA(OH)_2(H_2O)^+ + OH^- \rightleftharpoons CuAO(OH)(H_2O) + H_2O \quad (5)$$

or

$$CuA(OH)_2(H_2O)^+ + OH^- \rightleftharpoons CuA(OH)(OH)_2 + H_2O \quad (6)$$

The two possible hydrolysis products bear a tautomeric relationship to each other, and it is likely that an equilibrium exists between these structures.

That proton dissociation as indicated above and not higher complex formation occurs at the second



Possible hydrolysis products of the 1:1 copper chelate of DPG

inflection point is evident from the fact that disproportionation to a higher chelate would result in precipitation of an equivalent amount of cupric hydroxide according to the reaction

$$2CuA(OH)^+_2 + 2OH^- \rightleftharpoons Cu(A)(OH)_2)_2 + Cu(OH)_2\downarrow \quad (7)$$

No precipitation was observed in this titration.

2:1 Titration Curves.—Titration curves for solutions containing ligand/metal ratios of two are shown in Fig. 2. All curves, with the exception of Mn(II)–DPG, have an inflection at an "*a*" value of 0.5 corresponding to the formation of the 1:1 metal chelate

$$M^{+2} + 2HA + OH^- \longrightarrow MA^+ + HA + H_2O \quad (8)$$

The excess DPG is present in essentially the dipolar acid species in the *p*H range of the inflections. Subsequent consumption of a second half mole of hydroxide per mole of amino acid and the presence of a second inflection at $a = 1$ for all systems except Zn(II) results from further interaction of excess ligand and the 1:1 metal chelate according to eq. 9

$$MA^+ + HA + OH^- \longrightarrow MA_2 + H_2O \quad (9)$$

In the case of the Mn(II) system, the absence of an inflection at $a = 0.5$ indicates a strong overlapping tendency involving the MA^+ and MA_2 species.

The Fe(III)–DPG System.—Titrations of Fe-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

(III)-DPG mixtures with ligand/Fe(III) ratios of 1 and 2 are plotted in Fig. 3.

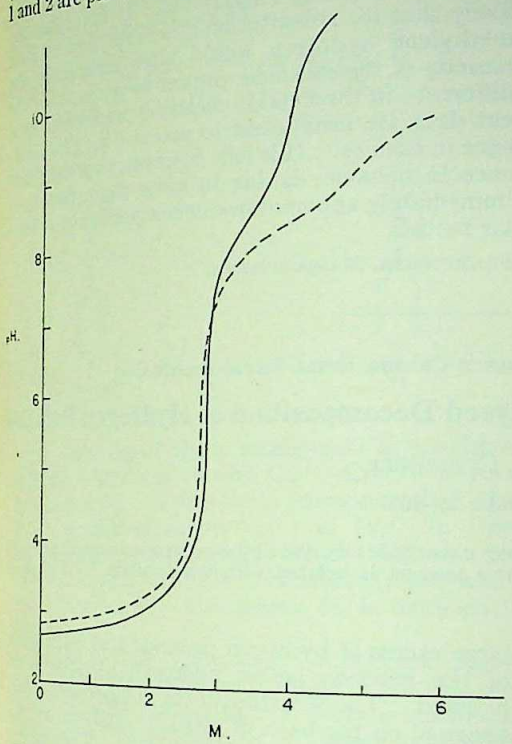

Fig. 3.—Titration of N,N-bis-(2-hydroxypropyl)-glycine in the presence of Fe(III) ions; —, Fe(III)/acid = 1:1; ---, Fe(III)/acid = 1:2; m = moles of base added per mole of metal ion.

The abscissa "m" of Fig. 3 denotes the number of moles of base added per mole of metal ion. The first inflection of both curves occurs at "m" $\approx$ 3, and a second weaker break is observed at "m" values of 4 and 5 for the 1:1 and 2:1 systems, respectively. Although the shapes and equivalence points for the Fe(III)–DPG system are strikingly similar to properties of the Fe(III)–bis-(2-hydroxyethyl)-glycine system for comparable ligand/metal ratios, the nature of the interactions are entirely different for these systems. Both 2:1 and 1:1 Fe(III)-DPG systems are characterized by the formation of ferric hydroxide at pH values of 2.75–3.0. Subsequent addition of standard base results in an extremely slow attainment of equilibrium and the precipitation of further amounts of the metal hydroxide. Consequently, the titration curves of Fig. 3 represent the stepwise formation of the ferric hydroxide and neutralization of DPG according to the reactions

1:1 titration curve

$$Fe^{+3} + 3OH^- \longrightarrow Fe(OH)_3\downarrow \quad \frac{3(OH^-)}{Fe} \qquad (10)$$

$$HA + OH^- \longrightarrow A^- + H_2O \quad \frac{1(OH^-)}{Fe} \qquad (11)$$

$\therefore$ inflections at $m = 3$ and $m = 4$

2:1 titration curve

$$Fe^{+3} + 3OH^- \longrightarrow Fe(OH)_3 \quad \frac{3(OH^-)}{Fe} \qquad (12)$$

$$2HA + 2OH^- \longrightarrow 2A^- + 2H_2O \quad \frac{2(OH^-)}{Fe} \qquad (13)$$

$\therefore$ inflections at $m = 3$ and $m = 5$

In spite of the behavior of this chelating agent in the acid and neutral pH range, it has been shown qualitatively that DPG chelates Fe(III) in alkaline solutions. Present data suggest, therefore, the formation of a ferric chelate which is considerably weaker than the corresponding Fe(III)–bis(2-hydroxyethyl)-glycinate. Experimental observations are consistent with the anticipated behavior of a weak ferric chelate which is extensively dissociated in acid solution.

Metal Chelate Formation Constants.—The first and second consecutive formation constants for the metal–DPG chelates are listed in Table I along with the corresponding values of the N,N-bis-(2-hydroxyethyl)-glycinate chelates (2-HxG).[1] The comparable affinities of both ligands for these metal ions are clearly evident from the corresponding log K data.

son of DPG and 2-HxG of Table I indicates little or no difference in the chelating tendencies of 2-hydroxypropyl relative to 2-hydroxyethyl groups.

That N,N-bis-(2-hydroxypropyl)-glycine and the corresponding N,N-bis-(2-hydroxyethyl) derivative exhibit comparable chelating affinities for the divalent metal ions is clearly evident from the results of this investigation. This behavior is certainly predictable on the basis of the close structural similarities and the comparable basicities of these two compounds. The differences between DPG and 2-HxG with respect to the chelation of Fe(III) is, however, unexpected. A comparison of molecular models of both ligands shows no apparent steric effect with relation to the orientation of the electron donor groups around the Fe(III) ion. It is further unlikely that the substitution of a methyl group for a methylene hydrogen would alter sufficiently the basicity of the ethanolic proton to account for the difference in the Fe(III) chelating properties. Present data are insufficient to account for this difference in affinity. It is felt, however, that the difference in behavior is due to some steric factor not immediately apparent from a comparison of molecular models.

Detection of $HO_2\cdot$ Radical in Metal Ion Catalyzed Decomposition of Hydrogen Peroxide

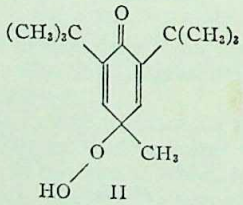
BY GALVIN M. COPPINGER

RECEIVED JANUARY 23, 1957

The appearance of $HO_2\cdot$ radical in the decomposition of hydrogen peroxide catalyzed by copper, iron or cobalt ions is detected by means of 2,6-di-*t*-butyl-4-methylphenol. A crystalline product is isolated with the structure 2,6-di-*t*-butyl-4-methyl-4-hydroperoxy-2,5-cyclohexadienone.

The radical $HO_2\cdot$ has been postulated as an intermediate in the decomposition of hydrogen peroxide in solution in the presence of a variety of metal ions.[1] Evidence for the existence of this radical is limited to inference drawn from final products of the decomposition and from the catalytic activity of the metal ion.

It has been possible to confirm the existence of the $HO_2\cdot$ radical in hydrogen peroxide decomposition by reaction of the radical with an antioxidant, utilizing a technique which has demonstrated the existence of other reactive radical intermediates.[2,3] When 2,6-di-*t*-butyl-4-methylphenol (I) is included in the system *t*-butyl alcohol, hydrogen peroxide, metal ion [Co^{++}, Fe^{++}, Fe^{+++}, Cu^{+}, Cu^{++}], a compound may be isolated whose structure is

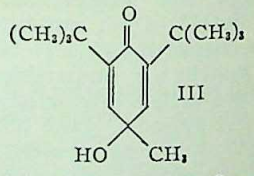


II

This compound is clearly the product of an intermediate in the metal ion catalyzed hydrogen peroxide decomposition. There is no reaction between the metal ions and the phenol in the absence of hydrogen peroxide and none between hydrogen peroxide and the phenol in the absence of metal ion under the same conditions. Oxygen has no direct effect on the reaction.

The isolation of II is accomplished by use of a large excess of hydrogen peroxide and interruption of the reaction before hydrogen peroxide is exhausted. The structure of the compound has been assigned on the basis of ultimate analysis, infrared spectrum and chemical reactivity. The infrared spectrum is the most distinctive characteristic of the cyclohexadienone structure, displaying a striking doublet at 6 μ.[4] Compound II also exhibits OH stretching bands with hydrogen bonding.

Compound II is reduced with Pt and H_2 to III. This compound (III) is also obtained from the air oxidation of 2,6-di-*t*-butyl-4-methylphenol in the presence of alkali.[5] The structure of III is assigned on the basis of analysis and infrared spectrum, OH stretching and doublet at 6 μ associated



III

with the cyclohexadienone configuration. It is transformed into 3,5-di-*t*-butyl-4-hydroxybenzyl acetate in acetic acid in the presence of a trace of strong acid.[6]

The hydroperoxide II is subject to metal ion catalyzed decomposition. The system II, Co^{++} and (I) in *t*-butyl alcohol, permits the isolation of three compounds: III, 1,2-bis-3,5-di-*t*-butyl-4-hydroxyphenylethane (IV) and 3,3′,5,5′-tetra-*t*-butyl-stilbene-4,4′-quinone (V). There is some

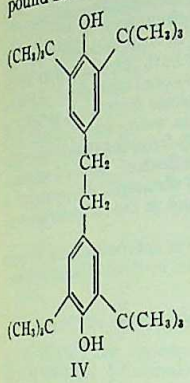
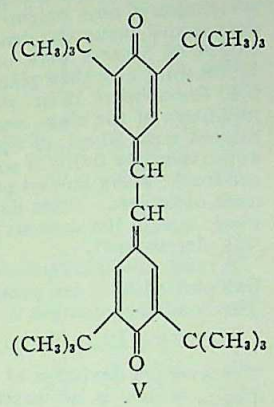
spectral evidence for the existence of a peroxy derivative of a dicyclohexadienone, but the compound has not been isolated.



IV



V

The isolation of these compounds is consistent with the reaction of II with Co^{++}–Co^{+++} to form RO· and RO_2·. It has been demonstrated that RO· is capable of converting I to IV.[7] In these reactions RO· is converted to ROH (III) with the apparent formation of a benzyl radical from I which then dimerizes IV. Compound IV is oxidized to V by RO·.[7]

The fate of RO_2· is not clear. Bickel and Kooyman[3] report that whereas a number of different peroxy radicals react with I to form peroxides of structures corresponding to II, triphenylmethylperoxy radical converts I in part to IV and V. It thus seems possible that a steric effect exists which depends upon the size of the R group in RO_2·, which determines whether RO_2· adds to the phenol or abstracts hydrogen from the phenol which results in the formation of a benzyl radical.

Experimental

4-Methyl-4-hydroperoxy-2,6-di-*t*-butyl-2,5-cyclohexadienone (II).—A solution of 0.1 mole of 2,6-di-*t*-butyl-*p*-cresol, 10 mg. of an appropriate metal salt and 1 mole of hydrogen peroxide (50w.%) in 250 ml. of *t*-butyl alcohol was allowed to stand at room temperature for 6 hr.; the metal salts used were cobalt naphthenate, cuprous chloride, cupric acetate, ferrous chloride and ferric chloride. The reaction is mildly exothermic. The copper salts occasionally produced a highly exothermic reaction. The decomposition is always accompanied by evolution of oxygen.

At the end of 6 hr. the solution is extracted with an equal volume of isoöctane and washed with water to remove the *t*-butyl alcohol. The isoöctane was removed at reduced pressure and the crystalline material was recrystallized from isooctane, m.p. 115°.

Anal. Calcd. for $C_{15}H_{24}O_3$: C, 71.5; H, 9.5. Found: C, 71.8; H, 9.4.

The yield of II varied from experiment to experiment. Calculations from the infrared spectra of the isoöctane extracts indicate the average yield of I was 25–30% of the parent phenol. The doublet at 6 μ was used for these estimations.

4-Methyl-4-hydroxy-2,6-di-*t*-butyl-3,5-cyclohexadienone (III).—Compound II was reduced in isoöctane solution with platinum-on-charcoal as catalyst, m.p. 112–113°. A mixed melting point with a sample of III obtained from air oxidation of 2,6-di-*t*-butyl-*p*-cresol in the presence of alkali was 112–113°.

Anal. Calcd. for $C_{15}H_{24}O_2$: C, 76.4; H, 9.7. Found: C, 76.7; H, 9.6.

3,5-Di-*t*-butyl-4-hydroxybenzyl Acetate.—A solution of 1 g. of III and 10 mg. of *p*-toluenesulfonic acid in 10 cc. of acetic acid was allowed to stand at room temperature for 24 hr. At the end of this time the acetate had partially crystallized. Additional acetate was obtained on dilution with water; total yield 1 g., m.p. 105–106°, mixed m.p. with a sample prepared by the method of Coppinger and Campbell,[6] 102–104°. The infrared spectra of the two samples were identical. Coppinger and Campbell report 98° as the m.p. for the acetate. Compound II does not undergo this rearrangement in acetic acid.

Reaction of I, II and Co^{++}.—A solution of 2 g. of II, 1 g. of I and 10 mg. of cobalt naphthenate in 25 cc. of *t*-butyl alcohol was allowed to stand at room temperature for 24 hr. The reaction mixture was extracted with 50 cc. of ether and washed free of *t*-butyl alcohol with water. The ether was removed and the residue was fractionally crystallized from methanol. The stilbene quinone V was isolated first, m.p. 293–295°, mixed m.p. 293–296°. Compound IV was obtained as the second fraction, m.p. 173–175°, mixed m.p. 173–175°. The third fraction obtained by removal of the methanol was recrystallized from isoöctane to obtain III, m.p. 110–112°, mixed m.p. 111–113°.

Substituent Effects on Naphthalene. Association Constants of Substituted Naphthalene–Picric Acid Complexes

BY PETE D. GARDNER AND WARREN E. STUMP

RECEIVED NOVEMBER 23, 1956

Association constants of the complexes formed by twenty-five systematically substituted naphthalenes with picric acid (picric acid) are equilibrated between chloroform and water and the extent to which the donor is capable of retaining the have been determined. The partition method was chosen for the study, wherein the donor compound and the acceptor acceptor in the chloroform phase is determined. It was found that complex stability is dictated by steric factors, inductive effects and resonance effects in the various series.

Molecular complexes formed by aromatic substances appear to be of two distinct types,[1,2] the type being determined largely by the nature of the acceptor. Those of the σ-type, exemplified by the aromatic–$HAlCl_4$[2] and aromatic–HBF_4[3] complexes, exhibit a very great stability dependence upon substituents, electron-donating substituents in the donor imparting increased strength to the complex. Complexation of the π-type,[2,4] on the other

hand, is not as easily defined, as it appears that the effect of substituents varies somewhat unpredictably with the nature of the acceptor.[2,5] It has been shown, for example, that stability in the benzene–silver ion complex is determined by substituents in the donor molecule so as to permit a correlation with Hammett's σ-values.[5] Such a correlation is not possible with complexes formed by substituted benzenes with picryl chloride and picric acid. The stability of the latter type of π-complex appears to reflect, among other things, the steric requirement[6] and the electron-withdrawing properties of the substituent.[7,8]

This paper is the first of several concerned with general substituent effects in naphthalene[9] and with those factors influencing π-complex formation by this compound. The method chosen for the present work is the partition method. Association constants determined in this way are invariably higher than those measured by the spectrophotometric method. There can be little doubt that complexation as measured by the partition method is more extensive than simple π-complex formation. The spectrophotometric method, on the other hand, appears to measure only π-complexation[10] involving the ring, and thus the two data correspond to two different processes. Whatever the differences are, they should not vary appreciably within a given class of substituents, and the series-correlations described below should be a reasonable measure of substituent effects. Apparent anomalies peculiar to the method include donors containing the nitro group and, as will be seen later, probably acetyl and alkoxy donors as well. For this reason caution must be exercised in the interpretation of data in these series. They are not without value, however, since one of the objectives of the study, which will include a later examination of the spectrophotometric method,[11] is an evaluation of those additional forces (dispersion, etc.) superimposed upon charge-transfer complexation and contributing to the higher association constants observed here.

Experimental

Partition Procedure.—The method used was a modification of that used by Moore, Shepherd and Goodall[12] and improved by Anderson and Hammick[6] in which the donor compound and the acceptor (picric acid) are equilibrated between chloroform and water, and the extent to which the donor is capable of retaining the acceptor in the chloroform phase is determined. Modifications incorporated are apparent from the description given below. This procedure proved to be less cumbersome than those previously used, and the precision and accuracy did not seem to be impaired.

Picric acid in the amount of 0.85–1.05 g. was weighed into each of four equilibration vessels by means of a weighing stick. Fifty milliliters of water was delivered into each vessel from a calibrated pipet, followed by the similar addition of 50.00 ml. of a chloroform solution of the compound (0.083–0.174 M) under investigation. The latter solution was prepared on a weight–weight basis and its concentration determined using the density of chloroform at 27°.[13] The stoppered vessels were tumbled at approximately 26° for 10–30 min. and then placed in a bath maintained at 27 ± 0.1° for at least 12 hr. with occasional agitation. Twenty milliliters of the clear, aqueous phase from each vessel was diluted with 50 ml. of equilibrium water and titrated with approximately 0.016 N sodium hydroxide solution (carbonate-free)[14] using methyl purple indicator[15] to the disappearance of brown. From data thus obtained, the quantity of picric acid in the aqueous phase and in the chloroform phase was determined.

A reference distribution curve was determined as a straight line plotted from ten points by the method of least squares. The resulting equation is

$$\log C_{CHCl_3} = 1.11564 \log C_{H_2O} + 1.27563$$

The average deviation of the ten points was 0.00270 in log C_{CHCl_3} which is an average deviation of 0.00066 in the "average" point. The probable deviation was 0.00021.

The change in picric acid content of the chloroform phase due to the presence of a donor compound was used to calculate the association constant for the interaction by eq. 1[6]

$$K_1 = \frac{Y - P}{Pz} \qquad (1)$$

where K_1 is the apparent stability constant, Y is the experimentally determined concentration of picric acid, P is the concentration of picric acid in the absence of donor compound and z is the concentration of donor compound. The "salting-out" effect of the donor substance on the solubility of picric acid in the chloroform phase was taken into account.[16,17] The association constant K_s is the sum of K_1 and the solubility-depression constant k.[6] It was found that, due to the considerably larger values of K_1 obtained in this work, one of the simplifying assumptions made in the original derivation of eq. 1[6] was not valid. Calculation of K_s values was therefore made using eq. 2.

$$K_s = \frac{1 - \sqrt{1 - 4P(K_1 + k)}}{2P} \qquad (2)$$

Confidence limits of the mean of K_s values were based on the "t" test of significance using the 90% confidence level. Rejection of individual determinations was decided upon after K_1 values were calculated, discarding any single value of the four which differed greatly from the remaining three, or upon comparing K_s values, again using the "t" test at the 90% confidence level. Eight determinations were used with many of the compounds.

Materials.—Chloroform was stored over calcium chloride and fractionally distilled before use. All reagents used were purchased or prepared by routine procedures except where noted. Solids were recrystallized to constant m.p. and liquids were fractionally distilled or, in many cases, purified by crystallization of the picric acid complex followed by decomposition of the complex and fractional distillation of the donor. No significant discrepancies with literature values of physical constants were found; consequently, references to these are not included. The preparation of compounds followed procedures abstracted in Beilstein's "Handbuch" or *Chemical Abstracts*.

Experimental Results and Discussion

Association constants for all naphthalene derivatives studied are given in Table I along with mean K_1 and k values. Some of these data are represented graphically in Fig. 1.

A few of the complexes described below have been studied in other laboratories. Unfortunately, the various temperatures used render impossible

[a] Kindly supplied in a good state of purity by Dr. R. R. Twelves, Department of Chemistry, University of Minnesota. [b] The significant discrepancy between this value and that previously reported[12] (0.17) cannot be explained. [c] P, purchased. L, prepared as described in the literature.

any correlations within series. The temperature-dependence of complexation is illustrated in thermodynamic functions calculated from association constants determined in this study of the naphthalene complex at 27° (K_s = 2.31) and 8° (K_s = 3.31). An Arrhenius plot of log K_s *vs.* T^{-1} gives ΔH −3.1 kcal. mole^{-1} and from this and the ΔF values, $\Delta F_{27°}$ = −670 and $\Delta F_{8°}$ = −500 cal. mole^{-1}, there is obtained ΔS = −8.7 cal. deg.$^{-1}$. These values differ significantly from those reported for this complex as determined by the spectrophotometric method.[18] This general phenomenon is discussed above and by Ross, *et al.*[10]

Alkylnaphthalenes.–It is apparent that complex stability in both series of alkylnaphthalenes is determined by the steric requirement of the substituent. The order is also that expected of hypercongugative participation of substituents. In view of the nature of the π-complex,[1] of which these are examples, there is little reason to suspect that hyperconjugation can contribute significantly to the π-electron density on the ring even under the demand of complexation.[19] The relative decrease in complex stability with increasing size of substituent in the 2-alkyl series parallels rather closely that observed in the alkylbenzene series, $CH_3 > C_2H_5 >$ iso-C_3H_7.[6] The relative decrease is even greater in the 1-series, a trend reported previously in the pair $CH_3 > C_2H_5$.

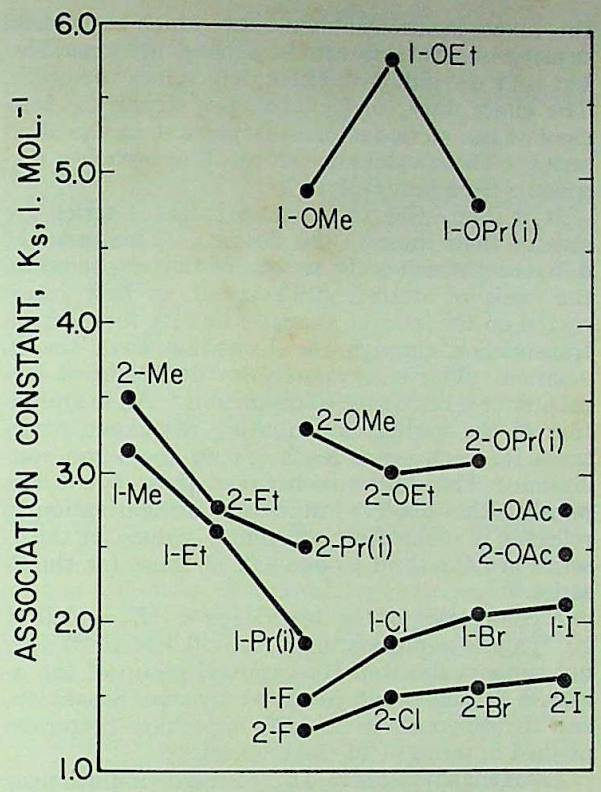

Fig. 1.

Halogenonaphthalenes.–As might be anticipated, association constants in these two series are much lower than those in the alkylnaphthalenes. The trend in both series is that dictated by the inductive effect of the substituent, constants in these series being in the order I > Br > Cl > F. It will be noted that this order is the reverse of that expected on the basis of steric requirement as well as that expected on the basis of the capacity for double bond formation by the substituent.[23] Values in these series parallel the order of substituent electronegativity.[24] Certainly it can be said that all of

the above-mentioned modes by which π-electron density on the ring can be altered are operative but that the inductive effect determines the order. The effect must, in fact, be very strong to overshadow the steric factor so important in the alkyl series. These values do not at all approach a reasonable Hammett σ-plot.[25]

It is interesting that values in the 1-series are greater than those in the 2-series. This order of difference, which is the reverse of that expected on the basis of steric considerations, is best interpreted on the basis of a greater facility for electron transmission through the 1-position than the 2-position. This is a capacity for double bond formation or a resonance phenomenon. An examination of the various contributing resonance structures for each series leads one to the same conclusion. The difference between these two series parallels that observed in molecular polarization as reflected in molar Kerr constants; values for the 1-series are one-third to one-half of those for the 2-series.[26]

A comparison of the acidities of α- ($K_a = 2.0 \times 10^{-4}$) and β-naphthoic acid ($K_a = 6.9 \times 10^{-5}$) does not support this, but the carboxyl group of the α-isomer is somewhat hindered by the 8-position, and the difference in acidities is perhaps better explained in terms of an "*ortho* effect."[27]

Alkoxynaphthalenes.–The 1-alkoxynaphthalene complexes are significantly more stable than those of the 2-series. Here again it is apparent that the difference between the two series is best explained in terms of a greater facility for double bond formation at the 1-position; resonance effects here, as in the halogenonaphthalenes, dictate the relative series difference. Values within each series, however, do not follow any reasonable order and as yet are unexplained.

Acetonaphthones.–The association constant for the 1-acetonaphthone complex is seen to be greater than that of the 2-isomer, but both values are significantly higher than might be anticipated. The presence of the acetyl group in either position should effectively diminish the π-electron density on the ring and thereby weaken the complex binding. The fact that these values are comparable with those of the ethylnaphthalenes, which have a similar steric requirement in the substituent, suggests that other factors are involved in the acetonaphthones. It is possible, for example, that the carbonyl group behaves as a "localized" donor as appears to be the case with aryl amines,[1] and possibly with the alkoxynaphthalenes considered above and the association constants reflect both types of complexation. This explanation is supported by the higher value for the 1-isomer; resonance effects, transmitted through the 1-position more readily than the 2-position, should permit greater polarization of the carbonyl group in the 1-isomer. In this regard, it should be noted that even 1-nitronaphthalene has an appreciable tendency to complex with picric acid.

AUSTIN, TEXAS

(25) This is perhaps apparent from a cursory inspection of the σ-values (*meta* or *para*) in the halogen series. The order of electron-withdrawing power is the reverse of that observed here.

Formation of the Silicon–Hydrogen Bond by the Reducing Action of Certain Sterically Hindered Grignard Reagents on Phenyltrichlorosilane

BY MACK C. HARVEY, WILLIAM H. NEBERGALL AND JOHN S. PEAKE

RECEIVED DECEMBER 10, 1956

Certain sterically hindered Grignard reagents have been found to react with phenyltrichlorosilane, $C_6H_5SiCl_3$, to form dialkylphenylsilanes, $R_2C_6H_5SiH$, and unsaturated hydrocarbons. By such reactions dicyclohexylphenylsilane and cyclohexene, dicyclopentylphenylsilane and cyclopentene, diisopropylphenylsilane and propene and di-*t*-butylphenylsilane and isobutylene have been obtained. Attempts to prepare di-*o*-tolylphenylsilane by this method were unsuccessful.

In 1933, Cusa and Kipping[1] reported that when no precautions were taken to exclude atmospheric oxygen, cyclohexoxydicyclohexylphenylsilane, $(C_6H_{11})_2C_6H_5SiOC_6H_{11}$, was formed when the product of the reaction of phenyltrichlorosilane with an excess of cyclohexylmagnesium bromide was hydrolyzed. When the reaction was carried out under nitrogen, however, the principal reaction product was found to be dicyclohexylphenylsilane, $(C_6H_{11})_2C_6H_5SiH$. These investigators suggested that $(C_6H_{11})_2C_6H_5SiMgBr$ was formed as an intermediate, which upon hydrolysis gave $(C_6H_{11})_2C_6H_5SiH$.

$$C_6H_5SiCl_3 + 2C_6H_{11}MgBr \longrightarrow (C_6H_{11})_2C_6H_5SiCl + 2MgBrCl$$

$$(C_6H_{11})_2C_6H_5SiCl + C_6H_{11}MgBr \longrightarrow (C_6H_{11})_2C_6H_5SiMgBr + C_6H_{11}Cl$$

$$(C_6H_{11})_2C_6H_5SiMgBr + H_2O \longrightarrow (C_6H_{11})_2C_6H_5SiH + Mg(OH)Br$$

It should be noted that tricyclohexylphenylsilane is not formed here due to the steric effects of the cyclohexyl group.[1,2]

Because various workers[3,4] have been unsuccessful in attempts to prepare stable Grignard type silicon–magnesium compounds, it was decided to repeat the work of Cusa and Kipping in an effort to determine the mechanism of the formation of

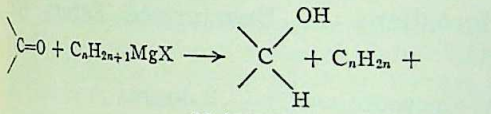
the silicon–hydrogen bond in dicyclohexylphenylsilane.

In the present investigation it was found that dicyclohexylphenylsilane is formed prior to the hydrolysis of the reaction mixture, which shows that the mechanism proposed by Cusa and Kipping[1] cannot be correct. It was also found that cyclohexene is a reaction product, an important fact that apparently was overlooked by the previous workers.

Because the steric effect of the cyclohexyl group is important in determining the course of the reaction, it was decided to try the action of other sterically hindered Grignard reagents upon phenyltrichlorosilane. Thus, it has been found that Grignard reagents containing the cyclopentyl, isopropyl and *t*-butyl groups react with phenyltrichlorosilane to form dicyclopentyl-, diisopropyl- and di-*t*-butyl-phenylsilane, respectively. The corresponding unsaturated hydrocarbons cyclopentene, propene and isobutylene were also identified as reaction products.

There are many reports in the literature concerning the reducing action of Grignard reagents toward carbonyl compounds. In these reactions the carbonyl compound is reduced to an alcohol and the alkyl group of the Grignard reagent is changed to an alkene.



$Mg(OH)X$ (after hydrolysis)

Generally, the reduction of carbonyl compounds by Grignard reagents has been observed in instances in which the normal addition reaction may be hindered sterically. Furthermore, reduction is observed usually with Grignard reagents which possess a hydrogen atom beta to the magnesium atom. According to mechanisms proposed by Whitmore[5] and by Wiberg and Bauer[6] for reactions of this type, the β-hydrogen shifts to the carbon atom of the carbonyl group and an alkene is formed.

The reduction of the silicon–chlorine bond by sterically hindered Grignard reagents appears to be similar to that observed for the carbonyl group. Thus we may write the following equations for the reaction of phenyltrichlorosilane with an excess of cyclohexylmagnesium bromide

$$C_6H_5SiCl_3 + 2C_6H_{11}MgBr \longrightarrow (C_6H_{11})_2C_6H_5SiCl + 2MgBrCl$$

$$(C_6H_{11})_2C_6H_5SiCl + C_6H_{11}MgBr \longrightarrow (C_6H_{11})_2C_6H_5SiH + C_6H_{10} + MgBrCl$$

Similar equations can be written for the reactions involved when cyclopentyl-, isopropyl- and *t*-butylmagnesium halides were employed. Additional evidence that a β-hydrogen atom is involved in the mechanism is provided by the fact that *o*-tolylmagnesium bromide, which does not contain an easily removable β-hydrogen atom, failed to reduce the silicon–chlorine bond of phenyltrichlorosilane.

Experimental

All reactions involving a Grignard reagent were carried out in an atmosphere of oxygen-free, dry nitrogen. The ether used as a solvent was previously dried over sodium. All melting points and boiling points are uncorrected.

Dicyclohexylphenylsilane.—Magnesium turnings (37 g., 1.53 g. atoms) were placed in a one-liter, three-necked flask fitted with a motor-driven stirrer, reflux condenser, dropping funnel and nitrogen inlet. The magnesium was covered with anhydrous ethyl ether and nitrogen passed through the system to remove all air. The Grignard reagent was prepared by adding slowly a 30% solution of cyclohexyl bromide (253 g., 1.53 moles) in ether. After the addition of the cyclohexyl bromide was completed, the reaction mixture was refluxed for 2 hr. Phenyltrichlorosilane (25 g., 0.118 mole) in an equal volume of ether was added slowly to the Grignard reagent. The reaction mixture was then heated to 160–170° with all the volatile material being condensed and collected. Redistillation of the distillate gave 21 g. (0.25 mole) of cyclohexene, boiling at 81–82° (747 mm.). This compound was identified by its boiling point, unsaturation and infrared spectrum. A small portion of the residue in the distillation flask was extracted with ethyl ether and the ether removed by distillation. An infrared spectrum recorded for the residual liquid showed a strong Si–H bond.[7] This showed that dicyclohexylphenylsilane was produced prior to hydrolysis. The remainder of the residue in the distillation flask was hydrolyzed by a mixture of ice and dilute hydrochloric acid. The organic layer was extracted with ethyl ether, the ether solution dried over Drierite and the ether removed by distillation. Distillation of the residual liquid under reduced pressure gave 8.0 g. of dicyclohexyl (100–140° at 2.5 mm., and 236° at 737 mm.), 21 g. (0.078 mole) of dicyclohexylphenylsilane (124° at 0.03 mm.) and a small quantity of high-boiling polymeric material. The yield of $C_6H_5(C_6H_{11})_2SiH$ was 66%, $n^{25}D$ 1.538.

Anal. Calcd. for $C_{18}H_{28}Si$: C, 79.3; H, 10.3. Found: C, 79.3; H, 10.3.

Another experiment was conducted in which the above procedure was modified by holding the reaction mixture at the reflux temperature of the solvent for 30 hr. before hydrolysis. The yield of dicyclohexylphenylsilane in this experiment was only 2.0 g. (6%). This shows that the reduction of the silicon–chloride bond by the Grignard reagent is favored by higher temperatures.

Diisopropylphenylsilane.—Isopropylmagnesium chloride was prepared using 188 g. (1.53 moles) of isopropyl chloride and 37 g. (1.53 g. atoms) of magnesium. To the Grignard reagent was added 25 g. (0.118 mole) of phenyltrichlorosilane in an equal volume of ether. After the addition was completed, all volatile material was distilled into an ice-cooled chloroform solution of bromine, with the distillation flask being heated to 160–170°. The chloroform solution was then washed with a saturated aqueous solution of sodium sulfite to remove excess bromine, and, after drying the chloroform layer over Drierite, the chloroform was removed by distillation. The residual 1,2-dibromopropane distilled at 139–141° (747 mm.). This compound was identified by its boiling point and infrared spectrum; yield 61 g. (0.32 mole).

The residue in the distillation flask was worked up as described in the above experiment. The product obtained was diisopropylphenylsilane, which distilled at 58–60° (1.2 mm.), $n^{25}D$ 1.495, yield 24 g. (50%).

Anal. Calcd. for $C_{12}H_{20}Si$: C, 75.0; H, 10.4. Found: C, 74.8; H, 10.5.

Dicyclopentylphenylsilane.—The procedure described above was repeated using the Grignard reagent prepared from 238 g. (1.53 moles) of cyclopentyl bromide and 25 g. (0.118 mole) of phenyltrichlorosilane. The volatile material produced by heating the reaction mixture to 160–170° was condensed and redistilled. The cyclopentene formed as a reaction product distilled at 43–44° (747 mm.), yield 8 g. (0.12 mole). This compound was identified by its boiling point, unsaturation and infrared spectrum.

The dicyclopentylphenylsilane, which was obtained upon working up the residue in the distillation flask, distilled at 100° (0.03 mm.), $n^{25}D$ 1.529, yield 14.3 g. (49%).

Anal. Calcd. for $C_{16}H_{24}Si$: C, 78.6; H, 9.90. Found: C, 78.8; H, 9.96.

Di-*t*-butylphenylsilane.—The procedure described above was repeated using the *t*-butylmagnesium bromide prepared from 279 g. (1.53 moles) of *t*-butyl bromide and 25 g. (0.118 mole) of phenyltrichlorosilane. The volatile material produced by heating the reaction mixture to 160–170° was passed into an ice-cooled chloroform solution of bromine. The chloroform solution was washed with an aqueous saturated solution of sodium sulfite to remove the excess bromine. The chloroform layer was dried over Drierite and the chloroform removed by distillation. The residual isobutylene bromide distilled at 149° (747 mm.), yield 27 g. (0.128 mole). This compound was identified by its boiling point and infrared spectrum.

The di-*t*-butylphenylsilane, which was obtained upon working up the residue in the distillation flask, distilled at 46° (0.4 mm.), yield 5.5 g. (10%), $n^{25}D$ 1.489.

Anal. Calcd. for $C_{14}H_{24}Si$: C, 76.4; H, 10.96. Found: C, 76.6; H, 10.90.

Attempted Preparation of Di-*o*-tolylphenylsilane.—The procedure described above was repeated using the Grignard reagent prepared from 190 g. (1.1 moles) of *o*-tolyl bromide and 11 g. (0.077 mole) of phenyltrichlorosilane. Ether was the only volatile compound recovered when the reaction mixture was heated to 160–170°. Upon working up the residue in the distillation flask and distilling the organic layer, toluene and a high-boiling, semi-crystalline material were obtained. An infrared spectrum of this material did not show the Si–H bond. This material was dissolved in a hot solution of alcoholic sodium hydroxide, from which 4 g. of a white crystalline solid precipitated upon cooling. Recrystallization from absolute alcohol gave a product which melted at 87–89°. Infrared spectral analysis showed the solid to contain the following groups: C_6H_5–Si, *o*-$CH_3C_6H_4$–Si–OH and Si–O. This compound may be di-*o*-tolylphenylsilanol, $(o\text{-}CH_3C_6H_4)_2C_6H_5SiOH$.

Anal. Calcd. for $C_{20}H_{20}OSi$: C, 78.9; H, 6.60. Found: C, 79.0; H, 7.2.

Another experiment was conducted in which the above procedure was modified by holding the reaction mixture at the reflux temperature for 4 hr. Upon hydrolysis of the reaction mixture a white solid was precipitated. This solid was recrystallized from hot toluene, giving 1.6 g. (0.07 mole) of product, m.p. 103°; identified as being *o*-tolylphenylsilanediol, $(o\text{-}CH_3C_6H_4)C_6H_5Si(OH)_2$.

Anal. Calcd. for $C_{13}H_{14}O_2Si$: C, 67.8; H, 6.10. Found: C, 67.8; H, 6.3.

Acknowledgments.—Analyses were by Miss J. Dickey of the Indiana University Microanalytical Laboratory. This paper is based upon work performed under contract Nonr-90802-Task NR 356-321 (Office of Naval Research).

Aliphatic Organo-functional Siloxanes. V. Synthesis of Monomers by Platinum-catalyzed Addition of Methyldichlorosilane to Unsaturated Esters and Nitriles[1]

BY L. H. SOMMER, F. P. MACKAY, O. W. STEWARD AND P. G. CAMPBELL

RECEIVED NOVEMBER 23, 1956

Extension of an important synthesis discovered by G. H. Wagner, which involves platinum-catalyzed addition of silicon hydrides to olefins, has resulted in simple synthetic routes to nine monomers for organo-functional siloxanes. The nitriles and esters being reported have a functionality of 2 at the silicon atom. Reaction of methyldichlorosilane with acrylate esters results in addition of the silyl group to the non-terminal olefinic carbon and thus gives products in which the ester group is readily cleaved from silicon. In important contrast, methacrylate esters give addition of the silyl group to the terminal olefinic carbon and yield adducts which are stable toward cleavage of the ester group from silicon. Olefins in which the functional group is not conjugated with the double bond give products resulting from addition of the silyl group to the terminal olefinic carbon.

Introduction.—If organosilicon chemistry is to progress appreciably beyond the point represented in organic chemistry by monomers and polymers in which the basic chain of atoms (C–C–C bonds in organic chemistry and Si–O–Si groupings in organosilicon chemistry) bears unsubstituted hydrocarbon substituents, it seems essential that simple synthetic procedures be developed for the preparation of monomers which can easily be converted to aliphatic organo-functional siloxanes.

Previous publications from this Laboratory have reported synthetic approaches to aliphatic organo-functional siloxanes involving selective cleavage of one methyl group from trimethylsilyl, Me_3Si, in a variety of organo-functional silanes through reaction with concd. sulfuric acid.[2a,b,c]

More recently, the direct synthesis of organosiloxane esters and acids from halomethylsiloxanes and halomethylethoxysilanes has been reported. These latter syntheses represented a definite improvement over the former method and involved reaction, in suitable solvents, of the halomethylsilanes with anions derived from ethyl malonate and ethyl cyanoacetate. Organofunctional monomers in which the silicon is mono- as well as difunctional can be made by this synthesis.[2d]

However, an even simpler and more direct synthetic route obviously was desirable. In the present paper we wish to record such a synthesis which leads easily to aliphatic organo-functional monomers in which the functionality at the silicon atom is 2.

The addition of trichlorosilane to simple olefins proceeds smoothly and in excellent yield in the presence of diacetyl peroxide or ultraviolet light.[3] Addition of compounds containing the Si–H bond

$$R{-}CH{=}CH_2 + HSiCl_3 \xrightarrow[\text{or u.v. light}]{(CH_3COO)_2} RCH_2CH_2SiCl_3$$

to olefins also takes place in the absence of a catalyst at elevated temperatures (about 300°).[4]

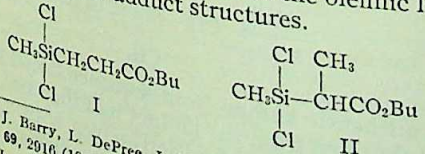
More recently, the addition of phenylsilane, diphenylsilane, phenylmethylsilane, amylsilane and tribromosilane to olefins in the presence of *t*-butyl perbenzoate has been reported.[5] However, attempts to extend this procedure to readily available olefins such as methyl acrylate or acrylonitrile resulted in rapid polymerization of the olefin. Thus, peroxide-catalyzed additions of silanes to olefins containing functional groups suffer from the limitations placed on this procedure by the polymerization of the readily available "vinyl monomers." A further limitation is provided by the greatly decreased reactivity of the Si–H bond in alkyldichlorosilanes as compared to trichlorosilane when a peroxide catalyst is used.[3]

In 1953, G. H. Wagner reported the use of platinum supported on finely divided charcoal as a catalyst for the addition of silicon hydrides to a number of olefins and to acetylene.[6] The addition reactions were performed at pressures of 45 to 115 p.s.i. and reaction temperatures of 100 to 300°. The olefins used were ethylene, allyl chloride, trichloroethylene, vinylidene fluoride and butadiene. Trichlorosilane was the silicon hydride most generally used. However, examples of addition reactions of triethoxysilane, ethyldichlorosilane and dichlorosilane also were reported.

In another publication Wagner and co-workers[7] reported the preparation of β-phenylethyltrichlorosilane by addition of trichlorosilane to styrene at 200° (20 hr. in a stainless steel pressure reactor) in the presence of *t*-butylcatechol (inhibitor) using 5% platinum on powdered charcoal. The yield of product was excellent.

In view of the above good results obtained with platinized charcoal catalyst using an easily polymerizable olefin such as styrene, it seemed that this catalyst might also be effective for the addition of silicon hydrides to other readily available "vinyl monomers." Application of this procedure to olefinic esters would provide a simple and direct route to the intermediates for organopolysiloxane ester systems.

Platinum-catalyzed Addition of Methyldichlorosilane to Acrylates and Methacrylates.—In the present work reaction of *n*-butyl acrylate with methyldichlorosilane (2% Pt–C catalyst) in an all-glass apparatus at atmospheric pressure proceeded slowly. During 16 hr. the boiling point of the reaction mixture increased from 67 to 145°. Fractionation gave a 42% yield of adduct which analyzed correctly for *n*-butyl methyldichlorosilylpropionate. Addition of Si–H to the olefinic linkage can lead to two adduct structures.

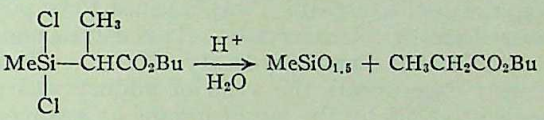


I

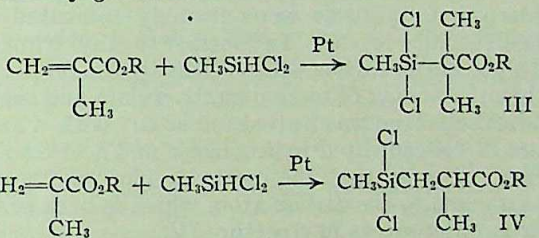
II

Structure II contains the Si—C—C=O grouping which is known to give carbon–silicon cleavage with acids and bases. For example, ethyl trimethylsilylacetate gives ethyl acetate when treated with dilute acid.[8] In contrast, structure I contains the

Si—C—C—C=O system which is stable toward cleavage of its C–Si bond with most reagents. When the adduct obtained from *n*-butyl acrylate was treated with water, a resinous solid separated and an oily upper layer formed. The organic layer upon distillation gave a 75% yield of *n*-butyl propionate. This result indicates structure II for the adduct.[9]



As another possible means of synthesizing the Si—C—C—C=O system through the platinum-catalyzed addition of silicon hydrides to olefins, the use of methacrylate esters was investigated next. The basis for this study was the possibility that the α-methyl group in methacrylate esters would lead to the desired mode of addition because of the steric requirements of that methyl group and/or its hyperconjugation with the olefinic double bond.



III

IV

The latter reaction was in fact realized with *n*-butyl methacrylate and compound IV (R = *n*-Bu) was obtained.

When methyldichlorosilane and *n*-butyl methacrylate were heated in the presence of 2% Pt–C, the boiling point of the reaction mixture increased to a maximum of 120° after 3 hr. Fractionation gave a 32% yield of *n*-butyl α-methyl-β-methyldichlorosilylpropionate, IV (R = *n*-Bu). This product when poured into water gave an oil but no solid. Treatment of this oil with hot acetic–hydrochloric acid mixture gave a stiff, acidic, silicon-containing polymer. If addition had given a product containing the silicon atom linked to the α-carbon of the methacrylate ester, the expected hydrolysis products would be methylpolysiloxane and *n*-butyl iso-

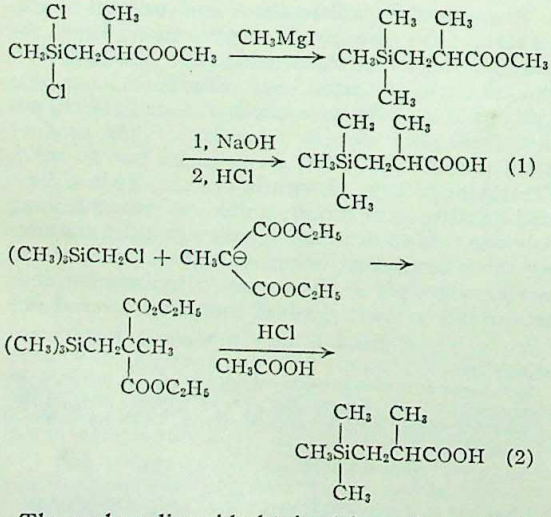
butyrate. Neither of these substances was formed on treatment of the adduct with water. (A definitive proof of the structures of the adducts obtained from methyl and ethyl methacrylates with methyldichlorosilane is given below.)

The addition of silicon hydrides to *methyl* methacrylate would provide an exceedingly convenient method for the preparation of silicon-containing esters since methyl methacrylate is more readily available than other methacrylate esters. Methyl methacrylate and methyldichlorosilane were heated together in the presence of 2% Pt–C. Within 3 hr. the boiling point of the reaction mixture increased from 54 to 142°. Fractionation gave a 58% yield of methyl α-methyl-β-methyldichlorosilylpropionate, IV (R = Me). There remained a large residue from the distillation which was believed to be polymerized methyl methacrylate. This corresponded to 24.5% of the starting quantity of ester. In subsequent experiments the yield of adduct was increased to 86% by the use of hexane as a solvent. An excess of methyldichlorosilane (100%) also increased the yield to 70%. Both of these procedures lowered the reaction temperature and greatly decreased the amount of polymerization of the methyl methacrylate. Similar results were obtained with ethyl methacrylate giving ethyl α-methyl-β-methyldichlorosilylpropionate, IV (R = Et) in 74% yield.

The structures of the methylacrylate methyldichlorosilane adducts were strongly indicated by their stability to acid. In contrast to ethyl trimethylsilylacetate, carbon–silicon cleavage did not occur when the adduct of methyl methacrylate and methyldichlorosilane was heated for 12 hr. with a mixture of concentrated hydrochloric and acetic acids. This indicates that the methyldichlorosilyl group is attached to the carbon atom which is beta to the carbonyl group as in structure IV.

A more definitive proof of structure for the methyldichlorosilane–methacrylate adducts was provided by the syntheses



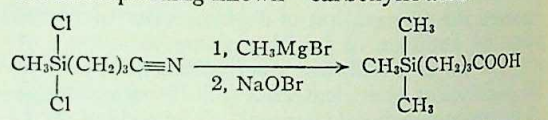
The carboxylic acid obtained from the methyldichlorosilane–methyl methacrylate adduct in sequence 1 was identical in physical properties with the acid obtained from the independent synthesis in sequence 2. The *p*-bromoanilide derivatives had the same m.p. and mixed m.p. Thus structure IV is shown to be the correct one.

Platinum-catalyzed Addition of Methyldichlorosilane to Unconjugated Olefinic Esters and Nitriles.—Table I gives data on the addition of methyldichlorosilane to nine olefinic esters and nitriles. Methyldichlorosilane reacts very readily with all of the unconjugated olefinic esters and nitriles in Table I. For the addition reactions of these olefins with methyldichlorosilane, it is usually advisable to add the silane slowly to the olefin and catalyst maintained at a temperature of 70–100°. The reaction is generally quite exothermic and may become very vigorous if all of the reactants are mixed and then heated. Platinum-on-charcoal catalyst (2% Pt) in the amount of 1 g. per mole of olefin is usually sufficient.

The methacrylates are far less reactive than the other olefins listed in Table I and hence can be mixed with catalyst and methyldichlorosilane and then heated.

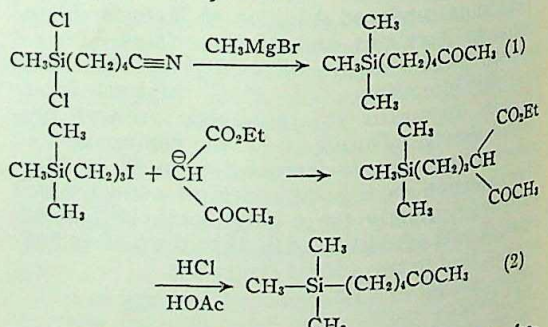
Evidence for addition of the silyl group to the terminal carbon of the unconjugated olefinic esters and nitriles of Table I was obtained by means of proofs of structure for three of the adducts.

The adduct from allyl cyanide was treated with methylmagnesium bromide to give 5-trimethylsilyl-2-pentanone and the ketone was then converted to the corresponding known[2a] carboxylic acid.



The authentic γ-trimethylsilylbutyric acid[2a] and the acid derived from the adduct had the same physical properties and gave derivatives with *p*-bromophenacyl bromide having the same melting point. A mixed m.p. showed no depression.

The adduct from 4-pentenonitrile was treated with methylmagnesium bromide to give 6-trimethylsilyl-2-hexanone. The same ketone was obtained from an acetoacetic ester synthesis using 3-iodopropyltrimethylsilane.



The authentic ketone from sequence 2 and the ketone obtained from the adduct had the same physical properties and gave derivatives with 2,4-dinitrophenylhydrazine having the same melting points. A mixed m.p. showed no depression.

The adduct from ethyl 4-pentenoate was treated with methylmagnesium bromide to give 6-trimethylsilyl-2-hexanol. The same alcohol, as

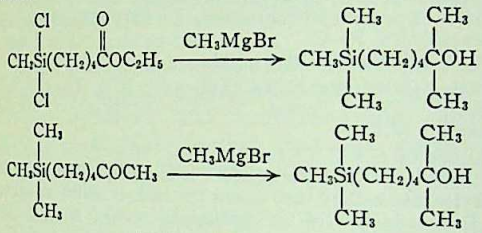
[a] Proposed structure for the adduct but definitive proof not obtained. [b] Yields are based on amount of olefin since an excess (about 10–20%) of methyldichlorosilane generally was used.

shown by physical properties and identical infrared spectrum, was obtained from reaction of 6-trimethylsilyl-2-hexanone with methylmagnesium bromide.



Experimental

Starting Materials.—Methyldichlorosilane, b.p. 41°, was obtained from Dow Corning Corp. and fractionally distilled before being used. Methyl methacrylate was used directly as obtained from Rohm and Haas Co. Ethyl methacrylate was the commercial grade supplied by Monomer–Polymer Inc. *n*-Butyl methacrylate was prepared by the reaction of methacrylic acid with *n*-butyl alcohol in the presence of sulfuric acid and hydroquinone. *n*-Butyl acrylate was supplied by Union Carbide and Carbon Corp. Ethyl vinylacetate was prepared from vinylacetyl chloride by the method of Jeffery and Vogel.[10] Dehydrochlorination of 4-chlorovaleronitrile, supplied by the du Pont Co., was effected in 50% yield by the use of quinoline, giving 4-pentenonitrile, b.p. 143° (730 mm.), $n^{20}D$ 1.4206.[11] 4-Pentenoic acid[12] was prepared by hydrolysis of 4-pentenonitrile. Ethyl 4-pentenoate was prepared from the acid by the method of Paul.[13]

The 2% Pt–C catalyst was supplied by Baker and Co.

Reaction of *n*-Butyl Acrylate and Methyldichlorosilane.—In an all-glass apparatus consisting of a 500-cc. flask and a glass-jointed condenser were placed 90 g., 0.7 mole, of *n*-butyl acrylate, 82 g., 0.71 mole, of methyldichlorosilane and 1 g. of 2% platinum-on-charcoal. After heating at reflux temperature for 16 hr., the temperature of the boiling reaction products was 145° as compared to an initial temperature of 67°. The reaction mixture was cooled, filtered to remove the catalyst and fractionated. There was obtained 71.7 g., 0.29 mole, of *n*-butyl methyldichlorosilylpropionate, b.p. 76° (3 mm.), 42% yield.

Anal. Calcd. for $C_8H_{16}SiO_2Cl_2$: Si, 11.5; Cl, 29.2. Found: Si, 11.7; Cl, 28.4.

When 20 g., 0.08 mole, of the adduct was poured into water, a solid and two liquid layers were formed. The solid was removed by filtration and the liquid layers were separated. Fractionation of the dried upper layer gave *n*-butyl propionate, b.p. 145°, 8 g., 0.06 mole, 75% yield, sapn. equiv. 131 (calcd. 130). This experiment clearly shows rapid C–Si cleavage and thus strongly indicates that the adduct is *n*-butyl α-methyldichlorosilylpropionate (II).

Reaction of *n*-Butyl Methacrylate and Methyldichlorosilane.—In an all glass apparatus consisting of a 500-cc. flask and a condenser were placed 72 g., 0.5 mole, of methyldichlorosilane, 1 g. of 2% Pt–C and 2 g. of hydroquinone (inhibitor). After heating for 3 hr. at reflux, the temperature of the reaction products in the flask had reached 120°. Heating at reflux was continued for 10 additional hr., but there was no further temperature rise. At this point the reaction mixture was cooled and 27 g., 0.23 mole, of additional methyldichlorosilane and 0.25 g. of Pt–C were added. Heating was then resumed, but the temperature fell to 87° where it remained during 12 more hr. of heating. Fractional distillation of the product gave *n*-butyl α-methyl-β-methyldichlorosilylpropionate (IV), 42.8 g., 0.16 mole, 32% of theoretical. When the product was treated with water, an oil was formed which contained no *n*-butyl isobutyrate. Further treatment of the oil with hot concd. hydrochloric–glacial acetic acid mixture gave no C–Si cleavage. A polysiloxane–polycarboxylic acid was obtained as a stiff polymer with considerable affinity for glass surfaces.

Reaction of Methyl Methacrylate and Methyldichlorosilane.—(a) In an all-glass apparatus consisting of a 500-cc. flask and a condenser were placed 110 g., 1.1 moles, of methyl methacrylate; 138 g., 1.2 moles, of methyldichlorosilane; 1.5 g., of 2% Pt–C and 1 g. of hydroquinone. This mixture was heated to the boiling point, 54°. The temperature rose steadily. After 3 hr. of heating, it had reached 142°. There was no additional temperature rise in 24 more hr. of heating. Fractionation gave methyl α-methyl-β-methyldichlorosilylpropionate, compound IV (R = CH_3), in 58% yield.

(b) The reaction was carried out in the same apparatus as above with the following quantities of materials: 50 g., 0.5 mole, of methyl methacrylate; 115 g., 1 mole, of methyldichlorosilane; 1 g. of 2% Pt–C; 1 g. of hydroquinone. These materials were heated from 60 to 87° (excess CH_3SiHCl_2 kept the temperature down) for 24 hr. The yield of product was 70% of the theoretical.

(c) The reaction was carried out with the following quantities of materials: 50 g., 0.5 mole, methyl methacrylate; 65 g., 0.56 mole, of methyldichlorosilane; 0.5 g. of 2% Pt–C; 1 g. of hydroquinone; 200 cc. of hexane as a solvent. These materials were heated from 64 to 75° for 16 hr. The yield of product was 86%.

(d) The reaction was attempted with the following materials: 100 g., 1 mole, of methyl methacrylate; 200 g., 1.8 moles, of methyldichlorosilane; 0.5 g. of *rhodium*-on-charcoal (Baker and Co.). When the rhodium catalyst was added to the methyldichlorosilane, there was a small flash of flame which immediately stopped. The reaction mixture was then heated at 56° for three days. No adduct was obtained.

Use of 5% palladium-on-charcoal and of Raney nickel as catalysts also gave *no* Si–H addition.

Additions of Methyldichlorosilane to Unconjugated Olefinic Esters and Nitriles.—A detailed description of the general procedure used in a typical reaction is as follows: Allyl cyanide, 101 g., 1.5 moles, and 0.75 g. of 2% Pt–C catalyst were placed in an all-glass apparatus equipped with a thermometer well, separatory funnel and condenser. (Rubber stoppers were *not* used in these preparations to avoid the possibility of sulfur poisoning of the catalyst.) The apparatus was vented through a concd. sulfuric acid Gilman trap. Allyl cyanide was then heated to reflux temperature

Digitized by Arya Samaj Foundation Chennai and eGangotri

and methyldichlorosilane, 195 g., 1.7 moles, was added dropwise over a period of 2 hr. The reaction mixture was then heated overnight to ensure complete reaction. Fractionation of the filtered reaction product by means of a column packed with glass helices gave the product in 73% yield.

Proof of the Structure of the Methacrylate–Methyldichlorosilane Adducts. A. Reaction of Methylmagnesium Iodide with the Adduct, Methyl α-Methyl-β-methyldichlorosilylpropionate.—Addition of methylmagnesium iodide, 1 mole in 300 cc. of ether, to 108 g., 0.5 mole, of the adduct during 5 hr. was followed by stirring at room temperature for 20 hr. Treatment with water and dilute hydrochloric acid followed by fractionation gave methyl α-methyl-β-trimethylsilylpropionate, 22.4 g., 0.16 mole, b.p. 78° (28 mm.), $n^{20}D$ 1.4202, 32% yield.

Anal. Calcd. for $C_8H_{18}SiO_2$: Si, 16.1; sapn. equiv., 174; MR_D, 50.57. Found: Si, 15.8; sapn. equiv., 173; MR_D, 50.50.

B. Saponification of Methyl α-Methyl-β-trimethylsilylpropionate.—A mixture of 19.3 g., 0.11 mole, of methyl α-methyl-β-trimethylsilylpropionate, 5 g., 0.12 mole, of sodium hydroxide, 10 cc. of ethyl alcohol and 10 cc. of water was refluxed on the steam-bath for 14 hr. It was then cooled and acidified with hydrochloric acid. The layers were separated and the water layer was extracted with ether. The ether extracts were combined with the main organic layer and the combined layers were dried over anhydrous magnesium sulfate. Fractional distillation gave 10.9 g., 0.068 mole, 62% yield, of α-methyl-β-trimethylsilylpropionic acid, b.p. 90° (3 mm.), $n^{20}D$ 1.4309.[14]

Anal. Calcd. for $C_7H_{16}SiO_2$: Si, 17.5; neut. equiv., 160. Found: Si, 17.6; neut. equiv., 159.

In a 50-cc. flask were placed 1 g. of α-methyl-β-trimethylsilylpropionic acid, 40 cc. of benzene and 0.5 g. of thionyl chloride. These materials were allowed to react at room temperature with shaking. After 2 hr., 1.2 g. of *p*-bromoaniline was added, and the reaction mixture was heated on the steam-bath for 2 minutes. The reaction mixture was then filtered. The filtrate was extracted with 5% hydrochloric acid and then evaporated to dryness. Recrystallization from hexane gave shiny white plates, m.p. 117.2–117.5°.

Anal. Calcd. for $C_{13}H_{20}O_2SiBrN$: Si, 8.50. Found: Si, 8.70.

C. Preparation of Authentic α-Methyl-β-trimethylsilylpropionic Acid.—This acid was prepared again by reaction in ethanol of sodiomethylmalonic ester with chloromethyltriethylsilane, followed by treatment of the resulting diethyl (trimethylsilylmethyl)-methylmalonate with concd. hydrochloric–glacial acetic acid mixture. Fractionation gave the acid having b.p. 90° (3 mm.), $n^{20}D$ 1.4311.

The *p*-bromoanilide prepared by the procedure described above had m.p. 117–117.5°. A mixed melting point of the derivatives gave no depression.

Proof of the Structure of the Allyl Cyanide–Methyldichlorosilane Adduct.—A solution of the adduct (γ-cyanopropyl)-methyldichlorosilane, 136 g., 0.75 mole, in 200 cc. of ether was added to 2.7 moles of methylmagnesium bromide in 700 cc. of ether. After stirring and refluxing for 12 hr., the reaction mixture was hydrolyzed and treated with hydrochloric acid. Fractionation gave 5-trimethylsilyl-2-pentanone, 33.6 g., 0.21 mole, b.p. 71° (13 mm.), $n^{20}D$ 1.4231, d^{20} 0.8279, 30% yield.

Anal. Calcd. for $C_8H_{18}SiO$: Si, 17.7; MR_D, 48.80. Found: Si, 17.3; MR_D, 48.90.

Oxidation of 5-trimethylsilyl-2-pentanone with sodium hypobromite gave γ-trimethylsilylbutyric acid in 41% yield, b.p. 123° (16 mm.), $n^{25}D$ 1.4308.[15]

The *p*-bromophenacyl bromide derivative of the acid obtained from the adduct had m.p. 61–62°. *Anal.* Calcd. for $C_{15}H_{21}O_3SiBr$: Si, 7.85. Found: Si, 7.89.

The *p*-bromophenacyl bromide derivative from authentic acid[15] also had m.p. 61–62° and gave no depression in a mixed melting point determination.

Proof of the Structure of the Adduct from 4-Pentenonitrile and Methyldichlorosilane.—The adduct, 98.1 g., 0.5 mole, dissolved in 200 cc. of ether was stirred with methylmagnesium bromide, 1.75 moles, for 2 days and the reaction mixture was then hydrolyzed with water followed by dilute hydrochloric acid. The water layer was extracted three times with ether and the combined ether layers dried over magnesium sulfate. Fractional distillation gave 6-trimethylsilyl-2-hexanone, b.p. 85° (10 mm.), $n^{20}D$ 1.4289, d^{20} 0.8281.

Anal. Calcd. for $C_9H_{20}OSi$: Si, 16.3; MR_D, 53.43. Found: Si, 16.6; MR_D, 53.62.

The 2,4-dinitrophenylhydrazone was prepared and had m.p. 92.4–93°.

Anal. Calcd. for $C_{15}H_{24}O_4SiN_4$: Si, 7.97. Found: Si, 8.14.

The following comprises a description of the synthesis of authentic 6-trimethylsilyl-2-hexanone.

(γ-Chloropropyl)-methyldichlorosilane was prepared by addition of methyldichlorosilane to allyl chloride in the presence of 2% Pt–C. The product had b.p. 80° (18 mm.) and was obtained in 59% yield.

Anal. Calcd. for $C_4H_9ClSiCl_2$: Si, 14.7; Cl (attached to silicon), 37.0. Found: Si, 15.0; Cl (titration with 0.1 *N* alkali), 37.2.

Failure of the C–Cl bond to react with dilute alkali on titration shows that the product is indeed (γ-chloropropyl)-methyldichlorosilane and is not the adduct which would result from addition of the methyldichlorosilyl group to the non-terminal olefinic carbon. The latter would contain a C–Cl bond beta to silicon and should react quantitatively with alkali giving β-elimination.[16]

Treatment of (γ-chloropropyl)-methyldichlorosilane with excess methylmagnesium iodide gave γ-chloropropyltrimethylsilane, b.p. 148° (733 mm.), $n^{20}D$ 1.4310, d^{20} 0.8825, in 80% yield.

Anal. Calcd. for $C_6H_{15}SiCl$: Si, 18.6; MR_D, 44.38. Found: Si, 18.8; MR_D, 44.19.

Reaction of γ-chloropropyltrimethylsilane with sodium iodide in dry acetone gave γ-iodopropyltrimethylsilane, b.p. 103° (47 mm.), $n^{20}D$ 1.4910, d^{20} 1.3334, in 63% yield.

Anal. Calcd. for $C_6H_{15}SiI$: Si, 11.6; MR_D, 52.40. Found: Si, 11.9; MR_D, 52.59.

A solution of 133 g., 0.55 mole, of γ-iodopropyltrimethylsilane in 100 cc. of absolute alcohol was heated to reflux, and ethyl sodioacetoacetate, 0.55 mole, dissolved in 250 cc. of ethanol, was added *to* the iodide during 2.5 hr. The reaction mixture was then brought to the neutral point with hydrochloric acid. After distillation of the ethanol, removal of sodium iodide by washing with water, and drying, fractionation gave ethyl (γ-trimethylsilylpropyl)-acetoacetate, 92.2 g., 0.38 mole, b.p. 132° (9 mm.), $n^{20}D$ 1.4389, d^{20} 0.9269, a 68% yield.

Anal. Calcd. for $C_{12}H_{24}O_3Si$: Si, 11.5; MR_D, 69.09. Found: Si, 11.6; MR_D, 69.30.

The above substituted acetoacetate on heating with concd. hydrochloric acid gave authentic 6-trimethylsilyl-2-hexanone, b.p. 85° (10 mm.), $n^{20}D$ 1.4289, in 82% yield.

The 2,4-dinitrophenylhydrazone derivative of the authentic ketone had m.p. 92.5–93°. A mixed melting point with the derivative obtained above from the ketone derived from the adduct gave no depression.

Proof of the Structure of the Adduct from Ethyl 4-Pentenoate and Methyldichlorosilane.—The adduct, 60.8 g., 0.25 mole, was treated with 1.4 moles of methylmagnesium bromide. Fractionation of the product gave 6-trimethylsilyl-2-methylhexan-2-ol, 35.7 g., 0.19 mole, b.p. 93° (8 mm.), $n^{20}D$ 1.4377, d^{20} 0.8294, a 76% yield.

Anal. Calcd. for $C_{10}H_{24}OSi$: Si, 14.9; MR_D, 59.61. Found: Si, 15.0; MR_D, 59.53.

Authentic 6-trimethylsilyl-2-methylhexan-2-ol was pre-

(14) α-Methyl-β-trimethylsilylpropionic acid was prepared previously by reaction of ethyl α-methyl-α-trimethylsilylmethylacetoacetate with sodium ethylate in ethanol followed by treatment with hydrochloric acid. This gave the carboxylic acid having b.p. 92° (4 mm.), $n^{20}D$ 1.4310; L. H. Sommer and N. S. Marans, THIS JOURNAL, **72**, 1935 (1950).

(15) γ-Trimethylsilylbutyric acid was prepared previously by carbonation of the Grignard reagent derived from γ-bromopropyltrimethylsilane and had b.p. 118° (10 mm.), $n^{25}D$ 1.4320 [L. H. Sommer, E. Dorfman, G. M. Goldberg and F. C. Whitmore, THIS JOURNAL, **68**, 488 (1946)].

The Chromatographic Separation and Identification of Some Peptides in Partial Hydrolysates of White Turkey Feather Calamus

BY W. A. SCHROEDER, LOIS M. KAY, NANCY MUNGER, NANCY MARTIN AND JOAN BALOG

RECEIVED DECEMBER 11, 1956

Chromatographic investigations of partial acidic hydrolysates of unoxidized and oxidized white turkey feather calamus have resulted in the isolation and identification of 59 peptides. The sequences which have been observed suggest that unusual sequences do not occur in feather keratin. The possible relation of some of the more prominent sequences to the spatial structure of the proteins is discussed. The isolation and identification of cysteic acid peptides by means of ion-exchange chromatography are described.

Many published investigations treat the feather as a more or less homogeneous unit despite its visually apparent and morphologically distinct parts and despite the fact that the parts of a feather are known to develop from specific portions of the papilla.[1] Recent analyses[2,3] have shown that the amino acid composition is not identical in all parts of a feather, so that a distinct and properly characterized part only should be utilized for chemical investigations. The relatively good orientation which is observed in certain feather parts by X-ray diffraction might lead one to conclude that they are composed of a reasonably homogeneous protein, but cell walls and cell debris from the original growing feather certainly are not absent. Purification of the protein without alteration unfortunately is impossible because of its insolubility, so one is forced to use the material as it is obtained. Woodin[4] has obtained soluble keratin from whole feathers in an apparently homogeneous state with a molecular weight of about 10,000. This material is not unaltered protein inasmuch as it has been isolated after either oxidation or reduction. In the present paper, we describe the isolation and identification of peptides from partial hydrolysates of unaltered protein and of oxidized protein from white turkey feather calamus. Although the rachis has usually been used when well-oriented feather protein is desired, we have chosen the calamus for four reasons: (1) rachis and calamus develop from the same portion of the papilla, (2) the amino acid compositions are essentially identical, (3) the X-ray diffraction patterns for most of the calamus and for the rachis are identical,[5] and (4) necessary amounts of calamus are easy to obtain whereas the separation of the rachis from the medulla is laborious.

Experimental

Source of Calamus and Preparation of Oxidized Calamus.—The sample of white turkey feather calamus was prepared in the way previously described.[2]

Oxidized calamus for the investigation of cysteic acid peptides was prepared in the following manner which combines features of the methods of Schram, Moore and Bigwood[6] and of Hirs.[7] Preformed performic acid was prepared by mixing 9 volumes of 90% formic acid and one volume of 30% hydrogen peroxide. After an hour at room temperature, the mixture was cooled to 0° in an ice-bath and 25 ml. was added to 500 mg. of calamus in the form of pieces about 1 mm. square and 0.1 mm. thick. The reaction mixture was maintained at 0° for 16 hr. during which time the pieces of calamus became swollen but did not dissolve to any obvious extent. The reaction mixture was transferred with 50 ml. of ice-cold water to 350 ml. of ice-cold water in a lyophilizing bulb. The solution was then frozen and the solvents were removed by lyophilization. The process was repeated after the addition of 80 ml. of water. The residue contained pieces in the form of original calamus as well as the usual voluminous residue which soluble substances form on lyophilizing and it was evident that considerable solution had occurred during some part of the procedure.

Partial Hydrolysis of Calamus and Oxidized Calamus.—A 300-mg. sample of calamus and 3 ml. of concd. hydrochloric acid (Baker's Analyzed Reagent Grade) were placed in a 5-ml. volumetric flask. The stem of the flask was attached parallel to a shaft which was inclined at 45° and rotated at 25 r.p.m. In this way, the reaction mixture was constantly agitated for 48 hr. at 37°. Within a few minutes after hydrolysis was begun, the pieces of calamus began to swell and continued to do so until the liquid was almost filled. Gradual dissolving took place and was complete in 3 to 3.5 hr. to give a light brown solution which darkened somewhat during the remainder of the hydrolysis. After about 24 hr., a very small amount of dark insoluble material had become attached to the flask at the surface of the liquid; it was somewhat greasy and had a density less than that of water. It may be composed of sterols or fatty acids.

A 240-mg. sample of oxidized calamus in 2.5 ml. of concd. hydrochloric acid was hydrolyzed at 37° for 48 hr. with constant agitation as above. Most of the material dissolved almost immediately and the remainder within an hour to give a light brown solution. The same type of insoluble residue appeared after about 24 hr. At the end of the partial hydrolysis, the reaction mixture was transferred with 100 ml. of water to a lyophilizing bulb, the solution was frozen, and

the solvent was removed. The residue was then taken up in 10 ml. of water which was again removed by lyophilizing.

Ion-exchange Chromatography of the Partial Hydrolysate of Calamus.—The partial hydrolysate of calamus was chromatographed on a column of Dowex 50-X4 that was 2.2 × 100 cm. in dimension. The resin (200–400 mesh, high porosity, Lot No. 3198-42) was purified in the manner that Moore and Stein[8] describe for Dowex 50-X8 and the column was packed as they suggest. The proportion of mesh sizes in the resin for this column was 4 parts of through-200-mesh resin and one part of 120–200 mesh resin. The detergent BRIJ35 and thiodiglycol were omitted from the buffers which otherwise were prepared as prescribed.[8]

The partial hydrolysate of calamus prepared as above was made up for chromatography by diluting with 42 ml. of *p*H 6.7 buffer after which the *p*H was brought to 2.1 with 3.8 ml. of 6 *N* sodium hydroxide. The 48 ml. of solution that was placed on the column contained the equivalent of 268 mg. of moisture- and ash-free calamus.

Development was begun with *p*H 3.42 buffer at a temperature of 55°. This temperature was maintained through the *p*H 4.25 buffer, but was reduced to 37° during the *p*H 6.7 and *p*H 8.3 buffers, and finally to room temperature when 0.2 *N* sodium hydroxide was used (see Fig. 1). Deaerated buffers were required at 55°. The flow rate of developer was 50 ml. per hr. and the fraction size was 5 ml. The ninhydrin procedure[9] was applied to 0.5-ml. portions of alternate fractions in order to determine the progress of the chromatogram.

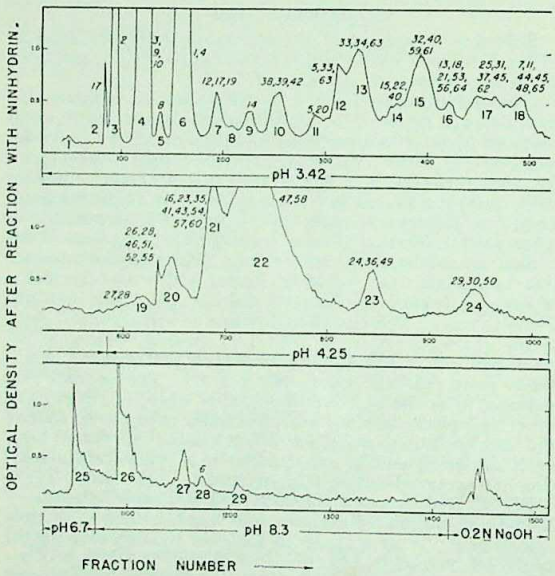

Fig. 1.—Chromatogram of a partial hydrolysate of unoxidized white turkey feather calamus on Dowex 50-X4. Zones are numbered consecutively. Italicized numerals identify compounds in each zone (see Table I).

Fractions containing a zone were pooled, neutralized to *p*H 6.5–7.5, evaporated at 35° to one-tenth their volume on a rotary evaporator,[10] finally evaporated to dryness in a vacuum desiccator over concd. sulfuric acid, and stored at −10° until investigated

Ion-exchange Chromatography of the Partial Hydrolysate of Oxidized Calamus.—The partial hydrolysate of oxidized calamus was chromatographed on a column of Dowex 1-X8 that was 1.6 × 100 cm. in dimension. The resin (200–400 mesh; Lot No. 3589-27; chloride form; medium porosity) was purified in the following way. A volume of about 300 ml. of resin was suspended in 750 ml. of water, the resin was allowed to settle for an hour, and the cloudy supernatant liquid was decanted; the process was repeated 4 times. The resin was then filtered, suspended in 200 ml. of 2 *N* hydrochloric acid, filtered and washed on the filter with 800 ml. of 2 *N* hydrochloric acid; this treatment was repeated once and the filter cake was finally washed with 500 ml. of water. The Dowex 1 was now passed wet through a 120-mesh sieve.[11] Fine particles were further removed at this point by seven suspensions and settlings in 500 ml. of water. The resin was converted to the chloroacetate form by suspending it in 600 ml. of *N* sodium chloroacetate, filtering, repeating this procedure twice and then washing on the filter with 1200 ml. of *N* sodium chloroacetate. This process was repeated with *N* chloroacetic acid and with 0.1 *N* chloroacetic acid and the resin was finally suspended in 600 ml. of the latter. The column was packed in the usual way and conditioned with 675 ml. of 0.1 *N* chloroacetic acid.

For chromatography, the residue that remained after the lyophilization of the partial hydrolysate was dissolved in 7 ml. of 0.01 *N* chloroacetic acid and placed on the column. Inasmuch as the moisture and ash content of the oxidized calamus was not determined, the amount of material that was placed on the column can only be estimated to be equivalent to 200–220 mg. of moisture- and ash-free protein.

The chromatogram was developed throughout with 0.1 *N* chloroacetic acid at room temperature (approximately 22°). The fraction size was 3 ml. and the flow rate of developer was 12 ml. per hr. to fraction no. 150, 18 ml. per hr. from there to fraction no. 400, and 24 ml. per hr. thereafter. The progress of the chromatogram was assessed by applying the ninhydrin procedure[9] to 0.5-ml. portions of alternate fractions.

Pooled fractions that contained a given zone were frozen and stored at −10°. For further investigation, the frozen solution was thawed and the chloroacetic acid was extracted with 2 × 25 ml. and 7 × 10 ml. of ether. Finally, aliquot portions of the extracted solution were removed and individually taken to dryness at 40° on a rotary evaporator.[10]

Further Separation and Identification of the Peptides.—The simpler mixtures of peptides which were obtained from the complex partial hydrolysate by means of the ion-exchange chromatography on Dowex 50-X4 were separated and identified by methods which did not differ appreciably from those previously utilized[12]; that is, the peptides in the pooled fractions were dinitrophenylated, separated by chromatography on silicic acid–Celite, estimated spectrophotometrically, and identified after complete hydrolysis. For peptides longer than dipeptides, the complete sequence was usually not determined; where the complete sequence is known it usually was obvious from the composition (thus, thr-val-val) or the peptide was difficult to hydrolyse and smaller peptides were isolated and identified.

Dinitrophenylation according to Levy and Chung[13] in aqueous solution is more satisfactory than in the aqueous alcoholic medium which was used heretofore.[12] Specifically, the procedure now used is this. The residue of buffer salts and peptides from the evaporation of the pooled fractions was dissolved in 10 to 15 ml. of water and the *p*H was adjusted to 8.5 to 9.5. A 20-mg. portion of sodium carbonate and 0.05 ml. of 2,4-dinitrofluorobenzene (DNFB) were then added and the reaction mixture was vigorously stirred at 40° for 3 hr. Extraction then followed the scheme previously used.[14] This method has the advantage that the buffer salts remain in solution but, what is more important, extraction of soln. 7[14] may not be necessary. Because of the absence of alcohol, the miscibility of phases during the extraction of excess DNFB from the basic reaction mixture (soln. 1[14]) is decreased and DNP-compounds are less likely to be carried over into soln. 7. If a yellow color is present in soln. 7 but disappears on acidification, it is caused by dinitrophenol and the solution may be discarded. Comparison of the two methods with test substances showed that the dinitrophenylation was equally quantitative in both.

Attempts to Separate DNP-Cysteic Acid Peptides Chromatographically.—Although definite separation of cysteic acid peptides was achieved by the use of Dowex 1, it is

hardly to be expected that the separation would be complete. Because DNP-peptides of other kinds can be so readily separated by chromatography on silicic acid–Celite, experiments with DNP-cysteic acid as test substance were begun in an attempt to find chromatographic conditions which might apply to DNP-cysteic acid peptides.

DNP-Cysteic acid itself can be prepared by dinitrophenylation in aqueous alcohol or in purely aqueous solution as above and can be extracted from the acidified reaction mixture with *n*-butanol. The product, however, is oily and less homogeneous than when the following procedure is used. To a solution of 10 mg. of cysteic acid (Nutritional Biochemicals Corpn.) in 5 ml. of water was added 0.25 ml. of 25% aqueous reagent trimethylamine (Matheson, Coleman and Bell). The *p*H was about 10. Then 0.05 ml. of DNFB (Eastman) was added and the reaction mixture was stirred vigorously at 40° for 3 hr. The reaction mixture was extracted with 4 × 25 ml. of ether to remove excess DNFB, then evaporated to dryness at 40° on a rotary evaporator, and finally evaporated twice to dryness after the addition of 5 ml. of water.

Unsatisfactory chromatograms resulted when DNP-cysteic acid was chromatographed on silicic acid–Celite by methods similar to those of Green and Kay.[15] DNP-Cysteic acid is very strongly adsorbed so that strong developers such as 7AA-35A-B and 8AA-40A-B are necessary. However, two zones are present on the chromatogram; the more strongly adsorbed when rechromatographed again produces two zones whereas the less strongly adsorbed is unchanged in its behavior on rechromatography. Apparently, the adsorbent forces a conversion to the less strongly adsorbed form.

Inasmuch as DNP-cysteic acid is highly polar and easily soluble in water, chromatography in systems in which the developer contained water were studied. These efforts for the most part have been fruitless. The separation of DNP-cysteic acid from DNP-cysteic acid peptides could be achieved (a separation was actually already accomplished with the undinitrophenylated compounds on Dowex 1) but the DNP-peptides did not separate from each other. The results of the experiments will be described briefly. Chromatography on Dowex 2-X10 in a manner similar to that for cysteic acid itself[6] apparently resulted in much destruction of the very strongly adsorbed DNP-cysteic acid. On Dowex 50,[8] the DNP-cysteic acid moved with the front of *p*H 3.42 buffer and although the DNP-peptides were retarded there was little evidence of separation. DNP-Cysteic acid is rather strongly adsorbed on starch when the developer is *n*-butanol–benzyl alcohol–water.[16] DNP-Cysteic acid peptides are less strongly adsorbed and some separation occurred but the procedure was not pursued further because of the apparent deleterious effect of butanol which has been mentioned above.

Many experiments were made to try to chromatograph DNP-cysteic acid on cellulose columns with developers patterned after those which are used in the paper chromatography of DNP-compounds. For this purpose, the following general procedure was used. Ten grams of Solka-Floc BW-200 (Brown Company, New York) was suspended in 50 ml. of developer, stirred vigorously for 30 min., filtered, and the process repeated. Finally, the Solka-Floc was suspended in 50 ml. of developer, the column was poured in the manner of starch columns[18] and then 25 ml. of developer was passed through. In a tube of 10 mm. inner diameter, most columns were about 30 cm. in length. The flow rate under identical conditions was dependent on the developer and was adjusted by positive or negative pressure to 5 to 10 ml. per hr. The following are typical of the developers which were studied: (1) 1:2:1 acetic acid–*n*-butanol–water,[17] (2) 1.5 *M* phosphate buffer at *p*H 6.0,[18] (3) *M* citrate buffer at *p*H 6.2,[19] (4) *t*-amyl alcohol saturated with 3% aqueous ammonia,[20] and (5) *t*-amyl alcohol saturated with 0.1 *M* phthalate buffer at *p*H 6.0.[21] With these developers in the order given, DNP-cysteic acid moves through the column with increasing slowness; thus, about 30 ml. of citrate buffer moves DNP-cysteic acid through a column of the above size whereas about 300 ml. are required with *t*-amyl alcohol–phthalate buffer. These experiments showed that several of these systems would separate DNP-cysteic acid from its DNP-peptides. However, there was no evidence that mixtures of DNP-peptides would separate. Development with citrate buffer is generally suitable for the identification of DNP-cysteic acid. Our experience has been that DNP-cysteic acid and its DNP-peptides tend to decompose rather readily.

Other Methods for Identifying the Cysteic Acid Peptides.—The degree of heterogeneity of the residue from particular pooled fractions of the Dowex 1 chromatogram was assessed by hydrolyzing a portion of the residue completely, dinitrophenylating the products of hydrolysis, extracting other DNP-amino acids from DNP-cysteic acid with ethyl acetate, and identifying the DNP-amino acids. When this procedure was applied to zones 0–4, 0–5 and 0–7, it was apparentt hat zones 0–4 and 0–5 contained mixtures of several peptides whereas zone 0–7 contained mostly (ser, cya[22]). For further investigation, another portion of zone 0–7 was dinitrophenylated prior to hydrolysis. From this hydrolysate, DNP-serine equivalent to about 20% of the quantity of peptide was isolated.[23] Although this result could be interpreted to mean that a mixture of ser-cya and cya-ser was present, this possibility was excluded by dinitrophenylating the amino acids in the extracted hydrolysate of the peptide: no DNP-serine was detected and it was concluded that ser-cya is the main constituent. Inasmuch as similar difficulty might be anticipated in the hydrolysis of other zones after dinitrophenylation, the final investigation of the cysteic acid peptides was made by hydrolyzing the undinitrophenylated residues from the pooled fractions, and identifying the constituent amino acids and estimating the amounts by chromatography on 100-cm. columns of Dowex 50.[8] In this way, if the several peptides in the mixture were present in sufficiently disparate amounts, the composition could be deduced by comparing the molar amounts of the constituents.

Results

The separations which were achieved by chromatographing the partial hydrolysate of unoxidized calamus on Dowex 50-X4 are depicted in Fig. 1. Although more satisfactory separations were obtained in preliminary small-scale experiments especially in the region of zones 11 to 18, there is relatively minor overlapping of the peptides from zone to zone.

All zones have been investigated and some compound has been identified in each with the exception of zones 1, 8, 25, 26, 27 and 29. The qualitative and quantitative results are presented in Table I. Minor components, identification of which was not attempted, were also present in most of the zones.

The anomalous behavior of asp-gly was again observed in this chromatogram: it was present in the non-adjacent zones 2 and 7. A similar unexplained behavior was observed in partial hydrolysates of Tussah silk fibroin.[24]

(21) S. Blackburn and A. L. Lowther, *Biochem. J.*, **48**, 126 (1951).

(22) The commonly accepted abbreviations for the amino acids use the first three letters of the name but because of obvious duplication with cystine and cysteine, cysteic acid is usually abbreviated cySO₃H. Further difficulty arises with glutamic acid and glutamine and with aspartic acid and asparagine. In the interest of simplicity, we would like to suggest the following usages: cysteic acid, cya; cysteine, cye; glutamine, glm; and asparagine, asg.

(23) Our experience has been that greater destruction of DNP-serine compared to other DNP-amino acids is common during the hydrolysis of DNP-peptides although the destruction usually is not as great as observed here. A. L. Levy and C. H. Li (*J. Biol. Chem.*, **213**, 487 (1955)) recovered only 10 to 20% of the expected N-terminal DNP-serine from ACTH.

[a] Recalculated to one g. of moisture- and ash-free calamus. The quantities of the DNP-peptides were determined spectrophotometrically. [b] The number of the zone which contained the major portion is italicized. [c] Inasmuch as the procedures did not distinguish between leucine and isoleucine, the designations "(iso)leucine" and "(i)leu" indicate that either or both may be present. [d] The presence of these peptides though probable is not definitely established. [e] Sequence may be identical; they were isolated from adjacent zones and in only one was the actual sequence identified.

Although zone 22 is the largest zone on the chromatogram, the quantity of peptides is insignificant and the main component is ammonia. Ammonia was not identified as such in this zone because much was inadvertently lost during the isolative procedures before it was realized that a volatile component was present. However, under these same conditions of chromatography, ammonia in a control chromatogram emerged in the same region. The exact point of emergence of this zone is somewhat dependent upon uncontrolled chromatographic conditions: in some chromatograms it has been well separated from a zone equivalent to zone 21 and has partially overlapped zone 23. It is rather surprising that ammonia emerges from the column so early in the chromatogram because Moore and Stein[16] report that it emerges near arginine with *p*H 11.0 buffer after several intermediate increases in the *p*H of the buffer. In the present experiments, ammonia emerged soon after the change to *p*H 4.25 buffer and the conditions differed from those of Moore and Stein essentially only in the use of about twice the volume of *p*H 3.42 buffer and a temperature of 55° instead of 37°.

Figure 2 shows the chromatogram which resulted when the partial hydrolysate of oxidized calamus was chromatographed on Dowex 1-X8. Most of the material in the hydrolysate emerges almost immediately from the column as would be expected; three poorly separated peaks can be detected in this region of the chromatogram. This chromatogram was continued only until shortly after the appearance of cysteic acid (zone 0–12). Preliminary chromatograms on 0.9 × 100-cm. columns failed to reveal any substances which were more strongly adsorbed than cysteic acid. Thus, in these chromatograms, development with 0.1 *N* chloroacetic acid was continued to about fraction no. 800 and was then changed to a linear gradient between 0.1 *N* and *N* chloroacetic acid. The apparatus described by Bock and Ling[25] in their Fig. 6 was used. By the use of 300 ml. in each reser-

(25) R. M. Bock and N. Ling, *Anal. Chem.*, **26**, 1543 (1954).

Digitized by Arya Samaj Foundation Chennai and eGangotri

voir of equal cross-sectional area, the influent concentration would be N chloroacetic acid when all had been used. The equilibrium is established somewhat less rapidly on Dowex 1 than on Dowex 50. Actually, the gradient was not apparent in the effluent until 200 fractions more had been collected. The concentration of chloroacetic acid in the effluent was about 0.5 N and in the mixer was about 0.75 N when the chromatogram was stopped 450 fractions after the change to gradient elution.

The peptides of cysteic acid which were tentatively identified are listed in Table II. As an example of the interpretation required to come to the conclusions given there, consider zone 0–5. Ion-exchange chromatography showed the presence of 6.5 μmoles of cysteic acid, 3.6 μmoles of serine, 4.0 μmoles of proline, 1.5 μmoles each of aspartic acid, glutamic acid and glycine, 1.2 μmoles of alanine, 0.8 μmole of (iso)leucine, and a trace of valine. Serine and proline are present in essentially equivalent amount (there is some destruction of serine during hydrolysis) and in more than twice the amount of any other amino acid except cysteic acid. If we assume that zone 0–5 must contain cysteic acid peptides, then it is reasonable to conclude that (cya, pro, ser) is present. If this is accepted, then about 2.5 μmoles of cysteic acid peptide are not accounted for and we have about 1.5 μmoles each of aspartic acid, glutamic acid, glycine and alanine unaccounted for. Hence, two other cysteic acid tripeptides may be present but it is futile to suggest their composition because so many possibilities arise. In this way, the peptides listed in Table II have been identified with reasonable certainty.

Table II

Tentative Identification of Cysteic Acid Peptides from a Partial Acidic Hydrolysate of Oxidized White Turkey Feather Calamus

Zone no. in Fig. 2	Compound	Approx. amt., μmoles/g.
0–1, 0–2, 0–3	Contain cysteic acid peptides in mixture with other peptides of hydrolysate	
0–4	Much overlap from zone 0–3. Possibly contains (phe, cya)	9
0–5	(cya, pro, ser)	18
0–6	(cya, glu, pro)	19
0–7	(cya, ser) probably ser, cya	50
0–8	(cya, glu, pro)	12
0–9	(cya, glu)	10
0–10	(cya, glu)	7
0–11	(cya, ser, glu?)[a]	..
0–12	cya	80

[a] Cysteic acid and serine are definitely present but the identification of glutamic acid is uncertain. A zone was present which emerged in the region where glutamic acid is expected but more rapidly than observed in other chromatograms.

Table III presents an accounting of the percentages of the amino acids in free and peptide form in these hydrolysates. If we calculate the amount of material in each of the zones on the basis of the ninhydrin color and compare this with the amount actually isolated and identified, a wide variety of values results. In some zones, nothing additional

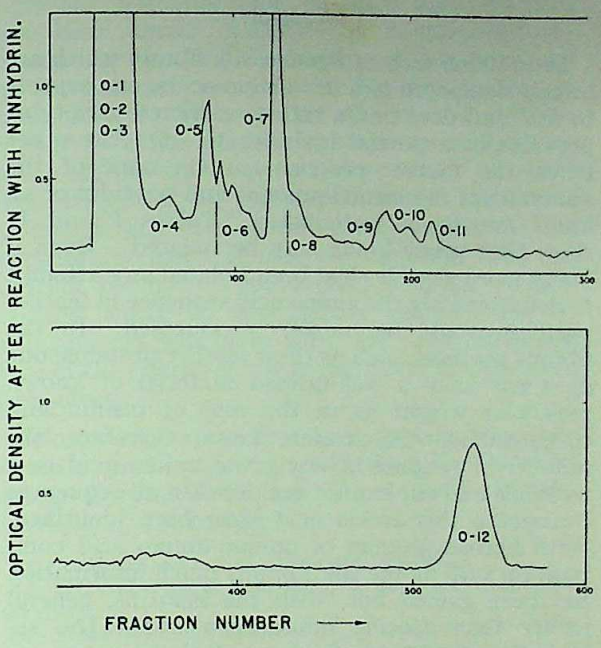

Fig. 2.—Chromatogram of a partial hydrolysate of oxidized white turkey feather calamus on Dowex 1-X8.

fied whereas in others the amount approaches or slightly exceeds 100%. In most of the major zones in Fig. 1, the amount accounted for on this basis was usually between 50 and 75%. These data must be treated with considerable reserve because the color yields of the peptides which constitute the zones are unknown. Approximately 10% of the protein has been accounted for in the form of free amino acids and about 20% in the form of peptides.

Table III

Percentage of Amino Acids in White Turkey Feather Calamus Accounted for by Peptides and Amino Acids of Tables I and II[a]

Amino acid	% accounted for by Free amino acids	Peptides	Total % accounted for
Ala	10	33	43
Asp	22	7	29
Glu	4	9	13
Gly	27	34	61
(I)leu	5	26	31
Lys	2	0	2
Phe	10	26	36
Pro	2	15	17
Ser	24	19	43
Thr	5	37	42
Tyr	5	2	7
Val	1	23	24
Cya	12	44[b]	56
Arg			0
Cys			0
Hist			0
Met			0

[a] Of the data from Table II, only cysteic acid is included here. If other amino acids from the cysteic acid peptides were added, possible double accounting might result because two hydrolysates are involved. [b] This amount was detected in peptide form, but the peptides themselves were not all identified.

Discussion

In proteins such as *Bombyx* silk fibroin which are largely composed of a few amino acids, one expects to find and does find a rather restricted variety of peptides in a partial hydrolysate. On the other hand, the feather proteins contain none of the amino acids in unusual amount and peptides of all kinds are to be anticipated. Tables I and II show that many kinds may be isolated. Even if many more peptides had been isolated any attempt to define exactly the amino acid sequence in feather proteins would be unlikely to succeed. In the fibrous proteins, such as these feather proteins, one does not have a well-defined material of known molecular weight as in the case of insulin and corticotropin. One cannot know, therefore, the number of residues of any given amino acid in a molecule and one cannot decide when all sequences containing this amino acid have been identified. With fibrous proteins of unique amino acid composition such as the silk fibroins much information has been gained but, with the keratins, general rather than specific information about the sequences and structure is about all that one can expect to obtain.

In a preliminary experiment with oxidized calamus, a 48-hr. hydrolysate was chromatographed on a smaller scale on Dowex 50 under the conditions of Fig. 1 and the results were compared with those obtained from a 48-hr. hydrolysate of unoxidized calamus. As would be anticipated, cysteic acid and its peptides were essentially unretarded under these conditions and emerged almost with the front of the developer. Throughout the remainder of the chromatograms, the shapes and sizes of the peaks were almost identical and one may conclude that the presence of cysteic acid rather than cystine in the protein has had little influence on the course of the acidic hydrolysis. This type of comparison, admittedly, is not very exact because the components of the individual zones may not be identical. On the other hand, when hydrolysates of separate individual feather parts were compared, there were slight differences in the chromatograms which could be correlated with differences in the amino acid composition. Thus, 48-hr. hydrolysates of turkey feather barbs, calamus, medulla and rachis were made as described in the experimental part of this paper and were chromatographed under the conditions of Fig. 1. The barbs, in contrast to the other parts, required about 12 hr. instead of about 3 hr. for complete solution. The calamus and rachis are essentially identical in amino acid composition[2] and X-ray pattern[5] and the chromatograms of their partial hydrolysates were not significantly different. On the other hand, the chromatogram of the barb hydrolysate showed much smaller amounts of the zones equivalent to zones 9, 15 and 21 of Fig. 1 and two zones were present in the position of zone 23; the medulla hydrolysate showed these same differences to a lesser extent. It may be that the slower rate of solution of the barbs is responsible for these differences. However, zones 9 and 15 contain alanyl peptides and the alanine content of barbs is much greater than that of calamus while that of medulla is intermediate. Likewise, zone 21 contains peptides of leucine and/or isoleucine and the feather parts differ in their content of these amino acids. The possible relation is less obvious in this case because leucine and isoleucine were not distinguished from each other in the identification of the peptides.

The 32 dipeptides which have been isolated from the hydrolysate of unoxidized calamus are an appreciable fraction of the total number of dipeptides which are possible from combinations of the 11 amino acids in peptide form. The quantities are very dissimilar and this fact is probably partly a reflection of the ease or difficulty of hydrolysis of the particular bonds which must be hydrolyzed to give the peptide. It is unprofitable to speculate upon the sequences in the tri-, tetra- and pentapeptides as the following examples will show. The sequence in the peptide, thr-pro-(i)leu, was definitely established but the isolation of thr-(i)leu and not thr-pro would have led to the suggestion that the more probable sequence was thr-(i)leu-pro. Likewise, the sequence in gly-(gly,(i)leu) might equally well be either gly-(i)leu-gly or gly-gly-(i)leu on the basis of the amounts of gly-(i)leu, (i)leu-gly and gly-gly which were isolated.

The chromatographic separation of the cysteic acid peptides is not entirely satisfactory because zones 0–1 to 0–3 which contain the main bulk of the other peptides also contain cysteic acid peptides in about half the amount to be found in zones 0–4 to 0–11. Probably the chromatogram should be started with a developer such as 0.5 *M* acetic acid[26] in order to separate the neutral and weakly acidic compounds and then changed to 0.1 *N* chloroacetic acid in order to remove the more strongly acidic ones. On Dowex 1, the cysteic acid peptides are all appreciably less strongly adsorbed than cysteic acid itself. In contrast, on Dowex 50 peptides generally tend to emerge after any of the constituent amino acids.

Six cysteic acid peptides have been identified with some certainty. In zones 0–6 and 0–8, the main peptide has the composition (cya, glu, pro) and in zones 0–9 and 0–10, the composition is (cya, glu). Inasmuch as the separation of peptides of identical composition but different sequence is frequently observed on Dowex 50 chromatograms, it is safe to assume that in these instances also the peptides differ in sequence. It is interesting to observe that in these peptides cysteic acid and hence cystine has glutamic acid, serine and proline as close neighbors. Likewise, in the A chain of insulin,[27] glutamic acid and serine are adjacent to cystine. In feather keratin, proline also seems to be closely associated with cystine; possibly the close proximity of a cross-link between chains and of an amino acid of restricted structure such as a proline plays an important role in the structure.

When a protein contains as much proline as does feather keratin in which about one residue in ten is proline, it seems probable that this amino acid, by virtue of its definite spatial state, must play an important role in determining the spatial arrange-

ment of the amino acids in the polypeptide chains. Because the ring system imposes such restrictions on proline, this amino acid will have a profound effect on the direction of the polypeptide chain whenever a prolyl residue is present in the sequence. Indeed, it is unlikely that the polypeptide chains in feather keratin would assume any of the pleated sheet or simple helical configurations[28,29] which have been suggested thus far. Is there any evidence from the present data or from other data that the amino acids adjacent to proline are restricted in any way? In the present investigation, 15 prolyl peptides have been identified. Of those peptides of determined sequence, gly-pro, and thr-pro-(i)leu are the most predominant. One may conclude tentatively that, in a sequence such as -X-pro-, X tends to be an amino acid with a relatively short side chain, for example, glycine, serine and threonine and that amino acids with longer side chains such as glutamic acid are less likely to be found in this sequence. This suggestion receives some support from the literature. Thus, in gelatin[12] and collagen,[30] -gly-pro- is an important sequence and -ala-pro- and -ser-pro- have been found. Likewise, in a melanophore-stimulating peptide, the sequences -gly-pro- and -ser-pro-pro- are present.[31,32] By comparison, a much different situation obtains in the corticotropins[33,34] which contain the sequences -lys-pro-val-, -arg-pro-val-, -tyr-pro-asp-, and -phe-pro-leu-. If, indeed, the proline residues are important in determining the spatial configuration of the polypeptide chains, it may be suggested that the adjacent residues in conjunction with the proline residues assist in maintaining certain specific arrangements which, in turn, are responsible for some of the characteristic properties of the proteins themselves.

Acknowledgments.—This investigation was supported in part by a contract between the Quartermaster Corps., U. S. Army, and the California Institute of Technology.

Pyrimidine Nucleosides. II. The Synthesis of 1-β-D-Arabinofuranosylthymine ("Spongothymidine")[1]

BY JACK J. FOX, NAISHUN YUNG AND AARON BENDICH

RECEIVED DECEMBER 19, 1956

1-D-Ribofuranosylthymine (I) was converted by a series of reactions to 1-β-D-arabinofuranosylthymine. Since this epimerization can occur only with nucleosides containing the β-D-glycosyl structure, the configuration at the glycosyl center of I and of other thymine nucleosides was firmly established as beta. 1-β-D-Arabinofuranosylthymine was shown to be identical with the naturally occurring nucleoside, "spongothymidine."

In Part I of this series[2] a method was described for the facile synthesis of thymine nucleosides by the condensation of poly-O-acylglycosyl halides with dithyminylmercury followed by removal of the protecting acetyl or benzoyl groups. In this manner 1-D-ribofuranosylthymine (I) and 1-D-xylofuranosylthymine (II) were prepared. The former was identical with a product prepared enzymically by Lampen[3] and also was shown to be similar to a compound isolated recently by Fink and co-workers[4] from rat liver slices incubated with radiothymine.

Spectral and metaperiodate-oxidation studies[2] with I and II showed that the sugar–pyrimidine linkage was at position 1 of thymine and, further, that the lactol ring structures were of the furanose type. It was demonstrated that I, II and 1-D-glucopyranosylthymine gave the same dialdehyde upon oxidation with metaperiodate. On the basis of the reasonable assumption that 1-D-glucopyranosylthymine (III) is a β-nucleoside,[5] it was tentatively concluded that I and II are nucleosides of the β-configuration.

An unequivocal determination of the structure at the glycosyl center of I would serve not only for the assignment of configuration to the biochemically produced materials of Lampen[3] and Fink,[4] but it would also help to provide a basis for future generalizations about the structure of nucleosides obtained by this new synthetic procedure with other pyrimidines. In this paper, a proof is given for the structure of 1-D-ribofuranosylthymine. As a corollary to this proof, a first synthesis and unequivocal proof of structure of "spongothymidine" are presented. A preliminary report on this study has appeared.[6]

A rigorous method for the determination of the

glycosylic configuration of certain nucleosides has been reported[7] which involves the formation of *cyclo*-nucleosides by intramolecular alkylation when 5′-tosyl derivatives of adenosine or cytidine are heated in inert solvents. An examination of molecular models shows that, for the formation of these *cyclo*-nucleosides to occur, the configuration at the glycosyl center must be beta. Michelson and Todd[8] have prepared O²,3′-*cyclo*thymidine and converted it to a 2′-deoxynucleoside (almost certainly the "deoxyxylosyl" analog) indicating that for the formation of this *cyclo*-nucleoside Walden inversion occurred at C³′.

An examination of molecular models shows that if, indeed, ribofuranosylthymine is a β-D-nucleoside, then the carbonyl oxygen atom at C² of the pyrimidine is favorably located for a rearward, nucleophilic attack upon either C², C³ or C⁵ of the sugar moiety. It should be possible, therefore, to isomerize I at C²′ or at C³′ *via* a *cyclo*-nucleoside intermediate starting from the appropriate sulfonic ester derivative of I.

1-D-Ribofuranosylthymine was converted into its 5′-trityl derivative IV by reaction with trityl chloride in pyridine.[9] Treatment of IV with methanesulfonyl chloride gave a sirup which resisted attempts at crystallization. This sirup should contain a 2′-O-mesyl derivative (V) and/or a 3′-O-mesyl isomer (VI). A 2′,3′-di-O-mesyl derivative also may be postulated as one of the reaction products along with some unreacted IV.

It should be noted that with structures V and VI (see Fig. 1) the vicinal hydroxyl functions are *cis* and the 5′-position is blocked by a trityl group so that elimination of the mesyloxy group with inversion at C²′ or at C³′ by a rearward attack by a sugar hydroxyl group is excluded. Treatment of this sirup with ammonia in aqueous methanol should effect *cyclo*-nucleoside formation with Walden inversion as a result of nucleophilic attack of O² of the pyrimidine upon either C²′ (in the case of V) or C³′ (from VI) to give VII or VIII, respectively (or both). Subsequent hydrolysis of the anhydro nucleoside(s) with acid (*cyclo*-ring opening) should also result in detritylation and give rise either to 1-β-D-arabinofuranosylthymine (IX) from VII or of 1-β-*D*-xylofuranosylthymine (X) from VIII (or both).[10] The latter nucleoside should be identical with II previously prepared directly *via* the mercuri procedure[2]; whereas IX would be 1-β-D-arabinofuranosylthymine, a new synthetic aldopentofuranosylthymine. It is clear from the foregoing discussion that (aside possibly from the recovery of starting material I) the only nucleosides which will be formed from this reaction sequence will possess a *trans* relationship between the 2′- and 3′-hydroxyl groups. Thus 1-β-D-lyxofuranosylthymine[11] cannot arise as a product of these reactions.

The experimental facts are that a product was isolated in crystalline form which was neither I nor X (II). The elemental analyses agreed with that for a pentosylthymine. This product was cleaved slowly by metaperiodate[12] with an uptake of one mole of oxidant per mole and without the liberation of formic acid in accord with a pentofuranosyl structure. The specific rotation of the dialdehyde solution resulting from this oxidation was identical with that obtained by similar treatment of I, II and III[2] demonstrating quite conclusively that the configuration at the glycosyl centers of all four compounds was similar (see Fig. 2).

On the basis of the non-identity of this nucleoside with I or X (or II), and since a lyxofuranosylthymine cannot arise from this synthesis, it is therefore obvious that the product obtained from these reactions is 1-β-D-arabinofuranosylthymine (IX). Consequently, the β-formulation must also be assigned to the glycosyl centers of I, II and III.

By virtue of the epimerization of I to IX, it is reasonable to assume that structures V and VII (not isolated) were intermediates in the synthesis of IX. Indeed, Brown and co-workers[13] have very recently reported the conversion of uridine to 1-β-D-arabinofuranosyluracil and have isolated a *cyclo*-uridine intermediate in crystalline form from a 2′-*O*-tosyl derivative of 5′-O-acetyluridine.

Bergmann and Feeney[14] have isolated a pentofuranosylthymine from certain Caribbean sponges. Spectral studies[15] as well as optical rotational data[14] indicated strongly that the sugar moiety was not D-ribose. On the basis of chemical and physicochemical studies, Bergmann and Burke[16] have assigned the 1-β-D-arabinofuranosyl structure to this thymine nucleoside.

We have compared IX with a sample of spongothymidine (kindly furnished by Drs. Bergmann and Burke) with regard to melting points, mixed melting points, optical rotation and detailed spectrophotometric behavior as a function of *p*H (including the high alkaline range[15]) and find them to be

(7) V. M. Clark, A. R. Todd and J. Zussman, *J. Chem. Soc.*, 2952 (1951); W. Anderson, D. H. Hayes, A. M. Michelson and A. R. Todd, *ibid.*, 1882 (1954).

(8) A. M. Michelson and A. R. Todd, *ibid.*, 816 (1955).

(9) IV gave a positive spray test for vicinal hydroxyls (J. G. Buchanan, C. A. Dekker and A. G. Long, *ibid.*, 3162 (1950)) thus confirming that tritylation had occurred at the 5′-position.

(10) This statement rests on the assumption that opening of the *cyclo*-nucleoside involves cleavage of the linkage between the oxygen atom of the *cyclo*-bridge and C² of the pyrimidine ring. Cleavage could occur also at the glycosyl linkage (≥C—N<) which, as pointed out by Michelson, *et al.*,[8] would give rise to glycosides. The latter type of compound would be unstable to the acidic conditions of the hydrolysis, and, indeed, in one of our experiments small amounts of thymine were isolated.

If a 2′,3′-di-O-mesyl derivative of IV had been formed and converted into a 3′- or 2′-mesylated derivative of VII or VIII, respectively, it may be postulated that in the course of these reactions a second rearward attack could occur with the formation of a 2′,3′-epoxide. The argument for the formation of IX or X is not altered since only *trans* isomers of I could arise from epoxide ring opening.

(11) Reference 30 in Part I of this series[2] contains these typographical errors; it should refer to 1-β-D-lyxofuranosylthymine instead of 1-β-D-xylofuranosylthymine. Reference 30 itself should read: "The synthesis of 1-β-D-lyxofuranosylthymine from 1-β-D-xylofuranosylthymine is underway in these laboratories."

(12) The slow uptake of metaperiodate is consistent with the presence of a *trans*-glycol system (C. C. Price and M. Knell, THIS JOURNAL, **64**, 552 (1942)). II and III also consume metaperiodate slowly, whereas with I the uptake is completed within a few minutes.[2]

identical. Thus the epimerization sequence of I → IX constitutes a synthesis and, concomitantly, an independent proof of structure of this naturally occurring sponge nucleoside.

Acknowledgment.—The authors are indebted to Dr. George Bosworth Brown for helpful discussions and continued interest.

Experimental[17]

1-(5′-Trityl-β-D-ribofuranosyl)-thymine (IV).—The procedure of Levene and Tipson[18] for the tritylation of uridine was employed with modifications. A solution containing 6.0 g. (0.023 mole) of 1-β-D-ribofuranosylthymine (I) in 100 ml. of anhydrous pyridine was treated with 7.0 g. (0.025 mole) of triphenylchloromethane. After one day at 10°, the reaction mixture was warmed on a steam-bath for 2 hr., cooled and poured into ice-water. Upon vigorous stirring, a yellow, viscous sirup formed. The water was decanted and the sirup taken up in warm acetone. After filtration from a small residue, the filtrate was concentrated to a solid *in vacuo*. This residue was heated with 500 ml. of boiling water for 30 minutes, filtered and the precipitate taken up in hot ethanol from which it crystallized as knobby clusters. The precipitate was filtered, washed with benzene and dried (6.2 g.), m.p. 153–160°. Elemental analyses indicated a contamination of this product with approximately 20% of triphenylcarbinol. Purification was accomplished by two recrystallizations from benzene–alcohol followed, finally, by recrystallization from absolute alcohol to give needles, m.p. 155° (to a viscous sirup which clears at 165°). Triphenylcarbinol was isolated from the mother liquors.

Anal. Calcd. for $C_{29}H_{28}N_2O_6$: C, 69.60; H, 5.60; N, 5.60. Found: C, 69.46; H, 5.74; N, 5.52.

Conversion of IV to 1-β-D-Arabinofuranosylthymine (Spongothymidine).—Unrecrystallized IV (2.0 g.) in 35 ml. of cold, anhydrous pyridine was treated with methanesulfonyl chloride (0.8 ml.) and kept at 10° for 24 hr. One milliliter

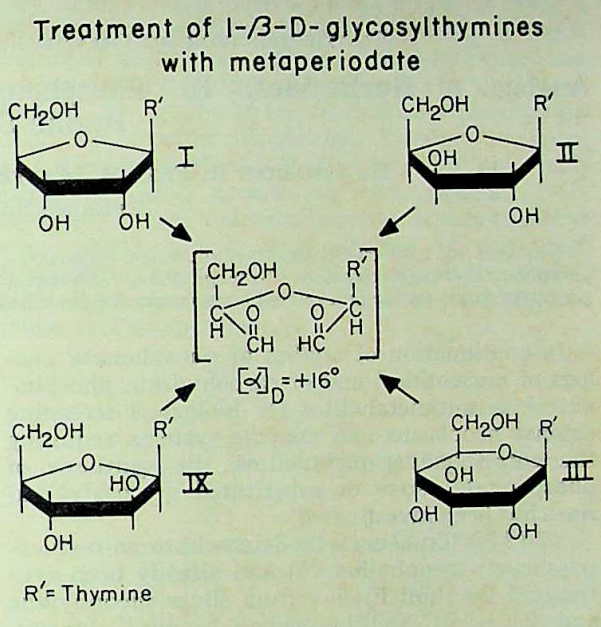

Fig. 2.

of water was then added to the cold mixture, and after 1 hr. the reaction mixture was poured into stirred ice-water. A precipitate formed which was washed well with water and dried.[19] This solid was added to 50 ml. of 95% methanol saturated with ammonia and let stand overnight at room temperature.

The solution was concentrated under vacuum, treated with water and acidified with sulfuric acid to *p*H 1 and refluxed for 2 hr. Upon cooling, triphenylcarbinol was removed by filtration and the filtrate made alkaline with barium hydroxide. The precipitated barium sulfate was removed and the filtrate treated with carbon dioxide (to *p*H 5). After filtration from barium salts, the filtrate was concentrated to approximately 10 ml. whereupon more inorganic salts precipitated. The filtrate obtained by separation from inorganic material was concentrated to 3 ml. Upon cooling, the nucleoside IX precipitated as clusters of needles, 0.15 g., m.p. 238–242° (undepressed by admixture with authentic spongothymidine). An additional 0.06 g. was obtained from the mother liquor. Recrystallization from 25% ethanol did not alter the melting point.

Anal. Calcd. for $C_{10}H_{14}N_2O_6$: C, 46.50; H, 5.46; N, 10.85. Found: C, 46.54; H, 5.62; N, 10.80.

The ultraviolet absorption spectrum of this product in aqueous solutions of various *p*H values (including the high alkaline range[15,20] was identical to that previously reported for spongothymidine.[15] As with spongothymidine,[14] IX consumed one mole of metaperiodate per mole without the liberation of formic acid. When IX was treated with metaperiodate in the same manner as were I, II and III,[2] a similar rotation ([α]D +16°) was obtained for the dialdehyde solution produced (see Fig. 2). The optical rotational prop-

(17) All melting points are uncorrected. Analyses performed by Dr. J. F. Alicino, Metuchen, N. J.

(18) P. A. Levene and R. S. Tipson, *J. Biol. Chem.*, **104**, 385 (1934); **108**, 419 (1934).

(19) This precipitate melts at approximately 100° and gives a low sulfur analysis (theory, 5.54: found, 1.48) indicating, at best, only 25% of mesylated product. A larger excess of methanesulfonyl chloride does not seem to improve the sulfur content of the crude product.

(20) The spectrum of spongothymidine in the high alkaline range (*p*H 12–14) shows large shifts,[15] far greater than those noted for I or

Analogs of Nucleotides. II. Phosphonate Esters of Ribose and Glucopyranosyl Purine Derivatives[1]

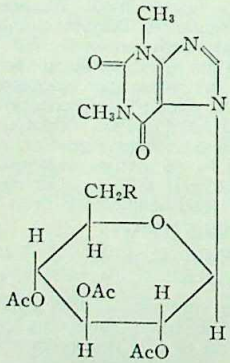
BY JEKISHAN R. PARIKH, MANFRED E. WOLFF AND ALFRED BURGER

RECEIVED NOVEMBER 29, 1956

Syntheses of 1,2,3-tri-*O*-acetyl-D-ribofuranose-5-deoxy-5-(diethyl phosphonate), 7-[2,3,4-tri-*O*-acetyl-6-deoxy-6-(diethyl phosphonate)-β-D-glucopyranosyl]-theophylline, 6-benzamido-9-[2,3,4-tri-*O*-acetyl-6-deoxy-6-(diethyl phosphonate)-β-D-glucopyranosyl]-purine and related compounds are described.

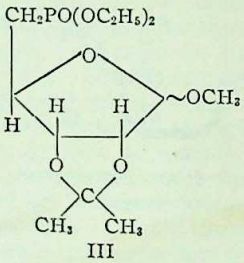
In continuation of studies of phosphonate analogs of nucleotides[2] and of carbohydrate phosphonates[3] as antimetabolites for biological screening against neoplasms and enzyme systems requiring the corresponding metabolites, the synthesis of phosphonate esters of substituted glycosidyl purines has been investigated.

7-(2,3,4-Tri-*O*-acetyl-6-deoxy-6-bromo-D-glucopyranosyl)-theophylline (I) had already been synthesized by Emil Fischer from silver theophylline and 2,3,4-tri-*O*-acetyl-6-deoxy-6-bromo-D-glucopyranosyl bromide.[4] It has now been found to undergo a Michaelis–Arbuzov reaction with triethyl phosphite, 7-[2,3,4-tri-*O*-acetyl-6-deoxy-6-(diethyl phosphonate)-β-D-glucopyranosyl]-theophylline (II) being formed in 40% yield. In attempts to introduce a 2,3-di-*O*-acetyl-5-deoxy-5-(diethyl phosphonate)-D-ribofuranosyl group into the 7-position of theophylline

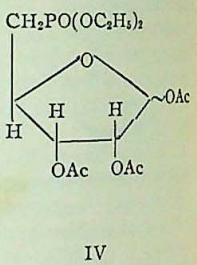


I, R = Br
II, R = $PO(OC_2H_5)_2$

methyl 2,3-isopropylidene-5-deoxy-5-iodo-D-ribofuranoside[5] was heated with triethyl phosphite, and the resulting methyl 2,3-isopropylidene-5-deoxy-5-(diethyl phosphonate)-D-ribofuranoside (III) was hydrolyzed and acetylated to 1,2,3-tri-*O*-acetyl-D-ribofuranose-5-deoxy-5-(diethyl phosphonate) (IV).

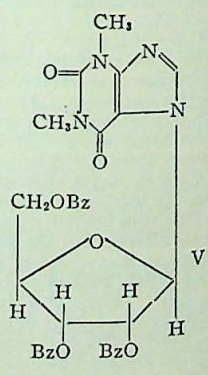


III



IV

The amorphous 1-chloro derivative obtained by treating IV with ethereal hydrogen chloride at 0° could not be condensed with either silver theophylline, or with 6-chloropurine mercuri chloride, although the reactivity of the 1-chlorine atom in a highly substituted ribose derivative was demonstrated by condensing 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl chloride[6] with silver theophylline to yield 7-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-theophylline (V).



V

Following the model experiment leading to II,

(4) E. Fischer, B. Helferich and P. Ostmann, *Ber.*, **53**, 873 (1920). The body of evidence in the literature suggests that the products from the condensation of purine metal adducts with 1-halogenoglucose and -ribose derivatives assume the β-configuration. It is likely, therefore, that I as well as other glycosidyl purines so designated in this article are β.

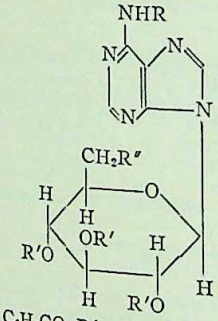
the mercuri chloride salt of 6-benzamidopurine[7] was condensed with 2,3,4-tri-*O*-acetyl-6-deoxy-6-bromo-α-D-glucopyranosyl bromide in xylene medium, and 24% of 6-benzamido-9-(2,3,4-tri-*O*-acetyl-6-deoxy-6-bromo-β-D-glucopyranosyl)-purine (VI) was obtained as the main reaction product. The assignment of position 9 to the glucosidic moiety in the adenine system is based on observations about glycosidation of the chloromercuri salt of 6-benzamidopurine[7,8]; in addition, 6-benzamidopurine exhibits characteristic absorption bands at 287 and 230 mμ, and VI at 281 and 235 mμ, respectively, while substitution in the 7-position of the purine system is known to cause a change in this pattern.

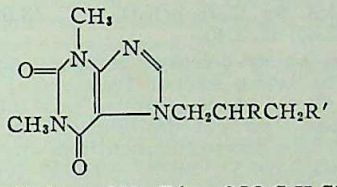
Two other compounds were also elaborated in appreciable quantities from the 6-bromoglucosidation of 6-benzamidopurine. One of them was recognized as 2,3,4-tri-*O*-acetyl-6-deoxy-6-bromo-β-D-glucopyranosyl chloride presumably formed by exchange of the 1-bromine atom by chlorine from the mercuri chloride salt, and probably accompanied by inversion at C-1.[9] Although its physical appearance, solubility and melting point were extremely similar to those of the isomeric 2,3,4-tri-*O*-acetyl-6-deoxy-6-chloro-α-D-glucopyranosyl bromide[10] the two isomers differ in their optical rotation. The structure of the 1-chloro-6-bromo derivative was confirmed by conversion to 1,2,3,4-tetra-*O*-acetyl-6-deoxy-6-bromo-β-D-glucopyranose.[4]



VI, R = C_6H_5CO, R′ = Ac, R″ = Br
VII, R = H, R′ = Ac, R″ = Br
VIII, R = R′ = H, R″ = Br
IX, R = C_6H_5CO, R′ = Ac, R″ = $PO(OC_2H_5)_2$

The benzamido group of VI was unusually labile. When the compound was heated with ethanolic picric acid solution, 6-amino-9-(2,3,4-tri-*O*-acetyl-6-deoxy-6-bromo-β-D-glucopyranosyl)-purine (VII) picrate was formed. Treatment of this salt with Dowex No. 1 anion-exchange resin[7] followed by alkalinization removed both the picrate ion and the acetyl groups and led to crystalline 6-amino-9-(6-deoxy-6-bromo-β-D-glucopyranosyl)-purine (VIII). Heating of VI with triethyl phosphite furnished 6-benzamido-9-[2,3,4-tri-*O*-acetyl-6-deoxy-6-(diethyl phosphonate)-β-D-glucopyranosyl]-purine (IX). Experiments to hydrolyze its amide and ester groups with dilute ammonium hydroxide or methanolic sodium methoxide did not give the expected product. When VI was heated with ethyl diphenyl phosphite,[3,11] a material which contained neither phosphorus nor halogen was obtained.

Another phase of this problem concerned the preparation of starting materials for the synthesis of purinylalkanolphosphonate esters. In one series of experiments, 1-(7-theophyllinyl)-2,3-propanediol[12] was tosylated selectively to give 1-(7-theophyllinyl)-2-hydroxypropyl-3-(*p*-toluenesulfonate) (X). The 3-iodide derivative XI prepared from X failed to enter a Michaelis–Arbuzov reaction which confirms the findings of Preis, *et al.*,[13] who could not prepare alkyl β-hydroxyphosphonates by analogous routes. Protection of the alcoholic hydroxyl group in XI did not alter this picture. Attempts to secure 1-(7-theophyllinyl)-2-acetoxypropanol-3 by tritylating the diol, acetylating the resulting 1-(7-theophyllinyl)-2-hydroxy-3-propyl triphenylmethyl ether (XII), and hydrogenolyzing off the trityl group failed because the protecting acetyl group of XIII was lost under the conditions required for the removal of the trityl group.



X, R = OH, R′ = $OSO_2C_6H_4CH_3$
XI, R = OH, R′ = I
XII, R = OH, R′ = $OC(C_6H_5)_3$
XIII, R = OAc, R′ = $OC(C_6H_5)_3$

Condensation of adenine with 1-chloro-2,3-propanediol in alkaline solution furnished an amorphous product which was identified as 1-(6-amino-*x*-purinyl)-2,3-propanediol by analysis of its dipicrate. Since the compound did not yield a satisfactory product on tosylation it was not investigated further.

Experimental[14]

7-[2,3,4-Tri-*O*-acetyl-6-deoxy-6-(diethyl phosphonate)-β-D-glucopyranosyl]-theophylline (II).—A mixture of 5.31 g. (0.01 mole) of 7-(2,3,4-tri-*O*-acetyl-6-deoxy-6-bromo-D-glucopyranosyl)-theophylline (I)[4] and 6.64 g. (0.04 mole) of triethyl phosphite was heated at 165° for 4.5 hours, the yellow product was freed of excess triethyl phosphite under reduced pressure at 95°, and the oily residue washed with petroleum ether. It was triturated with 30 ml. of ether, and 2.35 g. (40%) of long colorless needles was filtered. After recrystallization from benzene–isoöctane, they exhibited m.p. 167–168°, $[\alpha]^{27}D$ −10.40° (chloroform, *c* 1.942).

Anal. Calcd. for $C_{23}H_{33}N_4O_{12}P$: C, 46.93; H, 5.65. Found: C, 47.30; H, 5.66.

7-(2,3,4-Tri-*O*-acetyl-6-deoxy-6-iodo-β-D-glucopyranosyl)-theophylline.—A solution of 1.35 g. (2.5 mmoles) of I, 0.75 g. (5 mmoles) of sodium iodide and 0.2 g. of cuprous iodide in 30 ml. of anhydrous acetone was refluxed for 24 hours, and the solvent was removed under reduced pressure. The resinous residue was dissolved in 25 ml. of chloroform, filtered and washed with 5-ml. portions of water, 5% sodium thiosulfate solution and water. The solution was dried over sodium sulfate and the solvent evaporated under reduced

pressure. The colorless crude residue weighed 1.5 g. and crystallized from 20 ml. of absolute ethanol, m.p. 197° after softening at 125° and partially melting at 135–137°.

Anal. Calcd. for $C_{19}H_{23}IN_4O_9$: C, 39.45; H, 4.00. Found: C, 39.50; H, 4.21.

6-Benzamido-9-(2,3,4-tri-*O*-acetyl-6-deoxy-6-bromo-β-D-glucopyranosyl)-purine (VI).—A mixture of 15.0 g. (31.6 mmoles) of chloromercuri 6-benzamidopurine,[7,15] 18.0 g. (41.7 mmoles) of I, 12 g. of Celite and 500 ml. of dry xylene was stirred and refluxed for 1 hour, filtered and the solid washed with hot xylene. The filtrate on cooling deposited 14.5 g. of colorless crystals, m.p. 100–135°. Three recrystallizations from 40 ml. of absolute ethanol yielded 4.45 g. (24%) of material, m.p. 213–214°; $[\alpha]^{27}D$ −23.64° (chloroform, *c* 1.903); λ_{max} 0.01 *N* HCl 281 mμ (ε 22,699.6), λ_{min} 0.01 *N* HCl 235 mμ (ε 10,303.6).

Anal. Calcd. for $C_{24}H_{24}BrN_5O_8 \cdot H_2O$: C, 47.37; H, 4.30. Found: C, 47.74; H, 4.34.

Water of hydration was removed by drying at 139° (1 mm.) for 24 hours. The anhydrous material melted at 214–215°.

Anal. Calcd. for $C_{24}H_{24}BrN_5O_8$: C, 48.82; H, 4.09; N, 11.86. Found: C, 48.85; H, 4.18; N, 12.08.

The yellow picrate crystallized from ice-cold ethanol, m.p. 185–186° dec.

Anal. Calcd. for $C_{30}H_{27}BrN_8O_{15}$: C, 43.96; H, 3.32. Found: C, 43.85; H, 3.40.

2,3,4-Tri-*O*-acetyl-6-deoxy-6-bromo-β-D-glucopyranosyl Chloride.—The xylene solution (*vide supra*) from which VI had been filtered was concentrated to 30 ml. and diluted with petroleum ether. It deposited 1.1 g. of colorless needles which after recrystallization from absolute ethanol melted at 165.5–166.5°, $[\alpha]^{28}D$ +170.1° (chloroform, *c* 1.19).

Anal. Calcd. for $C_{12}H_{16}BrClO_7$: C, 37.18; H, 4.16; halogen, 25.89. Found: C, 37.36; H, 4.20; halogen, 24.35.

Treatment of 0.3 g. of this substance with a mixture of 0.16 g. of silver acetate and 5 ml. of glacial acetic acid at 95° for 30 minutes, filtration from silver chloride, evaporation of the solvent and dilution with 30 ml. of water yielded 0.26 g. of colorless needles which after recrystallization from ethanol melted at 126–126.5°. A mixture melting point with an authentic sample[4] of 1,2,3,4-tetra-*O*-acetyl-6-deoxy-6-bromo-β-D-glucopyranose showed no depression.

The ethanolic mother liquors from the recrystallization of the 14.5 g. of crude VI described above gave on concentration and cooling 1.6 g. of buff-colored crystals which were recrystallized from absolute ethanol, m.p. 203–204°. The compound contained halogen, reacted rapidly with silver nitrate, and showed *p*H 5.

Anal. Found: C, 24.6; H, 3.1.

6-Amino-9-(2,3,4-tri-*O*-acetyl-6-deoxy-6-bromo-β-D-glucopyranosyl)-purine (VII).—When VI was treated with a hot ethanolic solution of picric acid, the picrate of VII crystallized out, m.p. 231–232° dec.

Anal. Calcd. for $C_{23}H_{23}BrN_8O_{14}$: C, 38.61; H, 3.24. Found: C, 38.65; H, 3.26.

6-Amino-9-(6-deoxy-6-bromo-β-D-glucopyranosyl)-purine (VIII).—Removal of picrate ion from the picrate of VII with Dowex No. 1 anion-exchange resin (in the chloride form) in 50% aqueous acetone[7] followed by alkalinization with 10% ammonium hydroxide yielded colorless crystals which melted at 214–216° dec. after sintering at 200°.

Anal. Calcd. for $C_{11}H_{14}BrN_5O_4$: C, 36.67; H, 3.91. Found: C, 36.28; H, 4.10.

The yellow picrate crystallized from ethanol, m.p. 204–205° dec.

Anal. Calcd. for $C_{17}H_{17}BrN_8O_{11}$: C, 34.64; H, 2.90. Found: C, 34.27; H, 3.00.

6-Benzamido-9-[2,3,4-tri-*O*-acetyl-6-deoxy-6-(diethyl phosphonate)-β-D-glucopyranosyl]-purine (IX).—A mixture of 1.9 g. (3.2 mmoles) of VI and 2.65 g. (16 mmoles) of triethyl phosphite was heated at 160–165° for five hours and excess triethyl phosphite was distilled from the orange-red solution under vacuum. The oily residue was washed with petroleum ether, dissolved in 15 ml. of absolute ethanol, cleared with Norite and allowed to crystallize after addition of ether. The mother liquor was evaporated, and the residue crystallized from water. A total of 0.8 g. (45%) of material of m.p. 200–201° was obtained. In another run, the product was isolated in comparable yield by chromatography of the oily material over activated alumina.

Anal. Calcd. for $C_{28}H_{34}N_5O_{11}P \cdot H_2O$: C, 50.52; H, 5.45; N, 10.52; P, 4.65. Found: C, 50.05; H, 5.58; N, 10.28; P, 5.29.

A solution of 0.8 g. of IX in 15 ml. of 1:1 aqueous acetone was treated with ammonium hydroxide to *p*H 9 and allowed to stand at 6° for 16 hours. The solvents were evaporated *in vacuo* and the resinous residue dissolved in chloroform. The chloroform solution was washed with water, dried and evaporated. The residue crystallized from water as shiny plates, m.p. 112–113°.

Anal. Found: C, 50.47; H, 5.31; N, 9.85; P, 5.08.

Action of Ethyl Diphenyl Phosphite on VI.—When VI was heated with a fourfold excess of ethyl diphenyl phosphite[4,11] at 165°, the reaction mixture turned dark within 2.5 hours and decomposed on further heating. Since warming at 100° did not furnish a homogeneous solution even after 190 hours, the reactants were heated at 155° for 3 hours, in another run. The resulting dark yellow solution was heated at 131° for another 48 hours, and now the clear brown mixture no longer contained bromine. It was taken up in isopropyl ether, and a residual insoluble gum was triturated with ether until it became an amorphous solid. This material was chromatographed over alumina in benzene–chloroform. The main oily fraction became amorphous on treatment with isopropyl ether and ether. It contained neither halogen nor phosphorus and decomposed at 70°.

Anal. Found: C, 52.07; H, 4.78.

Methyl 2,3-Isopropylidene-5-deoxy-5-(diethyl phosphonate-D-ribofuranoside (III).—A mixture of 41.1 g. (0.131 mole) of methyl 2,3-isopropylidene-5-deoxy-5-iodo-D-ribofuranoside[5] and 120 g. of triethyl phosphite was heated at 160–170° for ten hours and fractionated. After a forerun consisting essentially of diethyl ethylphosphonate, the product distilled as a pale yellow sirup, b.p. 128° (0.05 mm.), $n^{30}D$ 1.451; $[\alpha]^{30}D$ −48.6° (*c* 2.984, in acetone). The yield was 31%.

Anal. Calcd. for $C_{13}H_{25}O_7P$: C, 48.14; H, 7.77. Found: C, 47.42; H, 7.81.

When, instead of triethyl phosphite, ethyl diphenyl phosphite[3,11] was used and the reaction mixture was heated as above but for 120 hours, distillation furnished an oil, b.p. 159–160° (0.07 mm.), as the main product while the ribosidic material decomposed. The composition of the oily distillate corresponds to that of diphenyl ethylphosphonate.[11]

Anal. Calcd. for $C_{14}H_{15}O_3P$: C, 64.12; H, 5.78. Found: C, 63.88; H, 5.97.

1,2,3-Tri-*O*-acetyl-D-ribofuranose-5-deoxy-5-(diethyl phosphonate) (IV).—A solution of 5.0 g. (0.0154 mole) of methyl 2,3-isopropylidene-5-deoxy-5-(diethyl phosphonate)-D-ribofuranoside in 100 ml. of 0.05 *N* aqueous ethanolic (1:1) hydrochloric acid was refluxed for three hours, 3 ml. of pyridine was added, and the solvents were removed by co-distillation with benzene under reduced pressure. The residual oil strongly reduced Fehling solution and formed a sirupy diethyl mercaptal.[16] It was dissolved in 100 ml. of dry pyridine, cooled to 0°, and allowed to stand with 40 ml. of acetic anhydride for 24 hours. Excess acetic anhydride was decomposed carefully with water, the solution was diluted to 500 ml. and extracted repeatedly with chloroform. The chloroform extract was washed with 20% sulfuric acid, sodium carbonate solution and water, dried and distilled.

(15) 6-Benzamidopurine was prepared by a modification of the directions of A. Kossel, *Z. physiol. Chem.*, **12**, 241 (1888), by heating adenine with benzoic anhydride at 180° for 30 minutes. The yield was 83%, m.p. 242–244° dec.; λ_{max} 0.01 *N* HCl 287 mμ (ε 12,429), λ_{min} 0.01 *N* HCl 230 mμ (ε 5812).

(16) Additional evidence for the hydrolysis of the methyl ribofuranoside linkage of III may be gathered from the fact that G. W. Kenner, C. W. Taylor and A. R. Todd, *J. Chem. Soc.*, 1620 (1949), had hydrolyzed methyl 2,3-isopropylidene-5-benzyl-D-ribofuranoside under the same conditions. Again, a selective hydrolysis of the isopropylidene group in methyl 2,3-isopropylidene-5-deoxy-D-ribofuranoside could be achieved only in 70% methanolic dilute sulfuric acid [C. H. Shunk, R. Spoerri, J. Haldar Folkers, THIS JOURNAL, **77**, 2210 (1955)].

The product (3.8 g., 62%) was a pale yellow oil, b.p. 165–168° (0.08 mm.).

Anal. Calcd. for $C_{15}H_{25}O_{10}P$: C, 45.48; H, 6.36. Found: C, 44.49; H, 6.29.

Treatment of IV with ethereal hydrogen chloride at 0° for 48 hours and thorough removal of the volatile reagents yielded a colorless amorphous product which gave a strong test for halogen and readily precipitated ethanolic silver nitrate solution.

7-(2,3,5-Tri-*O*-benzoyl-β-D-ribofuranosyl)-theophylline (V).—A solution of 0.02 mole of 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl chloride[6] in 35 ml. of anhydrous benzene was added to a stirred suspension of 6.98 g. (0.0242 mole) of silver theophylline in 50 ml. of dry xylene, the benzene was distilled off and the mixture stirred and refluxed for 3 hours. Silver chloride was filtered and the filtrate diluted with 500 ml. of low-boiling petroleum ether. The precipitated colorless soft needles (yield 25%) were recrystallized from isopropyl ether, m.p. 75° dec.; $[\alpha]^{22}D$ −22.1° (*c* 3.63, acetone).

Anal. Calcd. for $C_{33}H_{28}N_4O_9$: C, 63.45; H, 4.52. Found: C, 63.72; H, 4.35.

1-(7-Theophyllinyl)-2-hydroxypropyl-3-*p*-toluenesulfonate (X).—A solution of 85.0 g. (0.45 mole) of *p*-toluenesulfonyl chloride in 200 ml. of dry pyridine was added, over a period of 6 hours, to a stirred, ice-cold solution of 113.5 g. (0.45 mole) of 1-(7-theophyllinyl)-2,3-propanediol[12] in 300 ml. of dry pyridine and 250 ml. of dry ethylene dichloride. After stirring another 90 minutes at 0° and standing overnight, the mixture was treated carefully with 50 ml. of water, extracted with 200 ml. of water, and distilled under reduced pressure, moisture and some pyridine being removed by co-distillation with toluene. The semi-solid residue was taken up in 300 ml. of ethanol, 100 ml. of water was added, and the resulting colorless crystals (83.5 g., 45%) were collected. Recrystallization from ethanol gave a sample, m.p. 134–135°.

Anal. Calcd. for $C_{17}H_{20}N_4O_6S$: C, 49.99; H, 4.93. Found: C, 49.95; H, 5.17.

1-(7-Theophyllinyl)-3-iodo-2-propanol (XI).—This compound was prepared from X by heating with sodium iodide in acetone solution at 100° for 2 hours, and working up the mixture. It crystallized from absolute ethanol, m.p. 165–166°. The yield was 73%.

Anal. Calcd. for $C_{10}H_{13}IN_4O_3$: C, 32.98; H, 3.60. Found: C, 33.13; H, 3.67.

1-(7-Theophyllinyl)-2-acetoxypropyl-3-*p*-toluenesulfonate.—Acetylation of XI with acetic anhydride in excess dry pyridine at 0°, standing at 30° for 24 hours and decomposition with water, yielded 75% of a colorless product which was recrystallized from ethanol, m.p. 173–175°.

Anal. Calcd. for $C_{19}H_{22}N_4O_7S$: C, 50.63; H, 4.92. Found: C, 50.32; H, 5.11.

1-(7-Theophyllinyl)-2-acetoxy-3-iodopropane.—This compound was prepared in 54% yield from 1-(7-theophyllinyl)-2-acetoxypropyl-3-*p*-toluenesulfonate as described for XI above. The colorless plates (from ethanol) melted at 177–179° dec.

Anal. Calcd. for $C_{12}H_{15}IN_4O_4$: C, 35.48; H, 3.72. Found: C, 35.30; H, 3.68.

1-(7-Theophyllinyl)-2-hydroxy-3-propyl Triphenylmethyl Ether (XII).—A solution of 2.09 g. (0.01 mole) of 1-(7-theophyllinyl)-2,3-propanediol[12] and 2.79 g. (0.01 mole) of triphenylchloromethane in 20 ml. of dry pyridine was refluxed for 30 minutes, cooled and diluted with water. The gummy precipitate was washed with water, dried azeotropically with benzene, and crystallized from ethanol–pentane. The shiny plates melted at 174–176°.

Anal. Calcd. for $C_{29}H_{28}N_4O_4$: C, 70.14; H, 5.68. Found: C, 70.30; H, 5.86.

Acetylation with acetic anhydride in hot pyridine solution for 30 minutes gave **1-(7-theophyllinyl)-2-acetoxy-3-propyl triphenylmethyl ether** (XIII) which crystallized from ethanol, m.p. 169–171°.

Anal. Calcd. for $C_{31}H_{30}N_4O_5$: C, 69.13; H, 5.97. Found: C, 69.19; H, 5.85.

1-(6-Amino-x-purinyl)-2,3-propanediol Dipicrate.—A solution of 5.40 g. (0.04 mole) of adenine in 200 ml. of 0.2 *N* sodium hydroxide was treated with 4.42 g. (0.04 mole) of 1-chloro-2,3-propanediol, and the mixture was refluxed for five hours. The solvent was removed *in vacuo*, the residue was taken up in boiling methanol and filtered from sodium chloride. An amorphous precipitate was obtained by adding ether to the filtrate. It was converted to the yellow dipicrate which was recrystallized from a large volume of ethanol and did not melt below 300°.

Anal. Calcd. for $C_{20}H_{17}N_{11}O_{16}$: C, 35.99; H, 2.57. Found: C, 35.96; H, 2.42.

1,3-Bis-(7-theophyllinyl)-propanol-2.—To a suspension of 14.35 g. (0.05 mole) of dry silver theophylline in 350 ml. of dry dimethylformamide was added 6.85 g. (0.05 mole) of epibromohydrin. The mixture was stirred and heated at 130° but stirring had to be interrupted when a thick yellow precipitate separated. After standing for one hour, stirring and heating were resumed and continued for 4 hours. The granular precipitate was filtered, the solvent removed under reduced pressure, and the tan solid residue washed with cold acetone and ethanol. It was dissolved in dilute acid, reprecipitated with ammonium hydroxide, and weighed 4.5 g. (42%). Recrystallization from water with the aid of Norite gave colorless needles, m.p. 273–274°.

Anal. Calcd. for $C_{17}H_{20}N_8O_5$: C, 49.03; H, 4.84. Found: C, 49.09; H, 5.04.

(7-Theophyllinylmethyl)-oxirane.—When the reaction between silver theophylline and epibromohydrin described above was conducted in boiling xylene for 24 hours and the solvent was evaporated, a small amount of a solid could be extracted from the residue with boiling ligroin. The colorless product from the ligroin extract was recrystallized from ligroin–ethanol, m.p. 160–162°.

Anal. Calcd. for $C_{10}H_{12}N_4O_3$: C, 50.84; H, 5.12. Found: C, 50.33; H, 5.00.

Yeast Alcohol Dehydrogenase. III. Relation of Alcohol Structure to Activity[1]

BY JAN VAN EYS AND NATHAN O. KAPLAN

RECEIVED NOVEMBER 2, 1956

The specificity of yeast alcohol dehydrogenase toward alcohols has been investigated. It was concluded that three factors determine specificity: (1) nucleophilic character of the alcohol, (2) molecular dimensions of the alcohol, and (3) orientation of the alcohol molecule. The known stereospecificity of the enzyme is also apparent in the oxidation of truly asymmetric substrates. The absolute configuration of the suitable substrates is that of the L-series. The enzyme will serve as a lactic dehydrogenase, with ADP as an activator; this oxidation is specific for D(−)-lactic acid. The steric limitations of the alcohol oxidation are at least partially determined by the coenzyme used. The implications of these findings are discussed.

Introduction

The alcohol specificity of yeast ADH[2] has been studied by previous investigators.[3,4] However, no general conclusion was drawn from the structure of those alcohols which would function as a substrate for the enzyme. The only conclusion reached was that the enzyme is not specific for ethanol, but rather that many primary and secondary alcohols will be oxidized. It has recently been demonstrated that the oxidation of alcohol by yeast ADH is stereospecific with regard to ethanol.[5,6]

Previous work in this laboratory has shown that only one ethanol appears to be oxidized at a time,[7] even though four coenzyme molecules are bound.[7,8] In a search for explanations of this lack of stoichiometry an attempt was made to correlate the structure of the alcohol with its ability to serve as a substrate for yeast ADH. It was found that three factors govern the effectiveness of a given substrate: (1) the molecular dimensions of the substrate in the vicinity of the carbinol grouping; (2) the nucleophilic character of the alcohol; and (3) the orientation of the substrate with respect to the enzyme. In addition, data will be presented which indicate that the absolute configuration of the alcohol as oxidized is of the L-series.

Experimental

Enzymes.—Twice recrystallized yeast ADH was obtained commercially.[9] Crystalline beef heart LDH[9] was used as the L(+)-lactic acid specific lactic dehydrogenase; an ammonium sulfate cut between 50 and 75% saturation from a sonicate of *Leuconostoc mesenteroides* cells served as a source of D(−)-lactic acid specific LDH.[10]

Coenzymes.—DPN and ADP were obtained from the Pabst Laboratories. The coenzyme analogs were obtained by the action of pig brain DPNase on DPN in the presence of the appropriate pyridine base as described for the isonicotinic acid hydrazide[11] and acetylpyridine[12] analogs of DPN. DPNH was prepared enzymatically from DPN as described[11] previously.

Substrates.—All alcohols, when obtained as reagent grade, were used without prior purification. Those which were obtained in practical grade were purified by fractional distillation. Calcium D(−)-lactate and calcium L(+)-lactate were obtained from the California Foundation for Biochemical Research. Their purity was checked with the appropriate LDH, using acetylpyridine-DPN as coenzyme.[12] D(−)-Lactate contained less than 0.1% of the other isomer, but L(+)-lactic acid was contaminated with at least 5% of its enantiomorph. 2-Octanol was resolved *via* the brucine salt of the monohydrogenphthalates.[14]

Rate Determinations.—Rates were determined in a Beckman spectrophotometer, model DU, at the appropriate absorption maximum of the coenzyme used.[12,15] Rates were defined as the increase in optical density at the absorption maximum between the 15 and 30 second interval after starting the reaction with enzyme.

Results

Substrate Specificity

The Effect of Increasing Chain Length.—All primary alcohols tested will serve as a substrate for yeast ADH. In the straight chain homologous series, the reactivity decreases with increasing chain length. The only exception is methanol, which will be discussed below. The decrease in activity is not greater than can be expected from the decreased electronegativity of the carbinol grouping. Hine and Hine[16] have determined that the "acidity" of alcohols in a homologous series is approximately linearly related to the pK_a of the corresponding fatty acids. Thus, if one plots the logarithm of the relative rate of the straight chain alcohols *versus* the chain length, a straight line relationship should be obtained if the relative activity is due solely to the apparent dissociation ability of the alcohol. This indeed appears to be the case (Fig. 1). Variations of the concentration of the alcohols did not change the order of activity of the substrates.

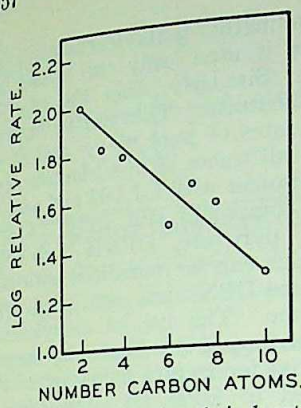

Fig. 1.—The effect of increasing chain length on the rate of oxidation: alcohol concentration 2.5×10^{-3} *M*, tris buffer, 0.05 *M*, *p*H 9.3, DPN 3.5×10^{-4} *M*. The value for amyl alcohol is not given, since the alcohol contained an inhibitor, which even on repeated fractional distillation could not be removed completely.

Effect of Steric Hindrance.—If the dissociation ability of the alcohol were the only determining step, compounds like chloroethanol or other alcohols with an electron attracting group should be better substrates than the corresponding primary alcohols. But this is not the case, chloroethanol is a poorer substrate than ethanol. The influence of substitution is indicated in Table I. It is clear that any substituent regardless of its electron donating or attracting ability, decreases the rate. That this effect is due to steric hindrance is best illustrated by the phenyl-substituted alcohols. This is shown in Fig. 2. Whereas benzyl alcohol and 2-phenylethanol are relatively poor substrates, 3-phenyl-1-propanol is oxidized at a quite rapid rate.

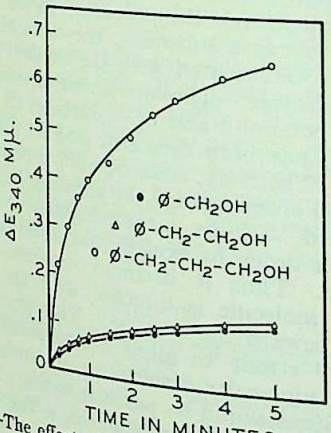

Fig. 2.—The effect of phenyl substitution on the rate of alcohol oxidation: substrate concentration 5×10^{-3} *M*, in tris buffer, *p*H 9.3, 0.05 *M*, DPN concentration 1.5×10^{-4} *M*, yeast ADH 250 mcg.

Effect of Orientation.—A third factor was found to play a role in the alcohol specificity. If steric hindrance were, together with nucleophilic character, the solely decisive factor, a large molecule would at all times be oxidized more slowly than a small molecule. However, *n*-decanol is not slower, relative to ethanol, than can be expected from the inductive effect of the sidechain. Therefore the

Table I

The Influence of Substitution on the Ability of Alcohols to Serve as Substrate for Yeast Alcohol Dehydrogenase

Alcohol[a]	Relative rate	Alcohol[a]	Relative rate
Methanol	8	Diethylamino-ethanol	0
Ethanol[b]	1000	2-Chloroethanol	8
n-Alkylcarbinols	[c]	Isobutyl alcohol	4
Methyl-*n*-alkyl carbinols	[d]	Isoamyl alcohol	4
Ethylene glycol	1.2	3-Hexanol	0
Glycerol	7	*t*-Butyl alcohol	0
Erythritol	2	D(−)-Lactic acid	3
L-Arabitol	1.5	Glycolic acid	17
2-Aminoethanol	22	DL-β-Hydroxy-butyric acid[e]	1
Dimethylamino-ethanol	0		

[a] The alcohols were tested at a concentration of 5.0×10^{-3} *M*, in tris buffer, 0.05 *M*, *p*H 9.3, DPN 1.5×10^{-4} *M*. Slow rates were checked with ADP as cofactor at a concentration of 7.0×10^{-3} *M*. [b] Arbitrarily assigned 1000. [c] See Fig. 1. [d] See Fig. 3. [e] Tested at double concentration.

"size" of ethanol and *n*-decanol appears to be the same for the enzyme. This can only be the case if both are oriented in such a way that only the carbinol moiety will attack the enzyme. This is even more clearly illustrated in the methyl-*n*-alkylcarbinol series. Even though isopropyl alcohol is relatively slowly oxidized, methylpropylcarbinol reacts faster although the dimensions of the latter are greater and the acidity of the carbinol is less. If one plots the logarithm of the relative rate of these secondary carbinols *versus* the chain length, a maximum is observed at 5 carbons (Fig. 3). The expected rate, assuming no

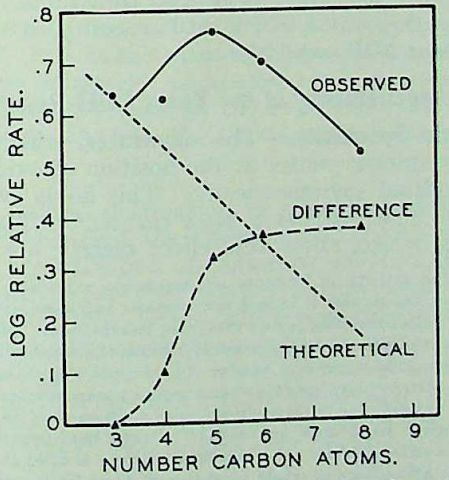

Fig. 3.—The effect of increasing chain length on the rate of oxidation of methyl-*n*-alkyl-carbinols: the concentration of alcohols was 2.5×10^{-3} *M* of the active isomer. The DL-isomers were employed for the alcohols of chain length of four carbons or more. Tris buffer, *p*H 9.3, 0.05 *M*, DPN 3.5×10^{-4} *M*. The theoretical rate was determined from the equation

$$\log \text{relative rate} = -0.09 (\text{no. carbon atoms}) + 0.88$$

This relationship was derived from the data in Fig. 1. The difference curve describes the deviation of the observed values from the theoretical relationship, and is proposed to

steric hindrance and a decrease in nucleophilic character similar to the *n*-alkylcarbinols, would give a decrease of the rate with increasing chain length. The difference between expected and observed rates shows that an increase occurs up to about six carbon chain length (Fig. 3). This can be interpreted as an indication of orientation of the molecule. Similarly, lactic acid is oxidized stereospecifically.[17] Yet, if steric hindrance is taken into account, both the carboxy group and the methyl group could attack the enzyme. It may be mentioned here, that even though compounds like lactic acid are very poor substrates, significant and even rapid rates can be observed using about 7×10^{-3} *M* ADP as an activator[18] (Fig. 4).

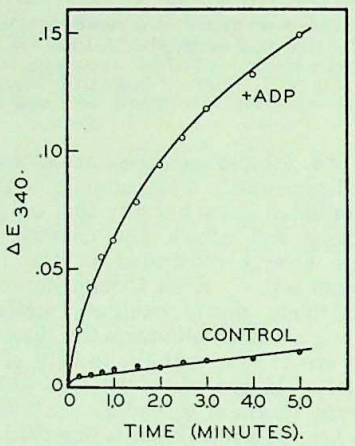

Fig. 4.—The effect of ADP on the rate of lactate oxidation: D(−)-lactic acid 7×10^{-3} *M*, DPN 1.5×10^{-4} *M*, in tris buffer, *p*H 9.3, 0.05 *M*, ADP concentration 8×10^{-4} *M*. Yeast ADH added 25 mcg.

Stereochemistry of the Yeast ADH Reaction

Steric Specificity.—The substrates, which have an asymmetric center at the position of oxidation, are oxidized asymmetrically. This holds even for ethanol,[5,6] which has a *meso* carbon.[19] The substrates which show this effect clearly are lactic acid and the methyl-*n*-alkylcarbinols. If the racemic mixture is used, only one isomer is oxidized (Table II). Similarly, only the D(−)-lactate is used as a substrate. This can be shown by comparing the rates of pure D(−)- and L(+)-lactate. Even when all traces of L(+)-lactate are removed from the D-isomer with L-LDH and acetylpyridine-DPN, the compound still serves as a substrate. Conversely, pyruvate, DPNH and ADH give a product which can be reoxidized with D-LDH and acetylpyridine-DPN, but not with L-LDH and the coenzyme. The use of acetylpyridine-DPN in these experiments is indicated by the more favorable potential for lactate oxidation of this analog as compared to DPN.[12,20] The effectiveness of the analog with many dehydrogenases recently has been demonstrated.[20]

TABLE II

THE STEREOSPECIFICITY OF YEAST ALCOHOL DEHYDROGENASE FOR SECONDARY ALCOHOLS

Alcohol oxidized[a]	μ Moles added	μ Moles DPN[b] reduced
Isopropyl alcohol	0.25	0.22
DL-2-Butanol	.25	.11
DL-2-Octanol	.25	.12
L(+)-Octanol-2[c]	.25	.25

[a] The substrates were tested in tris buffer, *p*H 9.3, 0.05 *M*, containing DPN 1.8×10^{-3} *M*, in a final volume of 3 ml. [b] Molar extinction coefficient of DPNH used: 6.22×10^3. [c] Monohydrogenphthalate $[\alpha]^{21}D$ +47.2° (*c* 0.65, ethanol); reported[14] +48.4°.

Influence of Orientation on Stereospecificity.—When 2-octanol was resolved, it became apparent that the isomer utilized was L(+)-octanol-2.

It was made likely above that *n*-alkyl carbinols are oriented in such a way that only the carbinol moiety will attack the enzyme. Since 3-hexanol cannot serve as a substrate, the octanol molecule appears to be oriented with the methyl group toward the enzyme. The correlation of configuration of L-(+)-octanol-2 and D(−)-lactate, as indicated in Fig. 5, has been demonstrated by Levene and Haller.[21] Therefore, since octanol is oriented with the methyl group toward the enzyme, lactate must be oriented with its carboxyl group toward the enzyme in order to explain the observed stereospecificity. Thus it becomes evident that the substrate molecule is directed with the negative grouping toward the enzyme. This orientation is sufficiently strong to allow stereospecificity even when the molecular dimensions are such that another position would be possible within the limitations imposed by the enzyme, as is the case with lactic acid.

Since the orientation of lactate and octanol appears to be strong, it is highly likely that ethanol will be similarly oriented. If we assume ethanol labeled with deuterium as in Fig. 5, the action of yeast ADH on this molecule would give rise to labeled acetaldehyde. The enantiomorph of the ethanol-*d* represented would give rise to deutero-labeled DPN.

(17) The activity of enzymes on uncommon substrates requires proof that the enzyme is indeed homogeneous and does not contain traces of a contaminating protein catalyzing this reaction. Yeast ADH as used is homogeneous by the physical criterion of ultracentrifugation, and the chemical criterion of number of coenzymes bound per mole of enzyme, both by ultracentrifugational separation techniques (ref. 8), and spectral shift due to the hydroxylamine addition reaction (ref. 7). Furthermore, yeast does not contain a lactic dehydrogenase, but rather a lactic acid oxidase. This latter enzyme is L(+)-lactic acid specific. All activity of whole yeast toward D(−)-lactic acid can be accounted for as due to ADH. This was shown by following the purification procedure of yeast ADH as described by Racker (E. Racker, *J. Biol. Chem.*, **194**, 313 (1950)), and measuring activity toward ethanol and D(−)-lactic acid thoughout the purification. The ratio of activity toward both substrates remained constant. The activity toward D(−)-lactic acid was also not due to trace contaminations with alcohols. This was shown by the following points: first, crystalline horse liver alcohol dehydrogenase failed to attack our D(−)-lactic acid preparation; secondly, D(−)-lactic acid can be oxidized stoichiometrically by the action of DPN and yeast ADH, and thirdly, pyruvate will serve as a substrate for yeast ADH. The product of this reaction will serve as a substrate for D-LDH.

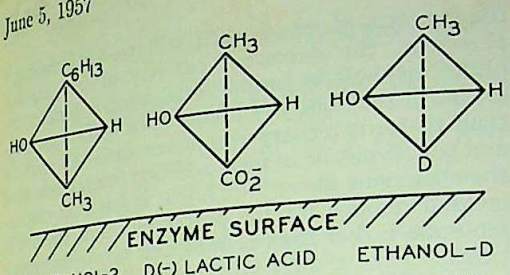

Fig. 5.—The configuration of substrates for yeast ADH.

Influence of Coenzyme on Magnitude of Steric Hindrance.—The enzyme appears to operate according to the reaction sequence[7,22]

Enzyme ⟶ enzyme–coenzyme ⟶
enzyme–coenzyme–substrate

The specificity of the reaction is therefore determined by the enzyme–coenzyme complex, and not by the enzyme alone. The steric limitations are largely governed by the coenzyme used. This can be shown by several lines of evidence. Previously described observations[15] show that some analogs of DPN will not catalyze ethanol oxidation even though the reduced form will reduce acetaldehyde.

Methanol is a poor substrate, since it is not oriented, and since it is too small to afford a fit on the enzyme. However, if one compares the rate of methanol oxidation relative to that of ethanol using different coenzyme analogs, a great variation in methanol effectiveness can be observed (Table III). It is seen that pyridine-3-aldehyde-DPN makes methanol become a reasonable substrate, while with acetylpyridine-DPN the rate with methanol is negligible. For isopropyl alcohol as substrate similar relationships hold. Thus one can assume that the "fit" of the substrate is afforded by the coenzymes and that relatively speaking pyridine-3-aldehyde-DPN gives a better "fit" for methanol than does DPN. The slow rates with acetylpyridine-DPN are not the result of its potential, since there seems to be very little potential difference between acetylpyridine-DPN and pyridine-3-aldehyde-DPN.[20] Furthermore the affinity of the enzyme for the three coenzymes is similar.[7]

TABLE III

THE INFLUENCE OF COENZYME ON THE SPECIFICITY OF YEAST ADH

Coenzyme	Relative rate of coenzyme reduction[a]	
DPN	Ethanol	Methanol
Acetylpyridine-DPN	100	0.8
Pyridine-3-aldehyde-DPN	22.3	.017
	7.3	.86

[a] All rates were performed in tris buffer, 0.05 *M*, *p*H 9.3. Coenzyme concentration, 1.5×10^{-4} *M*, substrate concentration, 5.0×10^{-3} *M*. Rate with DPN and ethanol assigned arbitrarily 100.

The Effect of Reduced DPN on the Rate of a Sterically Hindered Substrate.—The geometry of reduced DPN is markedly different from that of the oxidized form.[15] If the four DPN molecules on the enzyme are responsible for the magnitude of steric hindrance, the enzyme can be made less specific by keeping one of the coenzymes in the reduced state. Thus it can be shown that the rate with D(−)-lactic acid in the presence of ethanol is greater than the sum of the rates of the two substrates tested separately (Fig. 6A). One can postulate the following sequence to be operative

Enzyme-DPN_4 + ethanol ⟶
Enzyme-DPN_3–DPNH + acetaldehyde + H^+

Enzyme-DPN_3–DPNH + lactate ⟶
Enzyme-DPN_2–$DPNH_2$ + pyruvate + H^+

The same phenomenon is also observed with isopropyl alcohol, though the magnitude of the stimulation is not as marked as it is for lactate.

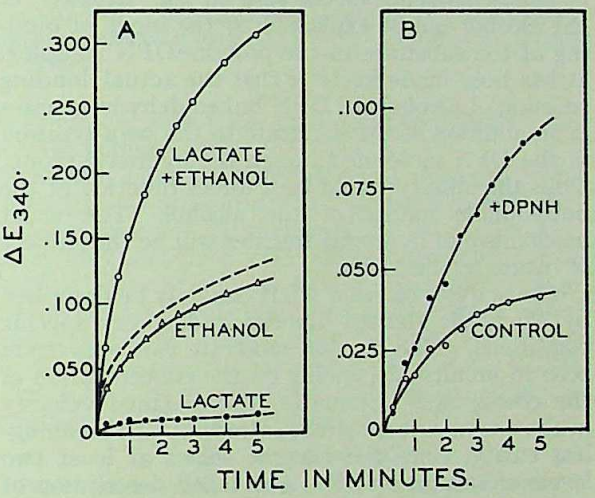

Fig. 6.—The effect of reduced coenzyme on the rate of lactate oxidation: A: Ethanol 5×10^{-3} *M*, D(−)-lactate 7×10^{-3} *M*, DPN 1.5×10^{-4} *M*, in tris buffer, *p*H 9.3, 0.05 *M*. The dashed curve represents the summation of the rates of lactate and ethanol taken separately. B: D(−)-lactate 7×10^{-3} *M*, DPN 1.5×10^{-4} *M*, in tris buffer, *p*H 9.3, 0.05 *M*; DPNH concentration 1.3×10^{-5} *M*.

The above postulation is strengthened by the observation that the addition of DPNH will activate the oxidation of lactate by DPN. This addition can be expected to yield the enzymatic species enzyme–DHN_3–DPNH, which is more efficient as a lactic dehydrogenase than is the species enzyme–DPN_4 (Fig. 6B). The effect is optimal by adding DPN and DPNH in a ratio of about 40 to 1. This is in accord with the stronger binding of DPNH by yeast ADH.[8] The addition of DPNH to a mixture oxidizing ethanol decreases the rate of ethanol oxidation as expected.

Discussion

The picture for alcohol specificity thus requires a model where the enzyme truly gives a place for the substrate to fit in. The easiest picture to explain this phenomenon is given by postulating the four DPN molecules close together and but one substrate molecule fitting in between. The size of the "hole" would be determined by the height of the DPN molecule and the distance between the four coenzyme molecules. A rigid geometry between

(22) J. van Eys and N. O. Kaplan, *Biochim. Biophys. Acta*, **23**, 574 (1957).

the enzyme–coenzyme complex and substrate is adequate to explain stereospecificity toward the substrate, even when no formal bond between enzyme and substrate exists. Similarly a rigid geometry implies equally a stereospecificity toward the coenzyme. These forms of stereospecificity indeed do exist.[5,6,23]

This picture of enzyme–coenzyme–substrate complex is supported by the fact that the enzyme binds four moles of coenzyme,[7,8] but appears to bind only one substrate molecule at a time.[7] Additional evidence is given by the fact that modification of the structure of the DPN-tetrad changes the specificity of the enzyme. This can be done both by changing from DPN to a DPN analog in the reaction, or by converting one DPN to DPNH.

The dependence of the rate on the "acidity" of the alcohol can be explained by the mode of binding of the substrate to the protein–DPN complex. It has been made likely[7,24] that the actual binding reaction of alcohols to DPN linked dehydrogenases is an addition of the substrate to the *para*-position of the DPN molecule through the hydroxyl group. Thus the affinity would be a direct function of the nucleophilic nature of the alcohol. The exact mechanism of hydrogen transfer will be the subject of future publications.

The activity of yeast ADH can only be described by Michaelis-Menten kinetics under very specific conditions. The K_m for substrate can vary from zero to infinity, depending on the concentration of the coenzyme.[25] Similarly, the maximal velocity of the enzyme at substrate saturation is a meaningless entity, since the enzyme shows at least two levels of saturation.[25,26] A detailed description of the kinetics of yeast ADH will be forthcoming.[27] However, the decreased activity of less nucleophilic alcohols is proportional with a similar decrease in the ability of homologous *n*-alkyl mercaptans to form ternary complexes with the enzyme and coenzyme, or to form addition compounds with the coenzyme alone.[27] Thus it is felt that the decreased affinity for the *para*-position of the DPN molecule rather than a decreased rate of hydrogen transfer (*i.e.*, a lower k_3) is responsible for the lower rates with unnatural substrates.

It is not possible to translate the stereospecificity of yeast ADH to lactate and LDH. It is necessary for the assignment of absolute configurational specificity to know both specificity and orientation. There is also no *a priori* indication so far which side of the DPN molecule is reduced. In general, it is necessary to point out that the data solely apply to yeast ADH and are not be generalized to other dehydrogenases until further information is available.

The configuration of the secondary alcohols which are substrates is in agreement with the old observations of Neuberg and Nord[28] that fermenting yeast acts upon 2-octanone, yielding dextrorotatory 2-octanol. It is highly probable that the present studies relate to the ADH inside the yeast cell. Thus it appears that the stereospecificity observed is not an artifact, but truly a property of the enzyme *in vivo*. The significance of activation by nucleoside-polyphosphates[18] within the intact cell remains to be seen. However, since the activation by ADP is quite large, the yeast ADH in the presence of this nucleotide becomes a very unspecific enzyme. It must be pointed out again, however, that no substrate becomes oxidized because of the presence of ADP; the nucleotide merely serves as a tool to give rates rapid enough for convenient comparison with other substrates.

The Structure of the Type VIII Pneumococcus Specific Polysaccharide[1a,b]

BY J. K. N. JONES AND M. B. PERRY

RECEIVED OCTOBER 30, 1956

Acid hydrolysis of the specific polysaccharide of the Type VIII pneumococcus (S VIII) gave D-glucouronic acid (1 part), D-glucose (2 parts) and D-galactose (1 part). Partial acid hydrolysis afforded three acidic oligosaccharides: (a) an aldobiouronic acid, 4-*O*-(β-D-glucopyranosyluronic acid)-D-glucopyranose; (b) an aldotriouronic acid, *O*-β-D-glucopyranosyluronic acid-(1 → 4)-*O*-β-D-glucopyranosyl-(1 → 4)-D-glucopyranose; (c) an aldotetraouronic acid, *O*-β-D-glucopyranosyluronic acid-(1 → 4)-*O*-β-D-glucopyranosyl-(1 → 4)-*O*-α-D-glucopyranosyl-(1 → 4)-D-galactopyranose; and (d) a neutral disaccharide, 4-*O*-α-D-glucopyranosyl-(1 → 4)-D-galactopyranose. Hydrolysis of the methylated S VIII polysaccharide gave 2,3-di-*O*-methyl-D-glucuronic acid (1 part), 2,3,6-tri-*O*-methyl-D-glucose (2 parts) and 2,3,6-tri-*O*-methyl-D-galactose (1 part). Esterification of the S VIII acidic polysaccharide with diazomethane followed by reduction of the product with sodium borohydride in aqueous solution yielded a neutral polysaccharide which on hydrolysis gave D-glucose (3 parts) and D-galactose (1 part). Methylation and hydrolysis of this latter polysaccharide gave 2,3,6-tri-*O*-methyl-D-glucose (3 parts) and 2,3,6-tri-*O*-methyl-D-galactose (1 part). Periodate oxidation of the S VIII polysaccharide showed a consumption of 1.03 moles of metaperiodate per hexose unit. It is considered that the S VIII polysaccharide is essentially a linear chain, high molecular weight polymer with the repeating unit -*O*-β-D-glucopyranosyluronic acid-(1 → 4)-*O*-β-D-glucopyranosyl-(1 → 4)-*O*-α-D-glucopyranosyl-(1 → 4)-*O*-α-D-galactopyranosyl-(1 → 4)-.

I. Introduction

The cross precipitin reactions observed between the S III and the S VIII polysaccharides and their corresponding antisera[2-4] can be related to the occurrence in these two polysaccharides of a common structural unit of 4-*O*-(β-D-glucopyranosyluronic acid)-D-glucopyranose.[5] Similarly the cross reactions observed between the S III antiserum and the polysaccharides from *Azotobacter chroococcum*,[6] *Rhizobium radicicolum*,[7] gum arabic,[8,9] Friedlander's bacillus[10] and oxidized cotton cellulose,[5] all of which possess closely related aldobiouronic acid units, illustrates the remarkable correlation which exists between the fine structure of the carbohydrate and its serological specificity.

The structure of the S III polysaccharide is known to be that of a linear chain of 4-*O*-(β-D-glucopyranosyluronic acid)-D-glucopyranose units joined together by 1 → 3 linkages having the β-configuration.[10-12] The aldobiouronic acids isolated from the partial acid hydrolysis of both the S III and S VIII polysaccharides proved to be identical, both being convertible to the one crystalline hepta-*O*-acetyl methyl ester derivative.[13] The physical and chemical properties of the purified polysaccharide used in this investigation agree very closely with those previously recorded for the S VIII polysaccharide.[2,3,13]

On the basis of immunological evidence using quantitative precipitin and quantitative agglutination techniques, Heidelberger, Kabat and Mayer[4] concluded that the S VIII polysaccharide was probably a linear polymer having 4-*O*-(β-D-glucopyranosyluronic acid)-D-glucopyranose units interposed between other anhydrohexose units and that it had a minimum molecular weight of 140,000. This theory is in agreement with the experimental findings described in this paper.

II. Experimental

Paper chromatography was performed by the descending method[14] on Whatman No. 1 filter paper using several solvent systems: (a) ethyl acetate–acetic acid–water (9:2:2 v./v.); (b) ethyl acetate–acetic acid–formic acid–water (18:8:3:6 v./v.); (c) butan-1-ol–ethanol–water (4:1:2 v./v.); (d) butan-1-ol–pyridine–water (10:3:3 v./v.). Sugars were detected on the chromatogram by spraying with a solution of *p*-anisidine hydrochloride[15] or with a solution of silver nitrate in acetone followed by ethanolic sodium hydroxide solution.[16]

The rate of movement of the sugars on the chromatogram is quoted relative to that of tetra-*O*-methylglucopyranose (R_G), to galactose (R_{Gal}) or to rhamnose (R_{Rh}).

Solutions were concentrated under reduced pressure. Melting points are uncorrected. Optical rotations were determined at 20° in water, unless otherwise stated.

Isolation and Purification of the S VIII Polysaccharide.—The polysaccharide, which had been prepared by a method specifically designed to cause as little breakdown of the molecule as possible during its isolation,[17] was supplied in the form of a white fibrous solid which dissolved in water to give a highly viscous acidic solution, $[\alpha]_D$ +115° (*c* 0.4). The polysaccharide (7 g.) was dissolved in Fehling solution A (alkaline tartrate) (*ca.* 150 ml.), and Fehling solution B ($CuSO_4$) was added dropwise to the stirred solution until no more precipitation of the polysaccharide complex was obtained. The complex was removed by filtration under gravity on a sintered glass filter and washed well with cold water. The copper was removed from the complex by the addition of *N* hydrochloric acid (*ca.* 60 ml.) to the material suspended in water (1 l.) kept at 0°. The viscous solution was centrifuged, and the clear solution was poured into ethanol (4 vols.) with vigorous stirring. The precipitated polysaccharide was collected on the filter, washed with

ethanol and dried *in vacuo* to give a fine white powder (6.2 g.).

The sodium salt of the S VIII polysaccharide was examined by electrophoresis using Whatman fiber-glass as the support and an electrolyte of crystalline borax (38 g.) in 0.12 *N* sodium hydroxide solution (1 l.). The paper was uniformly wetted with the electrolyte, and a 10% solution of the polysaccharide dissolved in the prepared electrolyte, was spotted on the base line.[18] After electrophoresis the carbohydrates were located by first spraying the paper with a 3% (w./v.) solution of α-naphthol in methanol followed by spraying it with concentrated sulfuric acid. The S VIII polysaccharide was thus located as a single discrete spot.

Electrophoresis of the S VIII polysaccharide (400 mg.) as described above, followed by extraction of the appropriate part of the paper with water, and deionization (resins), afforded the electrophoretically pure polysaccharide which had $[\alpha]_D$ +124° and equivalent weight 692. Hydrolysis of this polysaccharide with formic acid, followed by paper chromatographic examination of the hydrolyzate, showed it to be composed of glucuronic acid (1 part), galactose (1 part) and glucose (2 parts). The electrophoretically pure polysaccharide is chemically and physically indistinguishable from the starting material.

The polysaccharide could not be further fractionated by precipitation of its cetyltrimethylammonium salt and subsequent regeneration of the free polysaccharide.[19,20a,b] The S VIII polysaccharide obtained *via* its copper complex was deionized by passing its solution first through a bed of Amberlite ion-exchange resin IR 120(H) and then through a bed of IR 4B(OH).[21] The eluate was freeze-dried to give the ash-free polysaccharide which had $[\alpha]_D$ +121° (*c* 0.4) and equivalent weight of 703 (≡25.2% hexuronic anhydride), found by titration with standard alkali.

Anal. Calcd. for $[(C_6H_{10}O_5)_3.(C_6H_8O_6)]_x$ (polymer with a repeating unit of 3 hexose units and 1 hexuronic acid unit): C, 43.5; H, 5.72. Found: C, 43.6; H, 5.56; N, nil; P, nil.

The polysaccharide gave no color with iodine but gave a strong positive test for hexuronic acid with the naphthoresorcinol reagent.[22] Attempted autohydrolysis and attempted hydrolysis with 0.01 *N* sulfuric acid of 1% solutions of the polysaccharide at 100° for 8 hr. failed to liberate any sugars detectable on the chromatogram.

Component Sugars of the S VIII Polysaccharide.—The polysaccharide (1 g.) was heated with 90% formic acid (100 ml.) at 100° for 22 hr. The formic acid was removed by distillation and the residue further hydrolyzed by heating it with *N* sulfuric acid (15 ml.) for 2 hr. at 100°. After neutralization ($BaCO_3$) and filtration, a portion of the hydrolyzate was concentrated and examined on paper chromatograms. In solvent system d, detection with *p*-anisidine revealed two spots corresponding in position and color to galactose and glucose (visual ratio 1:2), and a component giving a red colored spot remained near the base line. In solvent system a, spots corresponding to galactose and glucose were again obtained together with a red spot (R_{Gal} 0.96) corresponding in position to a hexuronic acid. The main bulk of the hydrolyzate was passed first through a column of IR 120(H) resin (1.5 × 6 cm.) and then through a column of IR 4B(OH) resin (1.5 × 5 cm.). Concentration of the eluate gave the neutral sugars as a sirup (560 mg.) which was fractionated by partition chromatography on large sheets of filter paper using solvent system d as the mobile phase. Development was allowed to proceed for 5 days with intermediate drying of the papers at 24-hr. intervals. Extraction of appropriate sections of the paper afforded crystalline D-galactose, m.p. 165°, $[\alpha]_D$ +80° (*c* 1.1), which gave a 1-methyl-1-phenylhydrazone derivative, m.p. 186°, and D-glucose, m.p. 145°, $[\alpha]_D$ +50° (*c* 0.9) (mixed m.p.'s showed no depression).

The IR 4B column above was eluted with 10% formic acid and the formic acid then removed from the aqueous eluate by continuous extraction with ether. Examination of this latter eluate on paper chromatograms in solvent system a and detection with *p*-anisidine revealed one main spot (R_{Rh} 1.33) corresponding in position to authentic glucurono-6 → 3-lactone, and a faint spot (R_{Gal} 0.96) corresponding to glucuronic acid (galacturonic acid does not form a lactone and mannuronolactone has R_{Rh} 0.95). Concentration of this aqueous eluate to dryness and dissolution of the residue in glacial acetic acid on cooling afforded D-glucurono-6 → 3-lactone, m.p. and mixed m.p. 178°, $[\alpha]_D$ +18° (*c* 0.8).

Quantitative Estimation of the Component Sugars of S VIII.—Samples of the polysaccharide (*ca.* 30–40 mg.) were hydrolyzed for 20 hr. with 96% formic acid (3 ml.) in sealed tubes placed in a boiling water-bath. A weighed amount of L-rhamnose (*ca.* 15 mg.) was added and the formic acid removed by distillation. The residue was then hydrolyzed with *N* sulfuric acid (2 ml.) for a further 2 hr. at 100°. The acid was neutralized ($BaCO_3$), filtered, the filtrate concentrated to about 2 ml. and ethanol (6 ml.) was added. After standing at 5° for 8 hr. the precipitated barium D-glucuronate was removed on the centrifuge and the supernatant solution was concentrated to a small bulk and applied evenly to the base line of a paper chromatogram. The chromatogram was developed in solvent system d during 6 days with intermediate drying. The separated sugars were quantitatively extracted,[23] and the amounts of the sugars present were estimated colorimetrically by the benzidine method.[24] The results indicate that the galactose and the glucose are present in the ratio 1:2. Found: D-galactose, 21.4, 20.0, 24.0; D-glucose, 40.5, 42.1, 40.3 (based on the recovery of L-rhamnose).

The uronic anhydride content of the polysaccharide was determined by quantitative decarboxylation with 12% hydrochloric acid, and determination of the carbon dioxide produced, by an iodometric procedure.[25] Found: hexuronic anhydride, 27.8%, 26.8%, 27.8%.

Reduction of the S VIII Polysaccharide.—The freeze-dried ash-free S VIII polysaccharide (4 g.) was moistened with methanol and a solution of diazomethane in ether was added. When the initial vigorous liberation of nitrogen was over (10 min.) the excess diazomethane together with the solvents were removed by distillation. The residue was dissolved in water (150 ml.) to give a mobile solution which was added over 1 hr. to a solution of sodium borohydride (2 g.) in water (50 ml.) with vigorous stirring.[26] Stirring was continued overnight, and the excess borohydride was destroyed by acidification with 2 *N* sulfuric acid. The reaction mixture was poured with stirring into ethanol (4 vol.) and the precipitated polysaccharide was collected on the centrifuge. The above operations were repeated on this material after it had been deionized (resins) and freeze-dried again, to give a final product (3.2 g.) which was readily soluble in water to give a neutral mobile solution, $[\alpha]_D$ +130° (*c* 0.5). Attempted decarboxylation[25] yielded negligible amounts of carbon dioxide, and the naphthoresorcinol test[22] for uronic acid was negative.

The neutral polysaccharide (40 mg.) was hydrolyzed with 96% formic acid (4 ml.) in a sealed tube at 100° for 10 hr. and, after removal of the formic acid, hydrolysis was continued with *N* sulfuric acid (2 ml.) for 2 hr. at 100°. Examination of the neutralized ($BaCO_3$) hydrolyzate by paper chromatography in solvent system a revealed spots due to galactose and glucose, but no spot corresponding to glucuronic acid or its lactone could be detected. Prolonged development in solvent system d separated the two component sugars. Measurement of the intensities of the two spots produced with *p*-anisidine, using a photoelectric transmission densitometer,[27,28] indicated the galactose and the glucose to be present in the ratio 1:3.

Methylation of the S VIII Acidic Polysaccharide.—In order to prevent possible alkaline breakdown of the polysaccharide[29,30] during its methylation, the reducing end group was reduced to hexitol end group before methylation.

To the sodium salt of the S VIII polysaccharide (2.1 g.) in water (50 ml.) was added a solution of sodium borohydride (15 mg.) in water (10 ml.) and the mixture was stirred for 1 hr. The excess sodium borohydride was destroyed by acidification of the reaction mixture with acetic acid. To the above solution of the polysaccharide was added, simultaneously and dropwise, sodium hydroxide (14 ml., 30% w./v.) and methyl sulfate (10 ml.) with vigorous stirring and ice-cooling, at a rate such that the mixture remained slightly alkaline. After 5 hr., the reaction mixture was allowed to warm to room temperature and sodium hydroxide (280 ml., 30% w./v.) and methyl sulfate (95 ml.) were added dropwise over 6 hr. and the stirring continued overnight. The same quantities of reagents were added over 5 hr., and the stirring was continued for a further 40 hr. The reaction mixture was heated on a boiling water-bath for 30 min. to destroy the excess methyl sulfate, and the volatile products were removed by distillation. The ice-cooled reaction mixture was brought to *p*H 2 by the cautious addition of 2 *N* sulfuric acid; the partially methylated polysaccharide was precipitated and was removed on a sintered glass filter. The product thus separated was methylated again using the above conditions, sufficient acetone being added to keep the polysaccharide in solution. The product isolated on acidification of the reaction mixture was further methylated by refluxing it with methyl iodide (40 ml.) containing methanol (1 ml.), while silver oxide (6 g.) was added portionwise over 6 hr. The final product obtained on chloroform extraction (1.71 g.) had $[\alpha]_D$ +68° (*c* 0.98 in acetone).

Anal. Calcd. for $(C_{36}H_{62}O_{21})_x$: OMe, 44.8. Found: OMe, 44.1.

Fission of the Methylated S VIII Polysaccharide.—A portion of the methylated S VIII polysaccharide (0.691 g.) was hydrolyzed by heating with 90% formic acid (100 ml.) for 10 hr. at 100°, and after removal of the formic acid by distillation, hydrolysis was continued by heating with *N* sulfuric acid (15 ml.) for a further 4 hr. After neutralization ($BaCO_3$) the hydrolyzate was filtered, and the filtrate was passed first down a column of IR 120(H) ion-exchange resin followed by IR 4B(OH) to give an eluate which on concentration gave the neutral methylated sugars as a sirup (A, 0.498 g.). The IR 4B resin above was eluted with *N* sulfuric acid, the eluate was neutralized ($Ba(OH)_2$) and the filtered solution was passed through a small bed of IR 120(H) resin to give an acid eluate, which on concentration, afforded the acidic methylated sugar (B, 0.123 g.).

Examination of the Neutral Methylated Sugars (A).—Paper chromatographic examination of this fraction in the solvent system d revealed two spots, having R_G 0.83 and 0.91 in the visual ratio 1:2. The mobility of the two components and the colors they gave with *p*-anisidine corresponded to those of 2,3,6-tri-*O*-methyl-D-galactose and 2,2,6-tri-*O*-methyl-D-glucose. Spraying with a 2% solution of dimethylaniline in glacial acetic acid containing 5% trichloroacetic acid[18] gave two purple spots corresponding to those revealed with the *p*-anisidine spray. No spots corresponding to tetra-*O*- or di-*O*-methyl sugars were detected. The sirup was moistened with a little methanol and set aside. The crystals which formed slowly were collected and recrystallized from ethanol (A1, 0.201 g.). The residual sirup when examined on paper chromatograms showed an increased intensity of the slow moving component (R_G 0.83). This sirup was fractionated on a cellulose column (3 × 24 cm.)[31] using light petroleum (b.p. 100–120°): butan-1-ol (7:3 v./v.) as the mobile phase. Evaporation of appropriate parts of the eluate gave two sirupy fractions which were purified by dissolution in water, acetone and then ether and on seeding from ethanol–ether mixture, the crystals were proved identical with (A1) causing no depression of m.p. and the two lots were combined.

Fraction 1 was chromatographically identical with (A1), with intermediate filtration and evaporation, and dried. crystallization of the whole fraction crystallized. After re-

Fraction 2 had R_G 0.83 in solvent system d, and was chromatographically pure (A2, 0.135 g.).

Characterization of (A1) as 2,3,6-Tri-*O*-methyl-D-glucose.—The crystals had m.p. 122°, undepressed on admixture with authentic 2,3,6-tri-*O*-methyl-D-glucose and $[\alpha]_D$ +73° (*c* 1.0).

(31) L. Hough, J. K. N. Jones and W. H. Wadman, *J. Chem. Soc.*, 2511 (1949).

Anal. Calcd. for $C_9H_{18}O_6$: OMe, 41.9. Found: OMe, 40.2.

The bis-*p*-nitrobenzoate,[32] prepared in the usual way, had m.p. and mixed m.p. 188°, $[\alpha]_D$ −34° (*c* 0.8 in chloroform).

Characterization of (A2) as 2,3,6-Tri-*O*-methyl-D-galactose.—The sirup failed to crystallize. It had $[\alpha]_D$ +85° (*c* 0.9).

Anal. Calcd. for $C_9H_{18}O_6$: OMe, 41.9. Found: OMe, 40.6.

The sirup was dissolved in 1% methanolic hydrogen chloride (*c* 1.0) at 20° and the change in the specific optical rotation followed: $[\alpha]_D$ +46° (initial value), +20° (3 hr.), +2° (6 hr.), −10° (11 hr.), −28° (24 hr. constant value). This change in the specific optical rotation is that expected of 2,3,6-tri-*O*-methyl-D-galactose. The original sirup (A2, 50 mg.) was oxidized with bromine in the usual manner to give 2,3,6-tri-*O*-methyl-D-galactono-γ-lactone, 38 mg., m.p. and mixed m.p. 97°, $[\alpha]_D$ −37° (*c* 0.5).

Anal. Calcd. for $C_6H_{16}O_6$: OMe, 42.4. Found: OMe, 41.7.

Characterization of (B) as 2,3-Di-*O*-methyl-D-glucuronic Acid.—The sirup had $[\alpha]_D$ +36° (*c* 1.0).

Anal. Calcd. for $C_8H_{14}O_7$: OMe, 28.0. Found: OMe, 27.1.

Paper chromatographic examination of the sirup B in solvent system a revealed a single red spot with the *p*-anisidine spray R_G 0.64 which had the same rate of movement as authentic 2,3-di-*O*-methyl-D-glucuronic acid.

The sirup B (60 mg.) was refluxed with 1% methanolic hydrogen chloride (15 ml.) for 6 hr. and was neutralized (Ag_2CO_3). The methanolic solution was concentrated to dryness and the solution of the residue in dioxane–ether mixture (1:1 v./v., 8 ml.) was added dropwise with stirring to a solution of lithium aluminum hydride (0.1 g.)[33] in dioxane–ether mixture (1:1 v./v., 8 ml.). After stirring overnight, the excess lithium aluminum hydride was destroyed by the addition of ethyl acetate followed by water. The reaction mixture was brought to *p*H 8 by the addition of *N* sulfuric acid and the mixture filtered. The methyl-2,3-di-*O*-methyl-D-glucoside was extracted from the filtrate with chloroform. The concentrated chloroform extract was hydrolyzed by heating with 2 *N* hydrochloric acid (10 ml.) for 4 hr., neutralized (Ag_2CO_3), filtered and the filtrate evaporated to dryness. Extraction of the residue with hot ethyl acetate and concentration of the extract to a small bulk gave crystals of 2,3-di-*O*-methyl-D-glucose which had m.p. and mixed m.p. 109°, $[\alpha]_D$ +48° (*c* 0.7 in acetone).

Anal. Calcd. for $C_8H_{16}O_6$: OMe, 29.8. Found: OMe, 29.2.

Paper chromatographic examination of the above chloroform extract showed a single spot (R_G 0.73 in solvent system d, and R_G 0.71 in c), which had the same mobility as authentic 2,3-di-*O*-methyl-D-glucose.

Methylation of the Reduced S VIII Polysaccharide.—The neutral, reduced polysaccharide (3.4 g.) was methylated using sodium hydroxide and methyl sulfate as in the case of the acidic S VIII polysaccharide. The partially methylated product separated out during the final heating of the reaction mixture and the material was collected at this point. A product having OMe 36.6% was thus obtained, and its methoxyl content was raised[34] by dissolving the material (3.9 g.) in anisole (150 ml.) and freezing the solution using a Dry Ice-bath. Sodium (2 g.) in liquid ammonia (80 ml.) was added and the mixture allowed to warm to room temperature with frequent shaking. The ammonia was removed by distillation and the residue was refluxed with methyl iodide (48 ml.) for 8 hr. The reaction mixture was freed from excess methyl iodide and the distillation continued until about 10 ml. of anisole had been collected. The anisole solution of the polysaccharide remaining was again frozen, and lithium (2 g.) in liquid ammonia (100 ml.) was added and the above operations repeated. The reaction mixture was concentrated to near dryness, water being added at intervals during the distillation, until no more anisole

remained in the flask. The aqueous solution was extracted continuously with chloroform, and the extract in 50% ethanol was passed down a small bed of ion-exchange resin MB 3 (Rohm & Haas Co., Philadelphia 5, Pa.) and concentrated to a light golden sirup (3.9 g.), $[\alpha]_D$ +63° (*c* 1.2 in chloroform).

Anal. Calcd. for $(C_9H_{16}O_5)_x$: OMe, 45.6. Found: OMe, 44.1.

Fractionation and Fission of the Methylated Reduced (Neutral) S VIII Polysaccharide.—The methylated polysaccharide (3.8 g.) was dissolved in chloroform (25 ml.), and petroleum ether (b.p. 100–120°) was added portionwise, the precipitated fractions being removed before carrying out further precipitation.

FRACTIONATION OF THE METHYLATED REDUCED S VIII POLYSACCHARIDE

Fraction	Petroleum ether added, ml.	Weight, g.	$[\alpha]_D$ (in $CHCl_3$)
1	50	0.102	+69°
2	70	0.010	+66
3	100	2.10	+65
4	140	1.34	+65
5	Residue	0.280	+59

Fractions 1, 2, 3 and 4 were combined and hydrolyzed as described for the methylated acidic S VIII polysaccharide. On paper chromatographic examination of the hydrolyzate in solvent system d, spots corresponding to 2,3,6-tri-*O*-methylgalactose and 2,3,6-tri-*O*-methylglucose in the visual ratio 1:3 were detected. No spots due to tetra-*O*, di-*O*- or mono-*O*-methylhexoses could be detected. On standing, the concentrated hydrolyzate gave crystals of 2,3,6-tri-*O*-methyl-D-glucose which were removed and characterized as described previously. Fractionation of the residual sirup upon a cellulose column gave more 2,3,6-tri-*O*-methyl-D-glucose which was combined with the first crop of crystals (2.3 g.) and 2,3,6-tri-*O*-methyl-D-galactose (0.785 g.) which was characterized as its crystalline aldono-γ-lactone, m.p. and mixed m.p. 97°, $[\alpha]_D$ −37° (*c* 0.8).

Periodate Oxidation of the Reduced Mixture of Tri-*O*-methylhexoses.—A portion (10 mg.) of the mixed tri-*O*-methylhexoses, obtained on hydrolysis of the fully methylated reduced S VIII polysaccharide, in water (2 ml.) contained in a 5-ml. volumetric flask, was reduced by the addition of sodium borohydride (8 mg.). After standing at room temperature for 2 hr., the excess borohydride was destroyed by the dropwise addition of 3 *N* sulfuric acid, and the acid solution was allowed to stand for 1 hr. to ensure complete removal of the reagent. Saturated *p*-hydroxybenzaldehyde solution (1 ml.)[35] and 0.3 *M* sodium metaperiodate solution (1 ml.) were added to the contents of the flask and the volume adjusted with water, to 5 ml. The reaction mixture was kept in the dark at 20°, and 1-ml. samples were withdrawn at intervals and pipetted into centrifuge tubes containing 20% lead dithionite solution (1 ml.)[36] to precipitate the periodate as insoluble lead periodate which was removed on the centrifuge. One ml. of the clear supernatant liquid was added to a 0.2% solution of chromotropic acid (1,8-dihydroxynaphthalene-3,6-disulfonic acid) (10 ml.) in sulfuric acid (60% v./v.) and the mixed reagents were allowed to stand for 30 min. The lead sulfate was removed by centrifugation and the supernatant liquid was transferred to glass stoppered tubes and heated on a vigorously boiling water-bath for 40 min. The absorption of the solution at 570 mμ was read on a Hilger spectrophotometer. A standard graph of absorption at 570 mμ against formaldehyde concentration was prepared using erythritol as a standard. No formaldehyde was liberated during the periodate oxidation of the above mixed tri-*O*-methylhexitols.

Periodate oxidation of 2,3,4-tri-*O*- and 1,3,4-tri-*O*-methylhexitols prepared by the borohydride reduction of the corresponding 2,3,4-tri-*O*- and 3,4,6-tri-*O*-methylhexoses under the conditions described above were found to liberate exactly 1 mole of HCHO per mole of tri-*O*-methylhexitol (complete after 8 min.). Periodate oxidation of the 1,4,5-tri-*O*- and 1,3,5-tri-*O*-methylhexitols prepared by reduction of the 2,3,6-tri-*O*- and 2,4,6-tri-*O*-methylhexoses failed to liberate any formaldehyde.

The reduced mixed tri-*O*-methylhexoses obtained from the polysaccharide were examined on paper chromatograms in solvent system d. Detection with a spray reagent of 1% aqueous sodium metaperiodate (4 parts), mixed prior to use with a 1% solution of potassium permanganate in 2% aqueous sodium carbonate solution (1 part),[37] revealed the sugars initially as a single pink spot against a white background (R_G 0.69) later observed as a white spot against a brown background. The *p*-anisidine spray failed to detect any sugars.

Partial Hydrolysis of the S VIII Acidic Polysaccharide.—The polysaccharide (6 g.) dissolved in 0.15 *N* sulfuric acid (300 ml.) was kept at 95° for 10 hr., neutralized ($BaCO_3$), filtered and the filtrate passed down columns of ion-exchange resins IR 120(H) (3 × 10 cm.) followed by IR 4B(OH) (3 × 14 cm.). The acid effluent was neutralized ($Ba(OH)_2$), concentrated to about 30 ml. and ethanol (70 ml.) was added to precipitate the barium uronates which were collected on the centrifuge (C, 2.4 g.). The ethanol supernatant was passed through a small bed of ion-exchange resin MB 3 and the neutral eluate concentrated to a sirup (D, 1.08 g.). The IR 4B resin above, which retained the low molecular weight acid oligosaccharides, was eluted[38–40] with 0.3 *N* formic acid at the rate of 0.5 ml. per min., and the eluate was collected on a fraction cutter. Appropriate fractions were combined; tubes containing two components owing to slight overlap were combined and further fractionated on sheets of Whatman 3MM filter paper in solvent system b. Formic acid was removed from the fractions by continuous extraction with ether. The following fractions were obtained: U1, hexuronic acid, 0.084 g., R_{Gal} 0.96 (in solvent b); U2, aldobiouronic acid, 0.650 g., R_{Gal} 0.46; U_3, aldotriouronic acid, 0.255 g., R_{Gal} 0.10; and U4, aldotetraouronic acid, 0.030 g., R_{Gal} 0.05.

Characterization of U1 as D-Glucuronic Acid.—The acid was converted to crystalline D-glucurono-6 → 3-lactone, m.p. and mixed m.p. 178°, $[\alpha]_D$ +18° (*c* 0.5).

Characterization of U2 as 4-*O*-(β-D-Glucopyranosyluronic Acid)-D-glucopyranose.—The chromatographically pure acid had $[\alpha]_D$ +7° (*c* 2.0) and equivalent weight 359 by titration with standard alkali ($C_{12}H_{20}O_{12}$ requires equiv. wt. 356). Hydrolysis with formic acid followed by paper chromatographic examination of the hydrolyzate showed the presence of glucuronic acid and glucose.

Conversion of U2 to its Hepta-*O*-acetyl-methyl Ester.[41]—The acid (150 mg.) in methanol (9 ml.) was esterified by the addition of a solution of diazomethane in ether. After removal of the solvents the residue was dissolved in acetic anhydride containing 5% anhydrous zinc chloride (12 ml.), and the reaction mixture was kept at 60° for 90 min. The residue remaining after removal of the acetic anhydride was extracted with warm methanol (2 × 10 ml.). Water (20 ml.) was added to the extract and, after standing for 6 min. at 0°, the precipitated derivative was collected. Recrystallization from ethanol afforded a product (130 mg.) which had m.p. 251° and $[\alpha]_D$ +42° (*c* 0.7 in chloroform) (literature[13] m.p. 250°, $[\alpha]_D$ +41.7°).

Anal. Calcd. for $C_{27}H_{36}O_{19}$: C, 48.7; H, 5.55; OMe, 4.7. Found: C, 48.64; H, 5.31; OMe, 4.94.

Reduction of U2 to Cellobiitol.[41]—The aldobiouronic acid (150 mg.) was esterified with diazomethane, and the ester dissolved in water (10 ml.) was added dropwise with stirring to a solution of sodium borohydride (50 mg.) in water (6 ml.). Reaction was allowed to proceed at room temperature for 5 hr., and acetic acid was added to destroy the excess borohydride. Removal of the ionic material on ion-exchange resins gave a non-reducing eluate which was concentrated to dryness, extracted with hot methanol (3 × 8 ml.) and the extract concentrated to about 0.5 ml. On keeping, crystals of cellobiitol were obtained (120 mg.) which after three recrystallizations from methanol had $[\alpha]_D$ −7.8° (*c* 5.0) and m.p. 143°, undepressed on admixture with au-

thentic cellobiitol prepared by the borohydride reduction of cellobiose.

Characterization of U3 as *O*-β-D-Glucopyranosyluronic Acid-(1→4)-*O*-β-D-glucopyranosyl-(1→4)-D-glucopyranose.—The acid had $[\alpha]_D$ +12° (*c* 2.0) and equivalent weight 522 (calcd. for $C_{18}H_{30}O_{17}$: equiv. wt., 518). The acid was chromatographically pure, and determination of its reducing power by the alkaline hypoiodite method[42,43] gave a molecular weight of 528. Hydrolysis of the aldotrioruonic acid with formic acid followed by paper chromatographic examination showed it to contain glucuronic acid and glucose.

Methylation of U3.—The aldotrioruonic acid (100 mg.) was methylated using sodium hydroxide (105 ml., 30 w./v.) and methyl sulfate (24 ml.) in the usual way. The product was extracted with chloroform and further methylated using methyl iodide (8 ml.) and silver oxide (1 g.) to give a final product (92 mg.) which had $[\alpha]_D$ +11.5° (*c* 1.0 in $CHCl_3$).

Anal. Calcd. for $C_{29}H_{52}O_{17}$: OMe, 50.8. Found: OMe, 49.1.

The methylated aldotrioruonic acid (80 mg.) was hydrolyzed with formic acid (as for the S VIII polysaccharide) and the hydrolysate fractionated on a sheet of filter paper in solvent system d. The acidic component remained near the base line and after elution from the paper was passed through a little IR 120(H) resin and concentrated to dryness (19 mg.). This acid sugar was chromatographically pure giving a single red spot with the *p*-anisidine spray having R_G 0.84 in solvent system a and moved to the same position as authentic 2,3,4-tri-*O*-methylglucuronic acid. It had $[\alpha]_D$ +40° (*c* 0.5). The neutral methylated sugar gave a single spot R_G 0.91 in solvent system d and on keeping gave crystals of 2,3,6-tri-*O*-methyl-D-glucose (41 mg.) which had $[\alpha]_D$ +72° (*c* 0.8), m.p. and mixed m.p. 122°.

Reduction of U3 to Cellotriitol.—The aldotrioruonic acid (60 mg.) was converted to its methyl ester and reduced with aqueous sodium borohydride (as described for the conversion of U2 to cellotriitol), to give crystalline cellotriitol (48 mg.) which had $[\alpha]_D$ −5.5° (*c* 0.5) and m.p. 160° undepressed on admixture with authentic cellotriitol prepared by the borohydride reduction of cellotriose. The derivative co-chromatographed with authentic cellotriitol[44] having R_{Gal} 0.16 in solvent system a.

Characterization of U4 as *O*-β-D-Glucopyranosyluronic Acid-(1→4)-*O*-β-D-glucopyranosyl-(1→4)-*O*-α-D-glucopyranosyl-(1→4)-D-galactopyranose.—The barium uronates (C), obtained on the addition of ethanol to the acidic solution passing through the ion-exchange resins after partial hydrolysis of the S VIII polysaccharide, were examined on paper chromatograms in solvent system b. A component (R_{Gal} 0.05) corresponding in position to an aldotetraouronic acid was observed to be present. Separation of the uronates on sheets of Whatman 3MM filter paper in solvent system b during 5 days gave the chromatographically pure tetraouronic acid (280 mg.). It was identical in physical and chemical properties with U4 and the two parts were combined and examined together. No spot due to an aldopentaouronic acid could be detected on the chromatograms of the partially hydrolyzed S VIII polysaccharide.

The aldotetraouronic acid had $[\alpha]_D$ +65° (*c* 1.0), and equivalent weight 675 (required for an aldotetraouronic acid: equiv. wt., 670); hypoiodite oxidation[42,43] gave a molecular weight 698. Hydrolysis of U4 (8 mg.) with formic acid followed by paper chromatographic examination of the mixture of sugars showed it to contain glucuronic acid, galactose and glucose. Measurement of the spot intensities[27,28] indicated the galactose and glucose to be present in the ratio 1:2. The aldotetraouronic acid (10 mg.) was reduced directly with sodium borohydride (3 mg.) in water (5 ml.), and after deionization (resins) the reduced product was hydrolyzed with formic acid. Paper chromatographic examination of the hydrolyzate in solvent system d followed by detection with the *p*-anisidine spray revealed only glucose and a spot remaining near the base line (glucuronic acid). Detection with the silver nitrate spray showed in addition to glucose a spot on the chromatogram behaving in a manner similar to authentic dulcitol. The aldotetraouronic acid (U4, 120 mg.) was methylated as described for U3 to give a product (110 mg.) which had $[\alpha]_D$ +15° (*c* 1 in chloroform).

Anal. Calcd. for $C_{38}H_{67}O_{22}$: OMe, 49.7. Found: OMe, 48.8.

Hydrolysis of the methylated aldotetraouronic acid with formic acid and examination of the hydrolyzate on paper chromatograms in solvent d showed two spots with the *p*-anisidine spray, R_G 0.83 and 0.91 in the visual ratio 1:2, together with a third component which remained near the base line (tri-*O*-methylglucuronic acid). The components were separated on a sheet of Whatman 3MM filter paper in solvent system d to give: 1. 2,3,4-Tri-*O*-methyl-D-glucuronic acid, chromatographically pure. It gave a single red spot with the *p*-anisidine spray, had R_G 0.84 in solvent system a moving to the same position as an authentic specimen and had $[\alpha]_D$ +40° (*c* 0.4). The acid (19 mg.) in methanol (2 ml.) was neutralized with diazomethane and concentrated to dryness. The residue in water (8 ml.) was reduced by the addition of sodium borohydride (10 mg.), and the excess reagent was destroyed by the addition of *N* sulfuric acid. 0.3 *M* sodium metaperiodate (0.3 ml.) was added and the mixture kept at 40° for 4 hr. The reaction mixture was extracted with chloroform (4 × 8 ml.), the extract dried (anhyd. Na_2SO_4) and allowed to evaporate on a watch glass. Crystals of 2,3,4-tri-*O*-methyl-L-xylose, m.p. 89°, were obtained, which on examination on paper chromatograms in solvent system d gave a single red spot with the *p*-anisidine spray, R_G 0.96 corresponding in position with authentic 2,3,4-tri-*O*-methylxylose.

2. 2,3,6-Tri-*O*-methyl-D-galactose whose specific optical rotation in 1% methanolic hydrogen chloride fell from $[\alpha]_D$ +40° to −27° (28 hr.). The sugar (19 mg.) did not crystallize. It had R_G 0.83 in solvent system d and moved to the same position as authentic 2,3,6-tri-*O*-methylgalactose.

3. 2,3,6-Tri-*O*-methyl-D-glucose (32 mg.) which on keeping gave crystals, m.p. and mixed m.p. 121°, $[\alpha]_D$ +72°.

Partial Hydrolysis of the Aldotetraouronic Acid U4.—The acid (95 mg.) was partially hydrolyzed by heating it with 0.1 *N* sulfuric acid (10 ml.) for 4 hr. at 95°. Neutralization ($BaCO_3$) and examination of the filtered hydrolyzate on paper chromatograms in solvent system d showed the presence of a small amount of the aldotrioruonic acid (U3) (R_{Gal} 0.10), a neutral disaccharide, R_{Gal} 0.61 ($[\alpha]_D$ +140), a large proportion of an aldobiouronic acid (U2) (R_{Gal} 0.46) and galactose and glucose in the visual ratio 3:1. The component (17 mg.) with R_{Gal} 0.46 was separated on a paper chromatogram and on reduction of its methyl ester with sodium borohydride gave crystals of cellobiitol, m.p. and mixed m.p. 143°.

Examination of the Neutral Sugars (D) Obtained from the Partial Acid Hydrolysis of the S VIII Polysaccharide.—The sirup D was examined on paper chromatograms in solvent system d, and detection with the *p*-anisidine spray showed galactose and glucose in the visual ratio 2:1 together with a disaccharide, R_{Gal} 0.62, and a trace amount of a spot corresponding in position with a trisaccharide, R_{Gal} 0.33 (trace). The sirup (D, 980 mg.) dissolved in water (50 ml.) was passed down a column of charcoal–Celite (1:1 w./w.; 3 × 28 cm.)[45] and the column eluted with water until all the monosaccharides had been removed, whereupon the column was eluted with 5% ethanol solution in water. Appropriate portions of the eluate were combined and concentrated to give the disaccharide (121 mg.) and a trisaccharide (8 mg.).

Characterization of the Neutral Disaccharide as 4-*O*-(α-D-Glucopyranosyl)-D-galactopyranose.—The disaccharide was chromatographically pure and had $[\alpha]_D$ +140° (*c* 1.1). Determination of its reducing power by alkaline hypoiodite gave a molecular weight of 349 (required 342). Hydrolysis with 2 *N* sulfuric acid for 8 hr. at 100° and paper chromatographic analysis of the hydrolysate showed the disaccharide to be composed of glucose and galactose in the ratio of 1:1. The disaccharide (5 mg.) was reduced with sodium borohydride (3 mg.) in water (2 ml.) at room temperature for 6 hr.; after removal of the ionic material (resins) the solution was hydrolyzed with sulfuric acid and examined on paper chromatograms in solvent system d. Detection with the *p*-anisidine spray showed only glucose, while detection with the silver nitrate spray showed glucose to be present together with a second component which corresponded in position to dulcitol and which produced a dark spot on the

chromatogram at a rate corresponding to the authentic hexitol.

The disaccharide (78 mg.) was methylated with sodium hydroxide (15 ml., 30% w./w.) and methyl sulfate (5 ml.) followed by a second methylation using sodium hydroxide (10 ml., 30% w./w.) and methyl sulfate (4 ml.). The product, which was extracted with chloroform, was further methylated with Purdie reagents to give a sirup (70 mg.) having $[\alpha]_D$ +52° (*c* 1.0 in chloroform).

Anal. Calcd. for $C_{20}H_{38}O_{11}$: OMe, 54.6. Found: OMe, 54.2.

The methylated disaccharide (60 mg.) was hydrolyzed with 90% formic acid and the hydrolyzate examined chromatographically. In solvent system d *p*-anisidine revealed two spots, R_G 1.00 and R_G 0.83. The sugars were fractionated on a sheet of filter paper in solvent d and the sugars eluted from appropriate sections of the chromatogram. The fast moving component (R_G 1.00, 20 mg.) had $[\alpha]_D$ +80° (*c* 0.5) and gave an anilide which crystallized from light petroleum in the form of white needles, m.p. 132°. The slower moving component (R_G 0.83, 16 mg.) showed a change in its specific optical rotation from $[\alpha]_D$ +44° → −28° (28 hr.) when it was dissolved at 20° in 1% methanolic hydrogen chloride. The resultant glycoside was hydrolyzed, and the reducing sugar so obtained was oxidized with bromine water to give its aldono-γ-lactone, m.p. and mixed m.p. with authentic 2,3,6-tri-*O*-methyl-D-galactono-γ-lactone, 96°.

Periodate Oxidation of the S VIII Acidic Polysaccharide.—The polysaccharide (*ca.* 100 mg. accurately weighed) was dissolved in water (80 ml.), and the solution was adjusted to *p*H 2.2 by the addition of sulfuric acid; 0.3 *M* sodium metaperiodate solution (5 ml.) was added and the volume made up to 100 ml. A blank solution containing no polysaccharide was prepared similarly. Oxidation was allowed to proceed in the dark at 20°. At intervals, the periodate uptake was estimated by transferring samples (10 ml.), from the oxidation mixture and the blank, to a solution of 2 *N* sulfuric acid (15 ml.) containing 20% potassium iodide solution (4 ml.). The liberated iodine was titrated with 0.02 *N* sodium thiosulfate solution, using starch as an indicator. The molar periodate consumption per mole of anhydrohexose unit was as follows: 0.67 (after 8 hr.), 0.94 (20 hr.), 1.18 (48 hr.), 1.25 (72 hr.), 1.32 (96 hr.), 1.39 (120 hr.) and 1.44 (144 hr.). Extrapolation of the over oxidation part of the curve to zero time gave a value corresponding to a periodate uptake of 1.03 moles per anhydrohexose unit (*i.e.*, 165 g. for a polymer containing 1 hexuronic acid unit per 3 hexose units).

Hydrolysis of the Periodate Oxidized S VIII Polysaccharide.—The S VIII polysaccharide (110 mg.) was oxidized with periodate as described above. After 80 hr., ethylene glycol (5 ml.) was added to destroy the excess periodate, and the reaction mixture was dialyzed against water employing a cellulosic membrane. The concentrated non-dialyzable material was hydrolyzed with 90% formic acid (20 ml.) for 8 hr. at 100°. After removal of the formic acid, hydrolysis was continued with *N* sulfuric acid (8 ml.) for 2 hr. at 100°. Examination of the neutralized ($BaCO_3$) hydrolyzate on paper chromatograms failed to indicate the presence of hexose or hexuronic acid.

III. Discussion

The S VIII polysaccharide used in this investigation was prepared by E. R. Squibb and Sons, New Brunswick, N. J., and was supplied to us through the kindness of Professor M. Heidelberger. The polysaccharide which was free from protein and glucosan was first purified *via* its copper complex to give a material which is considered to be essentially homogeneous. It could not be further fractionated *via* its cetyltrimethylammonium salt, and on electophoresis using a glass fiber support and an electrolyte of borax and sodium hydroxide, the polysaccharide moved as a single sharp band. The polysaccharide recovered in both cases was chemically and physically indistinguishable from the original polysaccharide.

The polysaccharide had a high positive specific optical rotation $[\alpha]_D$ +121°, and its equivalent weight (703) is that expected of a hexose polymer having one hexuronic acid unit in four. The polysaccharide contained no nitrogen, phosphorus or ash and gave no color with iodine. Attempted autohydrolysis and attempted hydrolysis with 0.01 *N* sulfuric acid failed to liberate any reducing sugars, indicating the absence of furanose sugars. Total acid hydrolysis followed by paper chromatographic examination of the hydrolyzate showed the polysaccharide to be composed of galactose, glucose and glucuronic acid. The component sugars were separated chromatographically and identified as D-galactose, D-glucose and D-glucuronic acid. Quantitative estimation of the component sugars showed them to be present in the ratio D-galactose:D-glucose:D-glucuronic acid 1:2:1.

The S VIII acidic polysaccharide was reduced to the corresponding neutral hexose polymer by borohydride reduction of the esterified carboxyl group of the glucuronic acid. The original polysaccharide was freeze-dried in order to produce the largest possible surface area and was treated with a solution of diazomethane in ether. In the short contact time required to neutralize the polysaccharide, no secondary methylation occurred. Reduction of the aqueous solution of the esterified material with sodium borohydride effected an almost quantitative conversion of the glucuronic acid in the polymer to glucose. Acid hydrolysis of this new polysaccharide showed it to contain D-galactose (1 part) and D-glucose (3 parts).

Hydrolysis of the methylated S VIII polysaccharide afforded 2,3-di-*O*-methyl-D-glucuronic acid (1 part), 2,3,6-tri-*O*-methyl-D-galactose (1 part) and 2,3,6-tri-*O*-methyl-D-glucose (2 parts), each identified by the preparation of crystalline derivatives. As no other methyl sugars were detected, the above evidence indicates that the polysaccharide is a high molecular weight, straight chain polymer containing 1 → 4 links only.

The methylated, borohydride reduced S VIII polysaccharide appeared to be homogeneous and on hydrolysis afforded 2,3,6-tri-*O*-methyl-D-galactose (1 part) and 2,3,6-tri-*O*-methyl-D-glucose (3 parts). The absence of any 3,4,6-tri-*O*- or 2,3,4-tri-*O*-methylhexose, and hence the absence of any small proportion of any 1 → 2 or 1 → 6 links in the original polysaccharide, was shown by the fact that no formaldehyde was produced on the periodate oxidation of the reduced ($NaBH_4$) mixture of tri-*O*-methylhexoses.

In a subsidiary experiment it was found that the periodate oxidation of the tri-*O*-methylhexitols obtained on the borohydride reduction of 3,4,6-tri-*O*- and 2,3,4-tri-*O*-methylhexoses produced 1 mole of formaldehyde per mole of tri-*O*-methylhexitol. Periodate oxidation of the reduced 2,3,6-tri-*O*-2,4,6-tri-*O*-methylhexoses failed to liberate any formaldehyde. The proportions of 3,4,6-tri-*O*-methylaldohexose and 2,3,6-tri-*O*-methylaldohexose in a synthetic mixture were determined in this way with an error of less than 1%. The procedure has proved of use in the determination of the proportions of tri-*O*-methylhexoses in the hydroly-

zates of methylated polysaccharides especially when only micro amounts were available.

The evidence obtained from an examination of the hydrolysis products of the methylated neutral polysaccharide above again indicates that the original polysaccharide is a long straight-chain polymer joined throughout by 1 → 4 links.

Partial acid hydrolysis of the S VIII polysaccharide was effected with dilute sulfuric acid. The acid oligosaccharides were absorbed on ion-exchange resins and fractionally eluted with dilute formic acid. The neutral sugars were separated chromatographically to give the monosaccharides glucose and galactose, a disaccharide and a trisaccharide (trace, not examined). One aldobiouronic acid was obtained which was identical with that previously obtained and characterized by Goebel[13] as 4-*O*-(β-D-glucopyranosyluronic acid)-D-glucopyranose. The β-linkage originally assigned to the acid was confirmed by reduction of the methyl ester of the acid with sodium borohydride to give crystalline cellobiitol.

One aldotriouronic acid was obtained which on hydrolysis gave D-glucuronic acid (1 part) and D-glucose (2 parts). Hydrolysis of the methylated acid gave 2,3,4-tri-*O*-methyl-D-glucuronic acid and 2,3,6-tri-*O*-methyl-D-glucose. The low positive specific optical rotation, $[\alpha]_D$ +12°, indicated that both links had the β-configuration, a conclusion which was borne out by the reduction of the methyl ester of the acid with sodium borohydride, to give crystalline cellotriitol. The experimental evidence indicates the aldotriouronic acid to be *O*-β-D-glucopyranosyluronic acid-(1 → 4)-*O*-β-D-glucopyranosyl-(1 → 4)-D-glucopyranose. One aldotetraouronic acid was obtained which on hydrolysis gave D-glucuronic acid (1 part), D-galactose (1 part) and D-glucose (2 parts). Hydrolysis of a small amount of the directly reduced ($NaBH_4$) acid, followed by paper chromatographic examination of the hydrolyzate, showed the presence of glucuronic acid, glucose and dulcitol. Since no galactose or sorbitol could be detected in the hydrolyzate, the galactose must form the reducing end group of the molecule. Hydrolysis of the methylated acid gave 2,3,4-tri-*O*-methyl-D-glucuronic acid (1 part), 2,3,6-tri-*O*-methyl-D-galactose (1 part) and 2,3,6-tri-*O*-methyl-D-glucose (2 parts). Partial acid hydrolysis of the aldotetraouronic acid gave a small amount of the aldotriouronic acid previously characterized, a small amount of a neutral disaccharide, chromatographically identical with the disaccharide obtained from the partial hydrolysis of the original polysaccharide, and a large proportion of an aldobiouronic acid identified as 4-*O*-(β-D-glucopyranosyluronic acid)-D-glucopyranose. The experimental evidence indicates the structure of the aldotetraouronic acid to be *O*-β-D-glucopyranosyluronic acid-(1 → 4)-*O*-β-D-glucopyranosyl-(1 → 4)-*O*-α-D-glucopyranosyl-(1 → 4)-D-galactopyranose. The linkage between the glucose and galactose residue is assigned the α-configuration to account for the increase of the specific optical rotation from $[\alpha]_D$ +12° for the aldotriouronic acid to $[\alpha]_D$ +65° for the aldotetrauronic acid. The α-configuration assigned to this terminal link is also supported by the isolation of the neutral disaccharide 4-*O*-(α D-glucopyranosyl)-D-galactopyranose with the high optical rotation of $[\alpha]_D$ +140°, after hydrolysis of the tetrasaccharide. The neutral disaccharide which also was obtained from partial hydrolysis of the S VIII polysaccharide gave, on hydrolysis, glucose and galactose. Hydrolysis of a small amount of the reduced ($NaBH_4$) disaccharide followed by paper chromatographic examination of the hydrolyzate indicated the presence of glucose and dulcitol. This observation shows that galactose forms the reducing part of the molecule. Hydrolysis of the methylated disaccharide gave 2,3,4,6-tetra-*O*-methyl-D-glucose and 2,3,6-tri-*O*-methyl-D-galactose. The high specific optical rotation ($[\alpha]_D$ +140°) of the disaccharide, considered in conjunction with the above evidence, leads to the sugar being assigned the structure 4-*O*-α-D-glucopyranosyl-D-galactopyranose. No pentaouronic acid could be detected chromatographically, and since the composition of the original polysaccharide would not allow for one if the polymer is to be composed of a single structural repeating unit, the S VIII polysaccharide is believed to be composed of a four-unit repeating block with the structure of the tetraouronic acid. The nature of the link joining the galactose to the glucuronic acid unit in the polymer has not been decided, but the high positive specific rotation of the original polysaccharide indicates that it may be of the α-type. Partial hydrolysis of the neutral ($NaBH_4$ reduced uronic acid free) polysaccharide is at present being carried out in an attempt to isolate the 4-*O*-D-galactopyranosyl-D-glucopyranose disaccharide and to determine its mode of linkage.

The S VIII acidic polysaccharide was oxidized with metaperiodate in a solution adjusted to *p*H 2.2, a *p*H at which hydrolysis of the intermediate formyl esters is a minimum[46,47] and hence "over oxidation" is also at a minimum. Extrapolation of the "over oxidation" part of the periodate curve to zero time gave a value for the periodate uptake corresponding to 1.03 mole of periodate per anhydrohexose unit. An entirely 1 → 4 linked hexapyranose linear polymer should show an uptake of 1.0 mole of periodate per anhydrohexose unit. The experimental result is therefore in agreement with the structure of the polymer put forward as a result of methylation and partial hydrolysis studies. Hydrolysis of the periodate-oxidized S VIII polysaccharide followed by paper chromatographic examination of the hydrolyzate failed to reveal the presence of any sugars. This latter evidence indicates the absence of any 1 → 3 links in the polymer structure.

Acknowledgments.—These investigations were supported by The Banting Research Foundation, Toronto, and by the National Research Council, Canada. The generous assistance of Dr. M. Heidelberger, Professors Fred Smith and M. L. Wolfrom is gratefully acknowledged.

The Amino Acid Sequence of Glucagon. I. Amino Acid Composition and Terminal Amino Acid Analyses

BY W. W. BROMER, A. STAUB, E. R. DILLER, H. L. BIRD, L. G. SINN AND OTTO K. BEHRENS

RECEIVED NOVEMBER 19, 1956

Evidence is presented that glucagon is a small protein, consisting of a single chain of 29 amino acid residues. The N-terminal amino acid is histidine as determined by the dinitrophenylation method; the C-terminal residue is threonine on the basis of evidence obtained from hydrazinolysis and carboxypeptidase treatment. Glucagon contains single residues of 7 amino acids; among them, methionine, tryptophan, valine and alanine are liberated from the C-terminus of the molecule by carboxypeptidase.

Introduction

The preparation[1] in this Laboratory of a crystalline material of pancreatic origin, glucagon, has made available a model protein for fundamental biological and structural studies. This series of papers will present evidence leading to the elucidation of the complete amino acid sequence of glucagon. The present paper describes the quantitative amino acid analysis and other fundamental studies of primary importance to the sequence determination.

Experimental

Materials and Procedures.—The glucagon used throughout the structure work was a twice-recrystallized lot (#208-158B-292A) prepared from hog pancreas that was homogeneous according to end group analysis and zone electrophoresis on starch.[1] The high purity of the sample is also demonstrated by the analyses reported below which show good over-all recovery, a complete absence of isoleucine, proline and cystine, and, in general, good stoichiometric relationships of the amino acid residues.

Moisture content of the preparation was 10.9% as determined by drying for 24 hr. at 100° *in vacuo* over P_2O_5. The nitrogen content was 17.45% (Kjeldahl).

For the study of amino acid composition, accurately weighed samples of crystalline glucagon were hydrolyzed for 20 or 72 hr. in the absence of air at 107 to 109° in about 200 volumes of 5.7 *N* HCl redistilled three times in glass. The hydrolyzates were processed in a manner similar to that described by Smith and Stockell.[2] The hydrolyzates often contained traces of humin and had a faint blue-gray hue. The presence of trace metals in the crystalline preparation may have catalyzed the destruction of tryptophan since later crystalline preparations isolated in the presence of Versene produced light straw-colored hydrolyzates. Humin formation did not hamper the handling of the sample and probably did not affect the results.

Amino Acid Determination.—The comparatively rapid Levy[3] method, based on the paper chromatographic separation of the dinitrophenyl- (DNP-) amino acids, was employed initially in the work and was followed by the more rigorous Dowex 50 column chromatographic method of Moore and Stein.[4] The dinitrophenylation method furnished adequate preliminary data to support the structure work and, as will be reported, the two methods gave similar results.

The Dinitrophenylation Method.—Throughout this work dinitrophenylations were performed for 90 min. at 40°, *p*H 9.0, essentially following the Levy modification[3] of the method of Sanger.[5] Prior to the paper chromatographic separation of the DNP-amino acids, dinitrophenol was removed by sublimation according to the method described by Mills.[6] DNP-derivatives were identified by comparison with known DNP-amino acids.[7]

Only 20 hr. hydrolyzates were used with the Levy method since no DNP-peptides were observed. Recognizing that the correction factors published by Levy for the destruction of the amino acids in insulin may not be completely applicable to another protein handled under different conditions, new factors were determined for glucagon. This was accomplished by utilizing the insulin factors as a first approximation. From these data a synthetic amino acid mixture resembling glucagon was prepared, hydrolyzed and treated identically to a protein hydrolyzate. In this manner new destruction factors were calculated. This process was repeated, giving a more precise set of correction factors which were used in the calculation of the number of amino acid residues in glucagon. The correction factors are as follows: aspartic acid, 1.10; threonine, 1.22; serine, 1.32; glutamic acid, 1.20; glycine, 1.33; alanine, 1.28; valine, 1.20; methionine, 2.12; tyrosine, 1.60; phenylalanine, 1.20; histidine, 2.19; lysine, 0.70; and arginine, 1.38. Of interest is the finding that, in every instance, the factors are higher than those reported by Levy, averaging about 17% greater. Histidine and methionine particularly appear to be subject to greater losses than previously reported.[3]

Table I indicates the results of the preliminary amino acid analysis by the Levy method. With the relatively few analyses it is not surprising that the tyrosine and arginine values do not fall near whole-residue figures. Di-DNP-tyrosine analyses at best are quite variable,[3] and DNP-arginine, being water-soluble, is rather difficult to desalt completely prior to paper chromatography. Indeed, the water-soluble DNP-derivatives of histidine, lysine and arginine have generally proved to be difficult to handle. Ex-

[a] Values in parentheses not included in averages. [b] Average of 3 chemical analyses.[8]

traction from dilute acid solution into redistilled *n*-butanol provided a convenient method of preparing these derivatives for chromatography.

The values found for the other amino acids were reasonably close to whole residue units. The Levy method, used in this fashion, quickly and conveniently provided data on the amino acid composition of glucagon. These data provided an adequate working hypothesis during most of the structure determination.

Dowex 50 Method.—The elution curves in Fig. 1 illustrate the separation of amino acids achieved with the column chromatographic method of Moore and Stein.[4] The data of duplicate runs with two different hydrolyzates each at 20 and 72 hr. are given in Table II.

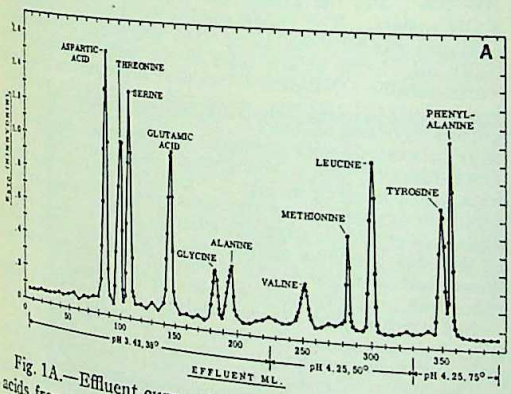

Fig. 1A.—Effluent curve of the neutral and acidic amino acids from a 72 hr. hydrolyzate of glucagon separated by chromatography on a 0.9 × 100 cm. column of Dowex 50-X8 resin. The quantity of hydrolyzate employed was 1.77 mg. The intensity of the color produced by reaction of the one ml. effluent fractions with ninhydrin was determined at 570 mμ in a Model B Beckman spectrophotometer. The elution curve obtained from these data is shown, with no corrections for base-line color or the various amino acid color yields.

In spite of the excellent repeatable separation of the amino acids, some variability in results was experienced. This was shown to be due to contamination with atmospheric ammonia. Because of these variations the data were subjected to the "t" test to determine whether or not the mean values found for 20 and 72 hr. differed significantly. It was found that the recoveries of aspartic acid, threonine, serine and tyrosine decreased with longer times of hydrolysis. Glutamic acid, methionine, histidine and arginine values appeared to decrease slightly; however, the difference between the 20 and 72 hr. values was not statistically significant.

The approximate percentage of destruction of these amino acids after 24 hr. of hydrolysis is: aspartic acid, 2%; threonine, 3.5%; serine, 11%; tyrosine, 5%. This rate of destruction is in reasonable accord with data published by Hirs, Stein and Moore,[9] Smith and associates,[2,10] and Rees[11] for other proteins and amino acid mixtures. Corrections for the losses of these acid-labile amino acids were calculated by extrapolation of the analytical data to zero time, assuming first-order kinetics for the decomposition (*cf.* 2, 9, 10). The method of calculation of Hirs, Stein and Moore[9] was employed.

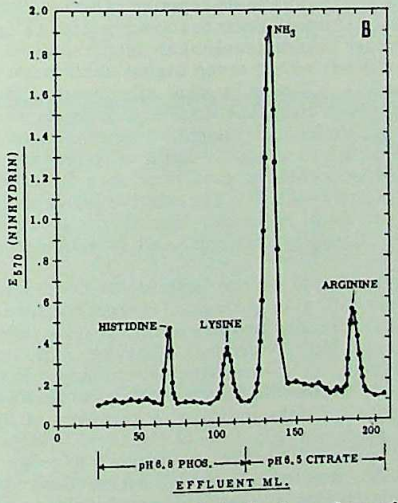

Fig. 1B.—Effluent curve of the basic amino acids from a 72 hr. hydrolyzate of glucagon separated by chromatography on a 0.9 × 15 cm. column of Dowex 50-X8 resin. The quantity of hydrolyzate analyzed was 1.77 mg. No corrections were applied for the base-line color or for the color yields of the various amino acids.

The amino acid composition and minimal molecular weight of glucagon calculated from these data are summarized in Table III.

[a] Not included in totals or averages. [b] Direct chemical analysis.[11] [c] Average molecular weight from all residues except methionine and histidine, whose recoveries appeared to be low. [d] Average molecular weight for all residues.

The values for the stable amino acids represent averages of at least seven determinations. For most of the labile amino acids each point on the extrapolation curve was an average of four analyses. The amide NH_3 value listed was obtained by direct chemical analysis[11] and is an average of four determinations. Extrapolation of the chromatographic data yielded a significantly higher result. It is likely that this discrepancy may be attributed to the accumulation of NH_3 from air and the buffers. That this was indeed the case was verified by direct NH_3 analyses of the hydrolyzates prior to chromatography. The values obtained after correction for NH_3 from the destruction of serine and threonine (*cf.* 2, 9, 10, 11) were similar to those reported in Table III.

The average minimal molecular weight of 3550 was calculated on the basis that seven amino acids were present as single residues. This is in good agreement with the value of 3485 derived from the empirical formula of glucagon. Preliminary molecular weight determinations in 2 *M* guanidine solutions using the artificial boundary cell in the ultracentrifuge provided evidence for a molecular weight of approximately 4000.[12] The relative insolubility of glucagon and the small molecular size of the molecule render such physical studies difficult, and further determinations are planned.

An average yield of one mole of di-DNP-histidine was obtained per 3500 g. of glucagon. Direct chemical analysis[13] provided evidence for two free amino groups; these may be attributed to the N-terminal histidine and the ϵ-amino group of lysine. The small quantity of sulfur in the protein is completely accounted for by a single methionine residue.

The analytical data indicated a recovery of 97% of the weight of glucagon and 95% of the total nitrogen. These losses are reflected in the determined average molecular weight, 3550, which is about 2% higher than the value of 3485 calculated from the resulting empirical formula.

The data obtained from the two methods of amino acid analysis (*cf.* Tables I and III) is in good over-all agreement. In our hands, the data obtained from the Dowex 50 column method was more precise than that obtained from the dinitrophenylation technique. As previously discussed, the latter method utilizes inherently large correction factors. In addition, uncertainty exists in the analysis for certain DNP-amino acids. Advantages of the Levy method appear to be speed, ease of operation, use of a small sample, and the ability to simultaneously analyze a number of samples. The method was of particular value in this work as a rapid means of determining the approximate amino acid composition of glucagon, and later as a convenient method of analysis for certain of the smaller degradation peptides of glucagon.

N-Terminal Analysis.—Seven mg. ($^2\mu$moles) of glucagon was dinitrophenylated for 90 min. according to the method of Levy.[3] Excess reagent was removed by extraction of the basic reaction mixture with ether. Upon acidification (*p*H 1.0) of the aqueous solution the yellow DNP-protein derivative precipitated. After washing with cold dilute acid, the precipitate was hydrolyzed in 5.7 *N* HCl for 24 hr. at 107–109°, and the excess HCl was removed *in vacuo* over KOH pellets. The yellow residue was redissolved in dilute acid and was extracted three times with ether, leaving essentially all of the yellow color in the aqueous phase. The water-soluble DNP-derivatives were subsequently extracted into *n*-butanol and were separated by the paper chromatographic system of Levy.[3] Two yellow DNP-amino acids were observed with properties indistinguishable from di-DNP-histidine and ϵ-DNP-lysine. A photograph of a chromatogram is given in Fig. 2. Calculations from the ultraviolet determination of the eluted spots indicated an average recovery from triplicate analyses of 0.49 mg. (1 μmole) of di-DNP-histidine per 3.5 mg. of glucagon. These data show that histidine is the N-terminal amino acid, and also corroborate that lysine is located within the chain.

C-Terminal End Group Analysis.—Two methods were used to examine the C-terminus of glucagon, hydrazinolysis[14] and carboxypeptidase treatment.

The hydrazinolysis of glucagon was carried out in a manner similar to that originally described by Akabori and coworkers.[14] Heating the dry protein with hydrazine caused a splitting of peptide bonds, with formation of the hydrazides of all amino acids except the C-terminal one. The hydrazides were removed, in this case by condensation with benzaldehyde to form dibenzals, and the free C-terminal amino acid was identified. Care must be exercised to exclude water from the reaction since hydrolysis of the peptide bonds may then occur. Glucagon was dried *in vacuo* for 24 hr. at 100° over P_2O_5. In a typical experiment 24.4 mg. (7 μM) of the dried preparation was dissolved in 3 ml. of fresh anhydrous hydrazine. The reaction mixture was quickly sealed under N_2 and was incubated at 125 ± 3° for 7.5 hr. The excess reagent was removed *in vacuo* over H_2SO_4. The dried, white residue was redissolved in 3 ml. of H_2O, and 0.3 ml. of benzaldehyde was added. The mixture was shaken for about 5 min., was centrifuged, and the light orange benzaldehyde phase was washed once with 1 ml. of water. The benzaldehyde layer was discarded, and the

process was repeated 3 times with the combined aqueous phase and wash.

At the end of the treatment both the aqueous and organic phases were water-clear. The resulting aqueous phase, about 7 ml., was evaporated under a stream of nitrogen and finally was washed into a 1-ml. volumetric flask. Aliquots were removed for one-dimensional paper chromatography in *n*-butanol–acetic acid–water (4:1:1), and for two-dimensional chromatography according to the method of Redfield.[15]

These paper chromatographic systems provided fast, qualitative identification of amino acids and, in addition, each was adapted for use in quantitative amino acid analysis. The analytical method of Connell, Dixon and Hanes[16] was used in conjunction with the chromatographic system using the solvent butanol:acetic acid:water. In the two-dimensional system of Redfield the chromatograms were developed by use of 0.2% ninhydrin in acetone. The ninhydrin-reacted amino acid spots were excised and were eluted with 75% acetone. The solutions were subjected to spectrophotometric analysis at 570 mμ. In both methods standard recovery curves of all the amino acids in glucagon were employed for quantitative analysis. Both methods were found to be useful in the analysis of hydrolyzates of small peptides as well as in the determination of the hydrazinolysis product.

In both chromatographic systems one major hydrazinolysis product was observed, indistinguishable from threonine. A photograph of such a chromatogram after the method of Redfield is given in Fig. 3. Traces of methionine were also found in some experiments. In these analyses 0.7–0.9 mole of threonine was found per mole of glucagon. Since the hydrazinolysis reaction clearly released only threonine in good yield, this amino acid must be the C-terminal residue of glucagon.

Carboxypeptidase Method.—To confirm the hydrazinolysis result, and to obtain additional data concerning the amino acids near the C-terminal end, glucagon was incubated with carboxypeptidase; the amino acids which were liberated were determined at various intervals during the incubation. The method of amino acid analysis employed in this work was essentially that of Levy[3] and was first used in this manner by Harris, Li, Condliffe and Pon.[17]

Crystalline carboxypeptidase[18] was washed three times with cold distilled water. The concentration of the enzyme was determined prior to each experiment by removing an aliquot of the suspension, dissolving the enzyme in dilute alkali, and determining the absorption at 280 mμ. The crystalline enzyme (0.6 μ*M*) was suspended in 1 ml. of 0.02 *N* $NaHCO_3$ and was dissolved by the dropwise addition of 0.1 *N* NaOH. The solution was immediately adjusted to pH 8.5 to 9 by the addition of 0.1 *N* HCl, and a 50-fold molar excess of diisopropylfluorophosphate (DFP) (0.1 *M* in isopropyl alcohol) was added. Upon the addition of DFP a sharp drop in *p*H occurred. The solution was quickly readjusted to *p*H 8.5 to 9 with 0.1 *N* NaOH, and was allowed to incubate at room temperature for 15 to 20 min.

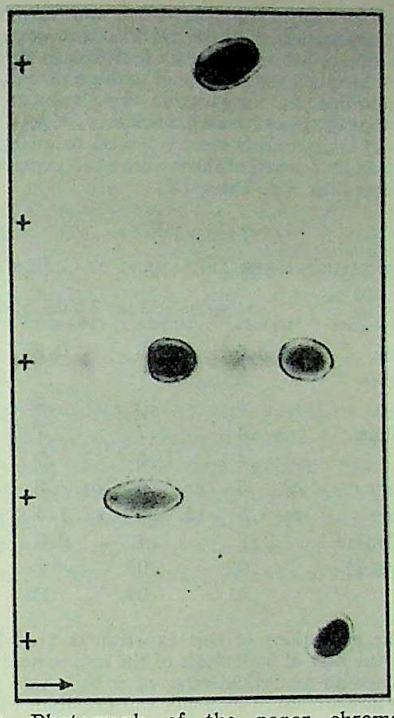

Fig. 2.—Photograph of the paper chromatographic separation of the DNP-derivatives resulting from the hydrolysis of DNP-glucagon. Reference lanes of authentic DNP-amino acids were run simultaneously. Spots were outlined in pencil for subsequent excision, elution and analysis.

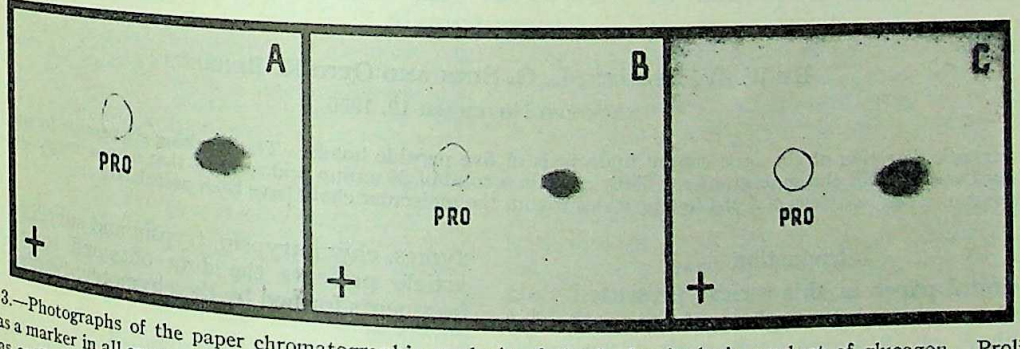

Fig. 3.—Photographs of the paper chromatographic analysis of the hydrazinolysis product of glucagon. Proline was added as a marker in all cases. Since ninhydrin reagent was used to visualize the amino acid spots, the faint yellow proline spot was outlined for purposes of identification: A, product of the hydrazinolysis of 0.04 μ*M* of glucagon; B, threonine (0.03 μ*M*); C, hydrazinolysis product plus 0.03 μ*M* of threonine.

The enzyme solution was added to 14 mg. (4 μmoles) of crystalline glucagon dissolved in 5 ml. of dilute NaOH (*p*H 9.0). The enzyme:substrate molar ratio was approximately 1:65. The volume was adjusted to 7.5 ml., the solution was incubated at room temperature (34°), and appropriate aliquots were removed at 20, 50 and 180 min., as well as at 24 hr. The aliquots were pipetted directly into 15-ml. beakers containing HCl sufficient to adjust the *p*H to approximately 2.5. Those aliquots which were not immediately dinitrophenylated were kept frozen until they could be reacted. In each instance dinitrofluorobenzene was added prior to raising the *p*H to 9.0. The DNP-amino acids were separated by paper chromatography as discussed previously. Since DNP-asparagine and DNP-glutamine do not separate under these conditions, this single spot was eluted and rerun

on a system described by Blackburn and Lawther[19] that gives good separation of these DNP-amino acids. DNP-aspartic acid was also positively identified in this manner. Because of the increased number of manipulations, the analysis of glutamine and asparagine was subject to more error than that of the other amino acids.

At least 11 amino acids were released to an appreciable extent after 24 hr.; seven of these were nearly quantitatively liberated after 3 hr. (*cf.* Table IV).

TABLE IV

CARBOXYPEPTIDASE TREATMENT OF GLUCAGON

Amino acid liberated by carboxypeptidase	μM amino acid per 3.5 mg. glucagon 20 min.	50 min.	180 min.	24 hr.
Threonine	0.6	0.8	0.8	1.1
Methionine	.5	.7	.7	0.9
Valine	.5	.6	.8	.9
Tryptophan	.4	.7	.7	.9
Leucine	.4	.6	.7	.9
Asparagine	*ca.* .5	*ca.* .6	*ca.* .8	*ca.* 1.0
Glutamine	*ca.* .5	*ca.* .6	*ca.* 1.4	*ca.* 1.6
Phenylalanine	.2	.4	0.6	0.6
Aspartic acid	.02	.05	.2	.5
Alanine	.01	.02	.06	.3

Under the conditions of this experiment very little differential in the rate of hydrolysis of the amino acids was observed. Since an analytical error of ±10% was expected, no absolute assignment of sequence was possible. However, the data in Table IV indicate that threonine was probably liberated most rapidly by carboxypeptidase. These data, in conjunction with the clear-cut hydrazinolysis result showed that threonine is the carboxyl-terminal amino acid. The enzymatic release of methionine, tryptophan, valine and alanine is of considerable importance since these amino acids occur only once in the molecule. Obviously these amino acids can serve as markers for orientation of peptide fragments near the C-terminus of the molecule. Since a small amount of alanine and somewhat greater amounts of phenylalanine and aspartic acid were liberated, these amino acids are probably located at a position further removed from the C-terminus. Similarly, the gradual increase in the glutamine analysis to a value greater than one may be interpreted in terms of release of a second residue nearer the center of the molecule.

If optimum conditions had been found for the enzymatic reaction, additional sequential information could be obtained. Such experiments were planned, but before they had been conducted other data became available[20] that obviated the need for further carboxypeptidase experiments.

The evidence indicated that glucagon is a single chain polypeptide. The data make possible formulation of the following partial structure for glucagon.

$$\text{His(ser}_4\text{,glu,gly,thr}_2\text{,phe,asp}_2\text{,tyr}_2\text{,lys,leu,arg}_2\text{)ala(asp,phe,}\underset{\text{glu}_2\text{,asp,leu,try,val,met)thr}}{\overset{\text{NH}_2\text{NH}_2}{|\quad|}}$$

The Amino Acid Sequence of Glucagon. II. The Hydrolysis of Glucagon with Chymotrypsin

BY W. W. BROMER, L. G. SINN AND OTTO K. BEHRENS

RECEIVED NOVEMBER 19, 1956

Chymotryptic digestion of glucagon caused hydrolysis of five peptide bonds. The resulting six peptide fragments were isolated by Dowex 50-X2 chromatography. They contain a total of 29 amino acid residues that have a composition identical to glucagon. The locations of 4 of these peptides within the molecular chain have been postulated.

Introduction

The inital paper in this series[1] presented data which demonstrated that glucagon consists of a single chain of 29 amino acids with a molecular weight of 3485. Single residues of methionine, tryptophan, valine, alanine, lysine, glycine and histidine were found. Histidine and threonine were determined as the N- and C-terminal residues, respectively. Furthermore, incubation with carboxypeptidase showed that methionine, tryptophan, valine and a small quantity of alanine, were liberated from the C-terminal portion of the molecule. To determine the sequence of the 29 amino acids in this polypeptide, an enzymatic degradative approach[2] was followed using the proteolytic enzymes, chymotrypsin, trypsin and subtilisin. This article presents the data obtained from peptide fragments formed by the chymotryptic digestion of glucagon.

Experimental

Materials.—Twice-recrystallized glucagon (Lot 208-158B-292A) was employed for all experiments.

Crystalline chymotrypsin (Lot CD 521) was obtained from Worthington Biochemical Corporation, Freehold, New Jersey.

Incubation of Glucagon with Chymotrypsin.—Glucagon (0.085%) was incubated with chymotrypsin (0.005%) at 37° in a dilute sodium acetate solution at *p*H 7.8 (enzyme: substrate molar ratio, about 1:120). Solution of the substrate was routinely accomplished by adjustment of the *p*H to 10 with 0.1 *N* NaOH. The reaction mixture was adjusted to *p*H 7.8 with 0.8 *N* HOAc and it remained essentially at this *p*H throughout the incubation.

In the preparative experiments the digests were acidified to *p*H 2.0, heated to 90° for 3 min., frozen and lyophilized.

(1) Reference to Paper I in this series, THIS JOURNAL, **79**, 2794 (1957).

(2) Consideration has been given to the possibility of enzyme-catalyzed rearrangements as first suggested by the work of M. Bergmann and O. K. Behrens, *J. Biol. Chem.*, **124**, 7 (1938); O. K. Behrens and M. Bergmann, *ibid.*, **129**, 587 (1939). Data obtained from a single enzyme should be interpreted with caution, and the examination of the degradation products from the action of more than one proteolytic enzyme is desirable.

The rate, nature and extent of hydrolysis was investigated by dinitrophenylation[3] of aliquots of the reaction mixture removed at various time intervals. Samples that were not immediately reacted were treated as described above in the preparative experiments. The DNP-peptides were hydrolyzed for 20 hr. at 107° in 5.7 *N* HCl; the DNP-amino acids were separated by paper chromatography and were determined by the Levy[3] method. Corrections for the destruction of DNP-amino acids during acid hydrolysis were made using the data of Porter.[4]

This method not only provides an excellent means of determining the rate of the reaction, and thus the optimum time of digestion, but also provides evidence for the degree of splitting of the bonds, and gives information on the nature of the N-terminal residue of the newly formed peptides. The measurement of the DNP-amino acids provides reasonable indication of the quantity and the number of peptides actually liberated under the given hydrolytic conditions.

Dowex 50-X2 Separation of the Peptides.—The peptides in the enzymatic digests were resolved by column chromatography at room temperature with Dowex 50-X2, Lot 3328-12, 200 to 400 mesh, obtained from the Dow Chemical Company, Midland, Michigan. The resin and columns were prepared in a manner similar to that described by Moore and Stein.[5] For the purpose of packing the column, 0.1 *N* sodium citrate buffer at *p*H 3.0 was employed. The lyophilized digests were brought into solution using a minimum volume of this buffer, and were applied to the columns.

Columns 50 × 1.5 cm. were used in the isolation experiments, with a flow rate of about 7.5 ml. per hr. Fractions of 5 ml. were collected automatically, and 0.15 or 0.25-ml. aliquots were removed and analyzed by the quantitative ninhydrin method of Moore and Stein.[6] A gradient elution technique was employed using citrate buffers ranging (in 0.5 *p*H unit intervals) from *p*H 3 to 6.5, with the Na^+ concentration varying from 0.1 to 0.58 *N*. At appropriate intervals a higher *p*H, higher ionic strength buffer was applied, producing a reasonably smooth increase in both *p*H and ionic strength in the effluent. Volumes of about 300 ml. of buffer were used. All buffers contained 0.5% each of BRIJ 35, thiodiglycol and benzyl alcohol.

Preliminary Desalting of the Peptides.—After the peptides had been located in the effluent fractions by use of ninhydrin reagent, appropriate fractions were combined so as to include, in most instances, 95% of the peptide material. The combined fractions were swirled one hr. on a rotary shaker with 5 to 10 equivalents of Dowex 50-X4, Lot 707, 20 to 50 mesh, in the hydrogen form. The supernatant was removed by decanting and then drawing off the remaining solution with a small pipet. In most instances the supernatant gave no test with ninhydrin reagent and was discarded. In the event of a positive test, additional resin was added and the shaking was repeated. The resin beads were washed three times with 2 volumes of water, once with EtOH, and finally twice with water. They were then eluted by swirling with about 3 volumes of 5 *N* NH_4OH at 20 to 25° for 30 min. The beads were washed twice with NH_4OH and the combined eluates were evaporated *in vacuo* over P_2O_5 and concentrated H_2SO_4. The dry white residue was dissolved in dilute HCl (*p*H 3 to 4) and was washed into a volumetric flask. Small amounts of thymol and a broad spectrum antibiotic were added, and the solution was refrigerated to minimize growth of microörganisms. Sufficient salt and buffer-additives were removed by this method to permit direct paper chromatography of the peptides, or paper chromatographic separation of the peptide hydrolyzates. Pilot experiments indicated that significant quantities of peptide material were lost during the desalting procedure, depending upon the nature of the peptide. Despite such losses the desalting method was used routinely, since the presence of salts interferes markedly with the resolution of amino acids and proteins in paper chromatography. Paper chromatography was used extensively throughout the structure investigation because of the relative ease and speed of the method.

Analysis of Peptide Fragments.—An aliquot from each combined group of fractions from the Dowex 50 effluent was dinitrophenylated as previously described to ascertain the nature of the N-terminal residue and to provide additional evidence regarding the purity of the peptide itself. Certain peptides were subjected to 2-dimensional paper chromatography to provide additional information on homogeneity. Arbitrary corrections for destruction during acid hydrolysis were made for serine (10%), threonine (3.5%) and tyrosine (5%) (*cf.* 1). Yields of the peptides were based on both the DNP-end group and amino acid analyses, with the assumption that a given peptide occurred only once in the protein molecule. Hydrolyzates of the larger peptides were generally analyzed by the column method of Moore and Stein,[5] and/or by the dinitrophenylation method of Levy.[3] The hydrolyzates of the smaller peptides were analyzed by the two paper chromatographic methods reported in the preceding paper[1] in the section describing the C-terminal analysis.

Results

Rate of Hydrolysis.—A study of the rate of glucagon hydrolysis by chymotrypsin is presented in Fig. 1. If chymotrypsin follows the generally accepted specificity pattern, 5 bonds should be split adjacent to the 5 aromatic residues. The data presented in Fig. 1 are consistent with this expectation. Four different amino acids were found

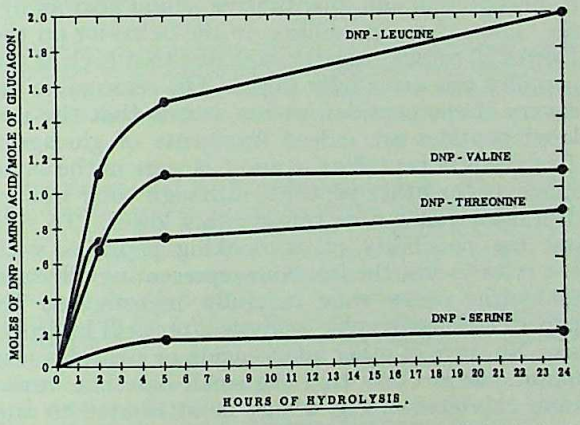

Fig. 1.—A study of the rate of the chymotryptic hydrolysis of the peptide bonds of glucagon, as followed by the dinitrophenylation method. Glucagon (0.085%) was digested with chymotrypsin (0.005%) at 37° in *p*H 7.8 buffer.

by the dinitrophenylation method as N-terminal residues of peptides newly formed by the chymotryptic rupture of peptide bonds Nearly quantitative splits were observed involving two leucine bonds, one valine bond and one threonine bond. In addition, a small yield of DNP-serine was obtained; data will be presented which indicate that the low recovery in the experiment is anomalous. In all likelihood a nearly quantitative split of the serine bond also was obtained. During the structure determination of corticotropin[7] similar difficulties with the dinitrophenylation method were experienced in determining serine as an N-terminal residue.

Separation of the Peptides.—In Fig. 2 is presented the Dowex 50-X2 effluent curve from the 8 hr. chymotrypsin digestion of 127 mg. (36.3 μmoles) of glucagon. Six major ninhydrin-positive peaks were detected, each of which represented a unique peptide fragment. Data on the analysis and recovery of each peptide are presented in Table I. No trace of peptide or amino acid impurities was

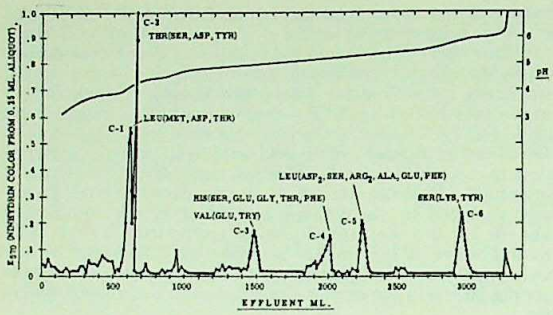

Fig. 2.—Separation of the peptides resulting from the 8 hr. chymotryptic hydrolysis of 127 mg. of glucagon. Chromatography was performed on a 1.5 × 50 cm. column of Dowex-X2 resin. The effluent was collected in 5-ml. fractions. The base-line variations were found to be caused by contamination with ammonia. A 0.2 *N* NaOH solution was used to clean the column, producing the final sharp rise in effluent *p*H.

detected in any of the 6 peptides by means of dinitrophenylation and quantitative amino acid analysis. These data, in addition to the behavior on the Dowex 50 column, clearly indicated that each of the peptides was essentially pure. The reasonable recovery of the peptides further attests that the isolated peptides are indeed fragments of glucagon. The yields of peptides C-3 and C-4 were in the same range as the other peptides, although their ninhydrin color yields were considerably lower. To rule out the possibility of overlooking peptides with low color yields, the fractions representing all small ninhydrin peaks were carefully investigated by paper chromatographic analysis after acid hydrolysis. No trace of other amino acids or peptides was found. It is likely that the small base-line variations exhibited in Fig. 2 may be attributed to ammonia contamination (*cf.* 1).

Table I

Peptides from the Chymotryptic Digestion of Glucagon

Peptide no.	Peptide compn. and anal.[a]	Yield, %
C-1	leu(met,asp,thr)	
	moles 1.0 0.8 1.2 1.0	40
C-2	thr(ser,asp,tyr)	
	moles 1.0 1.0 1.1 1.0	70
C-3	val(glu,try[b])	
	moles 1.3 0.6 1.0	60
C-4	his(ser,glu,gly,thr,phe)	
	moles 0.8 1.0 1.1 1.1 1.1 1.0	50
C-5	leu(asp_2,ser,arg_2,ala,glu,phe)	
	moles 0.9 1.9 1.0 1.8 1.0 1.0 0.8	50
C-6	ser(lys,tyr)	
	moles 0.9 1.3 1.0	50

[a] Hydrolyzates of the peptides were analyzed by the Moore and Stein[5] method, with the exceptions of C-3 and C-6 which were analyzed by paper chromatographic methods. [b] Chemical analysis.[8]

Twice as much C-6 peptide, containing N-terminal serine, was recovered as was expected from the rate study data. In view of this fact as well as the previously mentioned difficulty in the corticotropin structure work, it is likely that about the same degree of chymotryptic hydrolysis occurred in the case of the serine bond as was found with the other 4 bonds. If this hypothesis is correct the recovery of peptide C-6 was similar to that of the other peptides. The yields of the peptides are conservatively based on the assumption of 100% splitting, although the rate of hydrolysis data indicate that only 80 to 90% of the bonds were split after 8 hr. The shortest possible incubation time was chosen to minimize possible transpeptidation. The sum of the amino acid residues in all 6 peptides is 29, with a distribution of individual amino acids identical to that described for glucagon in the first paper of this series.[1] All evidence indicates that these peptides are fragments of glucagon produced by the specific hydrolytic action of chymotrypsin, and are not artifacts.

Discussion

It is appropriate at this point to consider the probable location of these peptides in the glucagon chain. Since only one histidine residue occurs in the molecule and it has been located in the N-terminal position, peptide C-4, His(ser,glu,gly,thr,phe), must be the N-terminus of glucagon. Threonine was shown to be the C-terminal amino acid; but, since there are three threonine residues in the protein, each in a different chymotryptic peptide, the establishment of the C-terminal peptide would seem to be more difficult. However the C-4 threonine-containing peptide already has been designated as the N-terminal peptide. Similarly, the threonine residue in peptide C-2, thr(ser,asp,tyr), cannot be C-terminal in glucagon since it already has been shown to be the N-terminus of peptide C-2. By process of elimination, peptide C-1, Leu(met,asp, thr) must be the C-terminal peptide in glucagon. Other evidence also supports this conclusion; the single residue of methionine, that has been located near the C-terminus because of rapid release by carboxypeptidase, is found in this peptide. Similarly, the absence of an aromatic residue from C-1 is consistent with this interpretation; the usual specificity of chymotrypsin requires that the rupture involves the carboxyl group of an aromatic amino acid. Only the C-terminal fragment should be devoid of such a residue. Additionally, the location of aspartic acid and leucine in the C-terminal peptide do not in any way disagree with the data obtained from carboxypeptidase.

Carboxypeptidase also liberated tryptophan, valine and a small quantity of alanine. Since these three amino acids occur only once in glucagon, they should be found in peptides adjacent to peptide C-1, the C-terminal peptide. On this basis, peptide C-3, val(glu,try), containing both valine and tryptophan, may be placed adjacent to the C-terminal peptide, C-1. Seven of the 11 amino acids liberated by carboxypeptidase now have been placed in relative position near the C-terminus of the molecule. The four remaining amino acids include the single alanine residue, phenylalanine, glutamine and aspartic acid. Of the 3 unplaced peptides only C-5 contains the combination of aspartic acid, glutamic acid, phenylalanine and, of course, the single alanine residue. Hence it would appear that peptide C-5 is adjacent to peptide C-3 which

in turn is next to the C-terminal peptide. No clues are as yet available for the location of peptides C-2 and C-6, although they are obviously within the protein chain and must be adjacent to each other. Additional information is needed to determine which is adjacent to peptide C-4 and which to peptide C-5.

(9) Brackets indicate that the sequence of peptides C-2 and C-6 has not yet been determined.

The evidence available to this point may be summarized in the following partial structure of glucagon

The Amino Acid Sequence of Glucagon. III. The Hydrolysis of Glucagon by Trypsin

BY W. W. BROMER, A. STAUB, L. G. SINN AND OTTO K. BEHRENS

RECEIVED NOVEMBER 19, 1956

Tryptic digestion of glucagon caused rapid hydrolysis of two peptide bonds and slower splitting of three additional bonds. The peptide fragments resulting from both a 2.25 and a 50 hr. digestion were isolated by use of resin chromatography and electrophoresis. The unique composition of the peptide fragments permitted the correlation of existing evidence into the following partial amino acid sequence of glucagon: His(ser,glu,gly,thr,phe)thr(ser,asp,tyr)ser.lys.tyr(leu,asp,ser,arg)-arg ala(glu,asp,phe)val(glu,try)leu(met,asp)thr.

Introduction

The first two papers of this series[1,2] have described the amino acid composition of glucagon, the end group analysis and the characterization of products of degradation by carboxypeptidase and chymotrypsin. Relative positions within the glucagon chain were assigned to 4 of the 6 peptides isolated from the chymotryptic digestion. To provide additional information useful for structural analysis glucagon has been hydrolyzed with another proteolytic enzyme, trypsin. The products of both 2.25 and 50 hr. tryptic hydrolyses of glucagon have been isolated and characterized.

Experimental

Materials.—Crystalline glucagon, lot 208-158B-292A, was used throughout this enzymatic study. Twice-recrystallized trypsin, lot T320, was obtained from the Worthington Biochemical Corporation, Freehold, New Jersey. The chymotrypsin content of this trypsin preparation was less than 0.2% according to analyses by the method of Ravin, *et al.*,[3] using N-benzoyl-DL-phenylalanine β-naphthyl ester as the substrate.

Hydrolysis of Glucagon by Trypsin.—An 0.085% solution of glucagon was incubated with 0.005% trypsin in a 0.05 *M* sodium citrate solution containing 1 mg. per ml. of $CaCl_2$. The enzyme:substrate mole ratio was approximately 1:100. The digestion was performed at 25°, *p*H 7.8, for as long as 50 hr. Excessive stirring of the incubate was avoided since trypsin was found to be inactivated under this condition. Aliquots were removed at various intervals for dinitrophenylation and for determination of the rate of appearance of the N-terminal residues of newly-formed peptides. Preliminary studies of the rate of hydrolysis provided evidence that certain bonds were split very rapidly, while others were ruptured quite slowly. Hence, in the preparative experiments aliquots were removed at both 2.25 and 50 hr.; these solutions were adjusted to *p*H 3 with HCl, were heated to 90° for 2 min., and were lyophilized.

Fractionation of the Trypsin Hydrolyzate.—The lyophilized digests were not completely soluble in the sodium citrate buffer (*p*H 3.0, 0.1 *N*) used in the Dowex 50-X2 chromatographic separation. The precipitate in each digest was peptide in nature, somewhat soluble in dilute alkali, but insoluble in the *p*H range 2.5 to 6.5. Because of the insolubility in the *p*H range of the buffers used in the Dowex 50 chromatography, the precipitate was removed by centrifugation, washed with cold dilute acid, redissolved in dilute alkali (*p*H 8.5 to 9.5) and frozen. The combined washes and supernatant were subjected directly to Dowex 50-X2 chromatography on 1.5 × 50 cm. columns as described in a previous report.[2]

End group analysis[4] of the acid-insoluble materials showed that the 2.25 hr. precipitate was not homogeneous, but the 50 hr. precipitate, isolated in small quantity, appeared to represent a single component. Because of the relatively high purity and small yield of the 50 hr. precipitate no further fractionation was attempted. However, the material which precipitated from the 2.25 hr. digest was subjected to electrophoresis on both starch and paper in 0.1 *N* sodium acetate (*p*H about 7.2) at a milliamperage and voltage of 15 and 300, respectively. The peptide material was eluted from the paper with 1% NH_4OH, and from one-half or one cm. sections of the starch with 5 ml. of water. The peptide material was located in both cases by use of the ninhydrin reagent.[5]

Results

Rate of Hydrolysis.—Glucagon was previously shown to contain one lysine and two arginine residues.[1] Because of the well-accepted specificity behavior of trypsin[6-10] in splitting only those bonds involving the carboxyl groups of these residues, it was expected that 3 bonds in glucagon would be split and 4 hydrolytic products would be formed. The rate of hydrolysis data presented in Fig. 1 show clearly that the tryptic hydrolysis of glucagon did

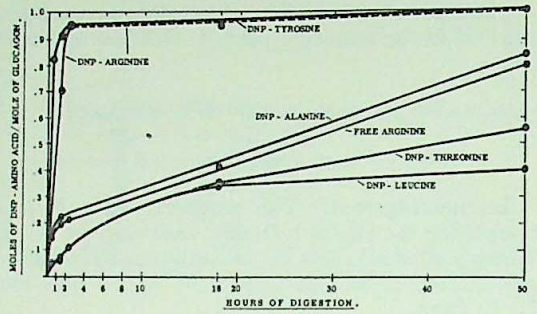

Fig. 1.—A study of the rate of the tryptic hydrolysis of the peptide bonds of glucagon, as determined by the dinitrophenylation method. An 0.085% solution of glucagon was digested with trypsin (0.005%) at *p*H 7.8 and 25°. Free arginine was determined by chromatography on Dowex 50-X8 resin.

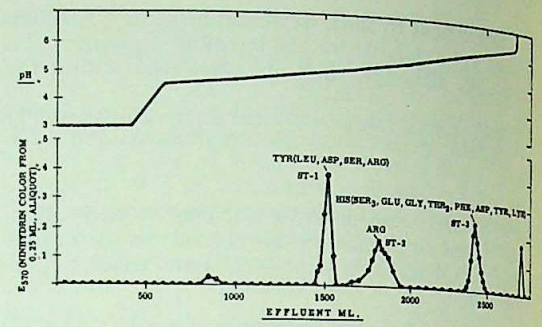

Fig. 2.—Separation of the acid-soluble peptides resulting from the 2.25 hr. tryptic hydrolysis of 146 mg. of glucagon. Chromatography was performed on a 1.5 × 50 cm. column of Dowex 50-X2 resin. Five-ml. effluent fractions were collected. A 0.2 *N* NaOH solution was used to clean the resin column, producing the final sharp rise in *p*H of the effluent.

not proceed in the expected manner. Within 2 hr. nearly complete hydrolysis of 2 peptide bonds occurred, since both di-DNP-tyrosine and DNP-arginine were obtained in high yield. With longer incubation, increasing quantities of DNP-alanine, DNP-threonine, DNP-leucine and free arginine were observed. None of these amino acids appeared to be quantitatively released even after 50 hr. digestion. The free arginine was determined by the analysis of aliquots of the digest on Dowex 50 columns according to the method of Moore and Stein.[11]

It is apparent that two peptide bonds were hydrolyzed rapidly during the trypsin digestion. At least some of these primary peptides must have been further degraded to yield 4 or more additional components.

Peptides from the 2.25 Hour Tryptic Digestion.—The effluent curve presented in Fig. 2 was obtained from the Dowex 50-X2 chromatography of the supernatant from 146 mg. (41.7 μmoles) of glucagon after digestion with trypsin for 2.25 hr. Separation of the components of the precipitate by paper electrophoresis is represented in Fig. 3 by the photograph of a paper strip developed with ninhydrin reagent. The quantitative amino acid analyses and recoveries of all the hydrolytic fragments are summarized in Table I.

TABLE I

	moles 1.0 2.1 2.1 0.7 1.0 1.0 1.3 0.5 1.3	~25

[a] All peptides analyzed by Moore and Stein method.[11] Small amounts of peptides ST–PA and ST–PB available for analysis. [b] Chemical analysis.[12]

DNP-end group analysis of the acid-insoluble material provided evidence for two major components, one containing alanine as the N-terminus and the other arginine as the end group. No other DNP-amino acids were observed. Traces of ninhydrin-positive material other than peptides ST-PA and ST-PB were found by paper and starch electrophoresis; however, the quantity of material was not sufficient for identification. The yields of fragments ST-PA and ST-PB were estimated on the basis of amino acid and end group analyses prior to electrophoretic separation. The amino acid analyses were performed on small quantities of peptides isolated after electrophoretic separation.

The three fragments represented by the effluent curve in Fig. 2 were isolated, desalted and analyzed as described in a previous report.[2] No other peptide material was detected. DNP-end group and quantitative amino acid analyses, along with the Dowex 50 data, demonstrated the high purity of the fragments. The yield of arginine (ST-2) was calculated from the direct analysis of aliquots of the reaction mixture according to the method of Moore and Stein[11] for basic amino acids. Chromatography before and after hydrolysis provided additional evidence for free arginine.

These 5 isolated fragments may be considered in light of the splits predictable from the data on the rate of hydrolysis. Three major degradation products were anticipated after 2.25 hr. digestion. These products should contain histidine, tyrosine and arginine as N-terminal residues (*cf.* Fig. 1). The data in Table I indicate that those three peptides isolated in the highest yield, ST-1, ST-3 and ST-PA, contain these amino end groups. Furthermore, the sum of the amino acids in these three degradation products is identical to the amino acid composition of the entire glucagon molecule. The relatively low yield of ST-3 is perhaps understandable when the large size and amino acid composition of the peptide are considered. The presence of two basic residues and two aromatic residues probably tended to retard elution of the peptide from the Dowex 50 column and from the resin during the desalting step.

In addition to the two major splits during the first 2.25 hr. of separate study data indicated that

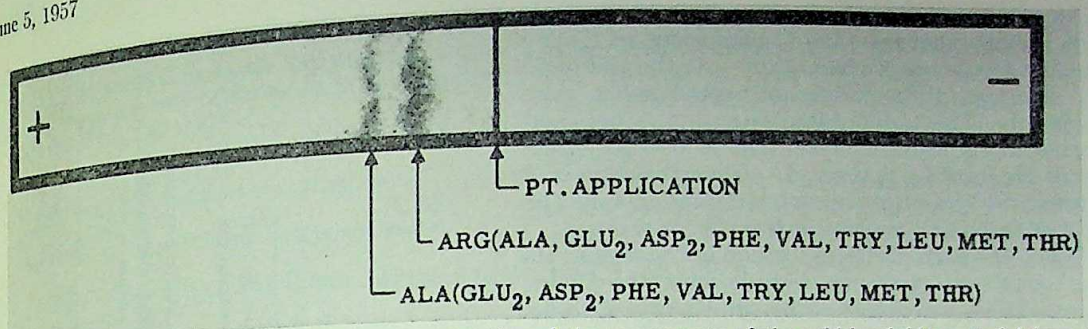

Fig. 3.—Photograph of the paper electrophoretic separation of the components of the acid-insoluble material from the 2.25 hr. tryptic digestion of glucagon. Electrophoresis was performed for 4 hr. at 5° in 0.1 *N* sodium acetate solution (*p*H 7.2), with a milliamperage and voltage of 15 and 300, respectively.

lesser splits had occurred which involved free arginine and N-terminal alanine. The two remaining fragments which were isolated, ST-2 and ST-PB, are in complete agreement with this prediction. On the basis of the yields and the composition of the fragments, it is probable that ST-2 and ST-PB arose from the degradation of ST-PA. The tryptic liberation of N-terminal arginine is somewhat unexpected in view of the resistance to tryptic hydrolysis of amino-terminal lysine in ribonuclease, as found by Hirs, Moore and Stein.[6]

Small yields (10%) of DNP-leucine and DNP-threonine were also detected in the rate study; no corresponding peptides were detected, possibly because the quantities were too small.

Peptides from the 50 Hour Tryptic Digestion.—Separation of the acid-soluble degradation products from 165.2 mg. (47.2 μmoles) of glucagon formed by a 50 hr. tryptic digestion is represented by the Dowex 50-X2 effluent curve in Fig. 4. Peak LT-5

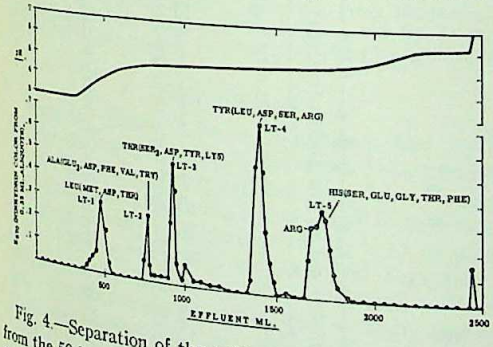

Fig. 4.—Separation of the acid-soluble peptides resulting from the 50 hr. tryptic hydrolysis of 165.2 mg. of glucagon. Chromatography was performed on a 1.5 × 50 cm. column of Dowex 50-X2 resin. Five-ml. effluent fractions were collected. A 0.2 *N* NaOH solution was used to clean the resin column, producing the final sharp rise in *p*H of the effluent.

was found by end group analysis to represent two components, one with arginine as the N-terminus and the other containing N-terminal histidine. Rechromatography of this mixture on Dowex 50-X8 columns described by Moore and Stein[11] for basic amino acids resulted in the separation of the two components, as demonstrated by the elution curve in Fig. 5. The elution pattern of peak LT-5B indicated that this component was identical with free arginine. Rechromatography after acid hydrolysis provided further evidence that a single arginine residue had been liberated. The analysis and recovery of the various isolated fragments is presented in Table II. End group and quantitative amino acid analysis provided evidence

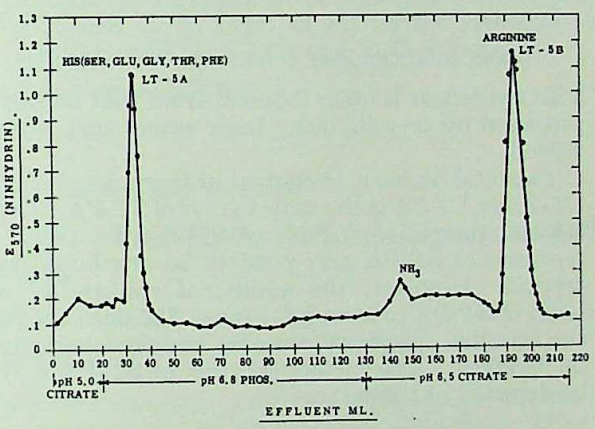

Fig. 5.—Rechromatography of the material represented by peak LT-5. Separation into two components was accomplished on a 0.9 × 15 cm. column of Dowex 50-X8 resin.

that LT-1 represented more than 80% of a single component. No evidence of amino acid or peptide impurities in the other peptides was observed, except that the acid-insoluble material contained a small amount of peptide probably identical to ST-PA.

TABLE II

PEPTIDES FROM THE 50 HOUR TRYPTIC DIGESTION OF GLUCAGON

Peptide no.	Peptide compn. and anal.[a]	Yield, %

As previously discussed, the rate of hydrolysis data indicate that two major splits occurred during the first few hours of incubation. At the end of 50 hr. digestion, three additional partial splits were observed. This complicated situation is not conducive to the clear analysis that is possible when bonds are completely cleaved. Nevertheless it is of interest to consider the isolated products in the light of the splits predictable from the rate study.

When the yield and composition of the fragments are considered, only one peptide from the 50 hr. digest, LT-4, was found to be similar to a 2.25 hr. digestion product. Presumably the other major fragments isolated from the 2.25 hr. incubate, ST-3 and ST-PA, must have been further degraded.

The sum of the amino acids in peptides LT-5A and LT-3 is identical to the amino acid composition of ST-3. Apparently the trypsin preparation split ST-3 in the following manner

his(ser,glu,gly,thr,phe,thr,ser,asp,tyr,ser,lys)

↓

his(ser,glu,gly,thr,phe) + thr(ser,asp,tyr,ser,lys)

This hydrolysis is quite different from that usually produced by trypsin, as no basic amino acid is involved.

The total amino acid content of fragments LT-1, LT-2 and LT-5A is the same as that of ST-PA. The release of arginine (LT-5B or ST-2) from the N-terminus of ST-PA may possibly be attributed to trypsin. However, the additional rupture of a bond in ST-PA to form LT-1 and LT-2 does not fit the accepted specificity, since no basic residues can be involved. The further splitting of ST-PA may be depicted as follows:

arg(ala,glu,asp,phe,val,glu,try,leu,met,asp,thr)

↓

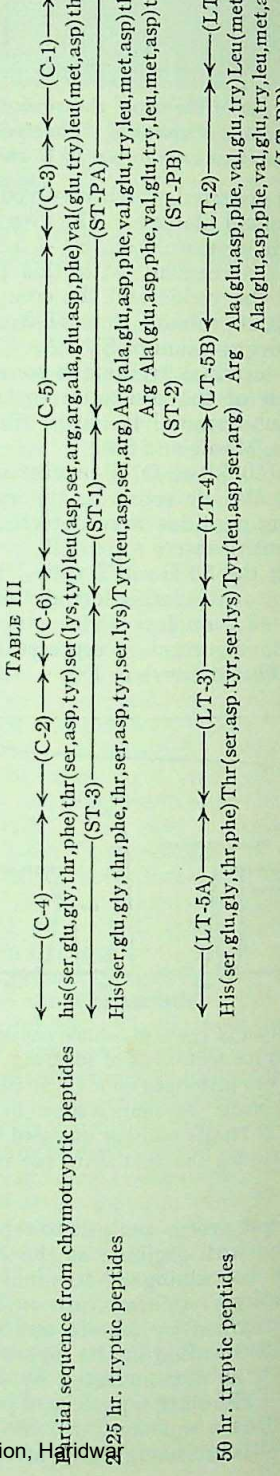
arg + ala(glu,asp,phe,val,glu,try) + leu(met,asp,thr)

Thus, a trypsin preparation has split two bonds in glucagon in addition to those predicted from the known specificity of trypsin. These observations are only incidental to the determination of the structure; nevertheless they are of considerable interest since nearly all other reports have confirmed the accepted specificity of trypsin. Two alternatives are possible; the activity is inherent in the trypsin, or it is caused by a proteolytic impurity such as chymotrypsin. The specificity of the hydrolysis is consistent with the latter interpretation; however, there is virtually no chymotrypsin in the trypsin preparation, only 2 of the known 5 chymotryptic splits were found, and the addition of β-phenyl propionate, a chymotrypsin inhibitor, to the incubate did not prevent the two splits in question.

Discussion

The information obtained from the tryptic digestion studies may be considered with respect to the structure of glucagon. Earlier work has shown that histidine and threonine are the N- and C-terminal residues of this chain, and that single residues of histidine, glycine, lysine, alanine, valine, tryptophan and methionine are present.

TABLE III



CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

June 5, 1957

The unique amino acid composition of peptide ST-3 may be utilized to locate the position in the glucagon chain of two peptides from the chymotrypsin digestion, C-2 and C-6.

(ST-3)
his(ser,glu,gly,thr,phe,thr,ser,asp,tyr,ser,lys)
(C-4) (C-2) (C-6)
his(ser,glu,gly,thr,phe)thr(ser,asp,tyr)ser(lys,tyr)

All other evidence is consistent with this interpretation (*cf.* Table III).

The three major fragments of glucagon formed after 2.25 hr. of trypsin digestion, ST-3, ST-1 and ST-PA, may be readily placed in position within the glucagon molecule. Peptide ST-3 contains N-terminal histidine, and ST-PA contains all of the amino acids liberated by carboxypeptidase, including potential C-terminal threonine which is not found in ST-1. Hence, ST-3 and ST-PA must be the N- and C-terminal peptides, respectively. This leaves only a position between these fragments for ST-1, producing a sequence of (ST-3)(ST-1)(ST-PA). As previously discussed, these three peptides account for the entire amino acid composition of glucagon. Since ST-2 (arginine) and ST-PB were, in all likelihood, formed by the degradation of ST-PA, the sequence involving these minor products can only be written as (ST-3)(ST-1)(ST-2)(ST-PB), again accounting for the amino acid composition of glucagon.

Extending these considerations to the peptides isolated from the 50 hr. trypsin digest, it may be recalled that LT-5A and LT-3 were formed from ST-3, and LT-5B, LT-2 and LT-1 were formed from ST-PA. Peptide LT-4 is identical to ST-1, hence the sequence of peptides can only be written (LT-5A)(LT-3)(LT-4)(LT-5B)(LT-2)(LT-1). LT-PB, isolated in small yield and identical in composition to ST-PB from the 2.25 hr. digestion, can be located in a similar position.

The evidence for the sequence of the peptides within the glucagon chain is summarized in Table III.

The Amino Acid Sequence of Glucagon. IV. The Hydrolysis of Glucagon with Subtilisin

BY L. G. SINN, OTTO K. BEHRENS AND W. W. BROMER

RECEIVED NOVEMBER 19, 1956

Ten of the peptide bonds of glucagon were ruptured by the proteolytic attack of subtilisin. The resulting mixture of eleven degradation products was fractionated by Dowex 50 chromatography and countercurrent distribution. The arrangement of the peptide fragments in the glucagon chain is correlated with existing information.

Introduction

Previous reports[1,2] have described the hydrolytic breakdown products of glucagon obtained from the action of chymotrypsin and trypsin. Each set of peptides isolated from an enzymatic digest has an amino acid composition identical to that of glucagon. The peptides can be arranged logically in only one manner. Since some areas of unknown sequence remained, glucagon was split by use of a third proteolytic enzyme, subtilisin. The eleven peptides formed by this digestion are characterized in this report.

Experimental

Materials.—Twice-recrystallized glucagon, Lot 208-158B-292A, and crystalline subtilisin[3] (preparation F, containing 20% Na_2SO_4) were used for all experiments.

Hydrolysis of Glucagon by Subtilisin.—Glucagon (0.09%) was incubated with subtilisin (0.003%) at 37° in 0.05 *M* sodium acetate solution at *p*H 7.5 for 24 hr. During the first few hours of the digestion the *p*H drifted slowly to 7, and required occasional readjustment.

The rate and nature of the hydrolysis was studied by dinitrophenylating aliquots of the digest that were removed at various time intervals. The DNP-peptides were hydrolyzed, and the DNP-amino end groups of each new peptide were determined quantitatively.[4] In the preparative experiments the reaction mixture was immediately subjected to Dowex 50-X2 chromatography as described in a previous report.[1]

Results

Rate of Hydrolysis.—The rate of hydrolysis of glucagon by subtilisin is represented by the curves in Fig. 1. The amount of the N-terminal amino acid of each newly formed peptide is plotted *versus* time. The specificity of subtilisin has not been rigidly established[5]; however, it is certain that the enzyme ruptures a rather wide variety of peptide linkages, forming small peptide fragments. According to the data in Fig. 1 subtilisin almost completely split three bonds involving aspartic acid, two involving leucine, and one each involving glycine, valine and threonine. In addition, sizable amounts of DNP-arginine and di-DNP-lysine were detected, but were not determined quantitatively. Bonds involving these residues were ruptured to a significant extent. A logical interpretation of these data was that glucagon was split by subtilisin in 10 places, giving rise to 11 peptide fragments.

The splitting of most of the bonds was essentially complete within 5 to 6 hr.; however, some of the

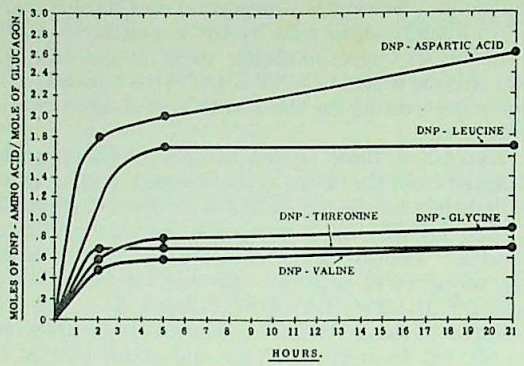

Fig. 1.—A study of the rate of the subtilisin hydrolysis of the peptide bonds of glucagon, as determined by the dinitrophenylation method. An 0.09% solution of glucagon was digested with subtilisin (0.003%) at *p*H 7.5 and 37°.

bonds required as long as 24 hr. for complete hydrolysis. Furthermore, since an uncertainty existed regarding the rate of splitting of arginine and lysine bonds, the incubation was continued for 24 hr. in the preparative experiments.

Separation and Analysis of the Peptides.—The Dowex 50-X2 effluent curve from the 24 hr. subtilisin digestion of 176.2 mg. (50.3 μmoles) of glucagon is presented in Fig. 2. The analysis and recovery of the peptide fragments is given in Table I.

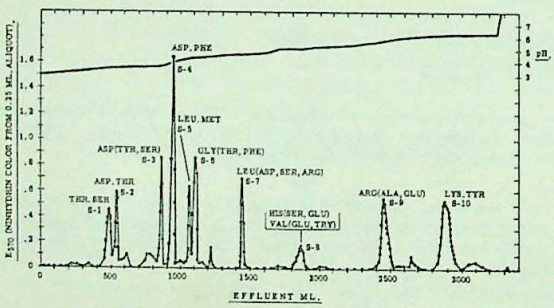

Fig. 2.—Separation of the degradation products resulting from the 24 hr. subtilisin digestion of 176.2 mg. of glucagon. Chromatography was performed on a 1.5 × 50 cm. column of Dowex 50-X2 resin. Five-ml. effluent fractions were collected. A 0.2 *N* NaOH solution was used to clean the resin column, producing the final sharp rise in *p*H of the effluent.

Peak no. 8 in the effluent curve in Fig. 2 was found to represent a mixture of two peptides. Upon application of the dinitrophenylation method both histidine and valine were identified as N-terminal residues. The DNP-derivatives of these peptides were separated by a 10 tube countercurrent distribution in 0.1 *N* HCl and ethyl acetate. The recovery of these two peptides was calculated after complete separation; the low yields were due, at least in part, to the increased number of manipulations. Both peptides, S-8A and S-8B, produced low color yields when reacting with ninhydrin, emphasizing the necessity for careful examination of all fractions which reacted with ninhydrin.

June 5, 1957

Paper chromatographic analyses of acid hydrolyzates of such fractions gave no evidence for peptide material other than the 11 peptides indicated in Table I.

With the methods used in this structure study, peptides might be overlooked that did not produce color with ninhydrin reagent. This possibility in itself is rather improbable. Furthermore, from the data on the rate of hydrolysis it has been possible to rather accurately predict the number of peptides formed in each incubation and the N-terminus of each peptide.

Discussion

Assuming that each peptide occurs only once in the chain, the distribution of the amino acids in the 11 peptides was identical to the amino acid composition of glucagon. Only peptide S-3, asp(tyr,leu), contained a measurable amount of impurity, having about 0.2 mole of threonine per mole of peptide. Dinitrophenylation and quantitative amino acid data, along with the behavior of the peptides on Dowex 50 columns and their generally good recovery, all pointed to the conclusion that these peptides were genuine fragments of glucagon arising from the hydrolytic action of subtilisin.

Integration of the 11 peptides from the subtilisin digestion into the glucagon chain is represented in Table II.

Acknowledgment.—The authors are indebted to H. L. Bird and C. T. Pugh for the paper chromatography, and to W. A. Tandy and R. G. Scheib for their technical assistance.

The Amino Acid Sequence of Glucagon. V. Location of Amide Groups, Acid Degradation Studies and Summary of Sequential Evidence

BY W. W. BROMER, L. G. SINN AND OTTO K. BEHRENS

RECEIVED NOVEMBER 19, 1956

Data is presented that elucidates the remaining unknown amino acid sequences in the glucagon chain, and that establishes the locations of the four amide groups. The following complete amino acid sequence of glucagon is proposed: His.ser.glu.-gly.thr.phe.thr.ser.asp.tyr.ser.lys.tyr.leu.asp.ser.arg.arg.ala.glu.asp.phe.val.glu.try.leu.met.asp.thr

Introduction

In preceding papers of this series[1–3] the degradation products of glucagon formed by the action of three different proteolytic enzymes have been described. These fragments of the glucagon chain can be arranged to fit together logically in only one manner; all of the data obtained are consistent with the proposed arrangement. However, the sequence of all the amino acids within the chain is not determined, and the location of the four amide groups can only be postulated from the behavior of the peptides on resin columns and from the carboxypeptidase data. This paper describes the elucidation of the unknown sequences, largely through partial acid degradation, and the final location of the amide linkages by means of chemical analysis.

Experimental

Partial Acid Degradation.—Peptides from enzymatic degradation of glucagon were dissolved in 11.7 *N* HCl at a concentration of about one μmole per ml., and the reaction mixture was incubated at 37° for 3 days. The excess acid was removed *in vacuo* over KOH pellets. The white residue was dissolved in water, and aliquots were subjected to paper chromatography in the solvent *n*-butanol:acetic acid:water, 4:1:1. The peptide degradation products were located by spraying an identification lane with ninhydrin reagent (*cf.* Fig. 1). Areas in the unreacted lanes corresponding to the ninhydrin-positive areas were excised, were eluted with 0.02 *N* HOAc, and were dinitrophenylated. The DNP-derivatives were hydrolyzed in acid, and the N-terminal residue and the amino acid composition were determined by paper chromatography.

Amide Analysis.—Two to 5 μmoles of a selected peptide was dissolved in dilute alkali at *p*H 8.5 to 9, and the solution was evaporated to dryness *in vacuo* over H_2SO_4. A solution of approximately 2 μmoles of peptide per ml. of 11.7 *N* HCl was prepared and was incubated at 37° for as long as 144 hr. At appropriate intervals, aliquots corresponding to 0.2 to 1 μmole of peptide were removed for ammonia analysis conducted either according to the method of Rees[4] or the procedure of Russell.[5] Each of the 7 peptides which were studied contained only one potential amide linkage.

In all cases a mixture of amino acids devoid of amide groups but otherwise simulating the peptide was treated similarly. Such control hydrolyses provided evidence for the amount of interfering substances or non-amide ammonia liberated.

Hydrolysis of Peptide C-3 with Carboxypeptidase.—A solution containing 0.02% peptide C-3, val(glu,try), and 0.024% carboxypeptidase was incubated under conditions identical to those employed in a previous report[6] enzyme:substrate mole ratio, about 1:65. Aliquots of the incubate were removed at various time intervals for dinitrophenylation and subsequent paper chromatography.[7]

Results

Partial Acid Degradation.—Three of the four remaining sequences were determined by characterizing the partial degradation products of the two enzymatically obtained peptides C-4, his(ser,glu)-

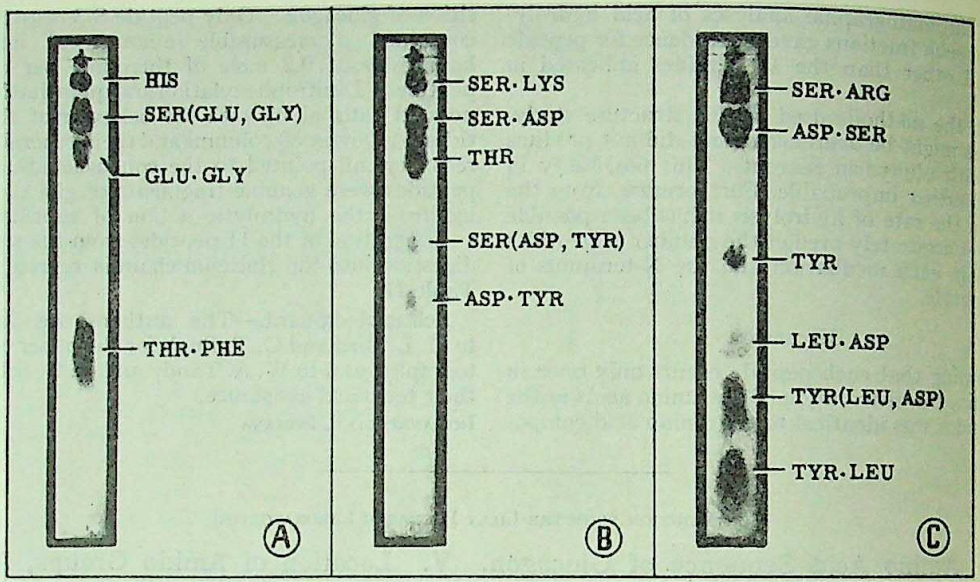

Fig. 1.—Photographs of the paper chromatographic separation of the acid hydrolysis products from peptides C-4, LT-3 and LT-4. The chromatograms were developed with *n*-butanol:acetic acid:water (4:1:1), and were treated with ninhydrin reagent: A, hydrolysis products of peptide C-4, His(ser,glu,gly,thr,phe); B, hydrolysis products of peptide LT-3, Thr(ser,asp,tyr,ser,lys); C, hydrolysis products of peptide LT-4, Tyr(leu,asp,ser,arg).

gly(thr,phe), and LT-4, tyr.leu(asp,ser,arg). In addition, peptide LT-3, thr.ser.asp.tyr,ser.lys, was similarly degraded. The quantitative amino acid composition of these peptides had been determined in the earlier described work.[1,2] Since acid degradation is not considered to promote rearrangements, such data elucidated the unknown sequences and also provided additional evidence for certain sequences which were proposed largely on the basis of data obtained from enzyme degradation.

Presented in Fig. 1 are photographs of the paper chromatographic separation of the acid hydrolysis products of the above three peptides.

The chromatograms were treated with ninhydrin reagent. In cases where overlapping of the spots occurred, the chromatograms were carefully excised to exclude the overlapping area. The analysis and recovery of the degradation products are presented in Table I. The figures on amino acid analysis are based on single or duplicate paper chromatographic analyses. Precise analytical data were not required to ascertain the amino acid composition of the degradation products since the parent peptides had been carefully analyzed and only one, LT-3, contained more than one residue of a given amino acid.

Small quantities of impurities were present in some of the hydrolytic products; this observation had been expected because of the non-specific degradative approach. Estimation of the purity of the fragments was based on end group analysis using the dinitrophenylation method. In the majority of cases at least 0.4 mole of a given amino acid residue was recovered per mole of starting peptide.

This recovery was considered acceptable since large losses had been expected due to the lengthy manipulation consisting of partial acid hydrolysis, paper chromatography, elution from the paper, dinitrophenylation, complete acid hydrolysis and

paper chromatographic analysis of both the free and the DNP-amino acids. The degradation of the parent peptides into relatively few fragments may be attributed at least in part to the high content of serine and threonine in the peptides. Bonds involving the amino groups of the hydroxy amino acids are known[8] to be particularly labile in concentrated acids at rather low temperatures.

Sequence of Peptide C-3.—Paper chromatography[7] of the dinitrophenylated aliquots from the carboxypeptidase time study of peptide C-3 revealed the presence of two major DNP-derivatives in approximately equal amount. DNP-tryptophan was recognized readily; however, the second derivative did not correspond to any known DNP-amino acid. Quantitative analysis[9] demonstrated the complete absence of tryptophan in the unknown DNP-derivative. After hydrolysis, followed by paper chromatographic separation, the unknown spot was identified as DNP-val.glu. The course of the hydrolysis is represented by the curves in Fig. 2, with the DNP-peptide calculated as if it

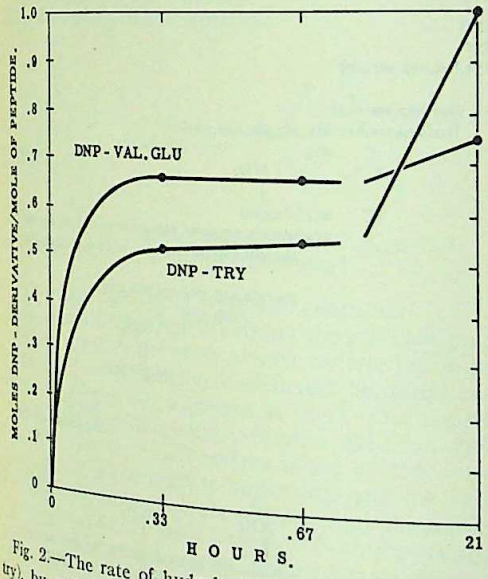

Fig. 2.—The rate of hydrolysis of peptide C-3, val(glu, try), by carboxypeptidase as determined by the dinitrophenylation method.

were DNP-valine. While the quantitative aspects of this experiment leave something to be desired, there can be little doubt that the sequence in peptide C-3 is val.glu.try. Both products of hydrolysis point to this conclusion; furthermore, this conclusion is in agreement with the usual specificity of chymotrypsin.

Location of the Amide Linkages.—The curves presented in Fig. 3 are representative of the results obtained from the amide analysis of peptides C-3, C-4, S-2, S-3, S-4, S-7 and S-9. In some cases the zero-time values for ammonia were abnormally high despite efforts to remove extraneous ammonia by concentration to dryness *in vacuo* from a weakly basic solution. Because of this difficulty it is possible that the quantitative recovery of the ammo-

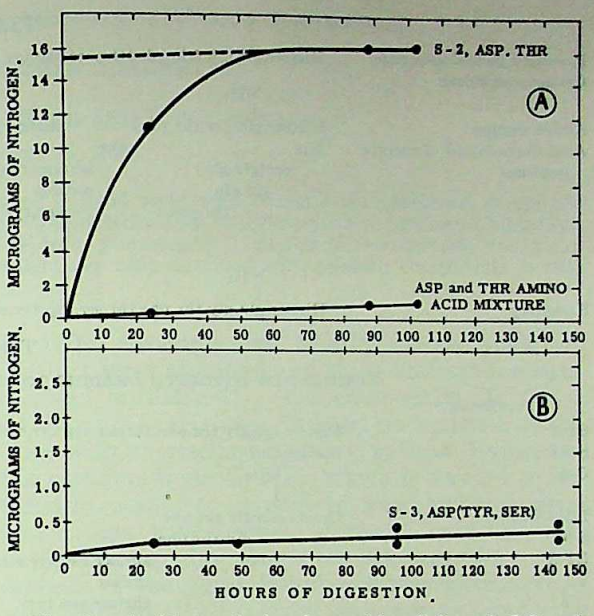

Fig. 3.—Amide analysis of peptides S-2 and S-3: A, ammonia nitrogen liberated from 1.2-μM aliquots of peptide S-2, and from equal quantities of a mixture of aspartic acid and threonine. Extrapolation to zero time provides a value of approximately one μM of NH_3 formed per μM of peptide S-2. B, Ammonia nitrogen liberated from 0.2 μM-aliquots of peptide S-3. Less than 0.1 μM of NH_3 was formed per μM of peptide S-3.

nia was masked by the initial high value, particularly in the cases of peptides C-4 and S-9

Despite this factor, the gradual release of ammonia during the digestion clearly showed which peptides contained the amide linkages. The quantitative data are presented in Table II. Of the 7

TABLE II

AMIDE ANALYSIS OF PEPTIDES FROM GLUCAGON DEGRADATION

Peptide no.	Peptide compn.	Moles of amide per mole of peptide
C-3	NH_2 | Val(glu,try)	1.1
C-4	NH_2 | His(ser,glu,gly,thr,phe)	0.6
S-2	NH_2 | Asp.thr	.9
S-3	Asp(tyr,ser)	.03
S-4	Asp,phe	.03
S-7	Leu(asp,ser,arg)	.0
S-9	NH_2 | Arg(ala,glu)	.5

peptides tested, only C-3, C-4, S-9 and S-2 yielded significant quantities of ammonia when incubated with strong acid. This is in agreement with the number of amide linkages found by chemical analysis of glucagon, and with the behavior of the peptides on resin columns. The data presented earlier on the release of amino acids from glucagon by the action of carboxypeptidase are also consistent with the conclusions that have been presented. Three amide-containing residues were liberated.

[a] Prefix of the peptide number indicates the hydrolytic agent: ST = trypsin (2.25 hr.), S = subtilisin, C = chymotrypsin, LT = trypsin (50 hr.).

Two, as glutamine, occur in peptides C-3 and S-9. One, as asparagine, has been found in the terminal peptide, S-2. Finally, a residue of aspartic acid was released slowly by carboxypeptidase; the identification of this residue with the aspartic acid occurring in peptide S-4 is a logical interpretation.

Discussion

The results obtained by degradation of certain peptides with acid and with carboxypeptidase have been integrated into existing knowledge of the glucagon structure as shown in Table III. At least one line of evidence is available for each sequence in the chain, and in many cases more than one proof has been presented. In no case was it necessary to rely on the specificity of a proteolytic enzyme for a structure proof; however, with the exception of 2 or 3 minor splits caused by trypsin, the accepted specificity patterns of trypsin and chymotrypsin were confirmed. Of critical importance is the fact that all data, with no exceptions, are consistent with the final structure as proposed in Table III. A summary of all the evidence described in this series of reports is presented in Table IV.

Pyridylethylated Benzoxazinediones[1]

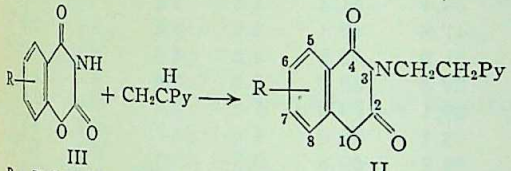
BY SEYMOUR L. SHAPIRO, IRA M. ROSE AND LOUIS FREEDMAN

RECEIVED DECEMBER 13, 1956

Pyridylethylation of 1,3-benzoxazine-2,4-diones has been effected in good yield with 2- and 4-vinylpyridines in the absence of a catalyst. Hydrolysis of some of these products to the N-pyridylethylated salicylamides and further to 2-pyridylethylamines has been demonstrated. Pyridylethylated products from phenobarbital, saccharin, succinimide and theophylline are also described. Interesting pharmacological responses have been obtained with selected compounds in this series.

The reported analgesic activity[2] of N-(2-(2-pyridyl)-ethyl)-phthalamide (I) suggested investigation of the corresponding 3-pyridylethylated 1,3-benzoxazine-2,4-diones (II) which embrace the structural elements of I as well as the analgetically active salicylamide structure. Recognition of enhancement of salicylate activity[3,4] by ring substituents indicated similar exploratory requirements for II.

Pyridylethylation of the 1,3-benzoxazine-2,4-diones (III) proceeded readily without catalyst and without solvent other than an excess of the vinylpyridine according to the equation



III II

R = H, 6-Cl, 6-Br, 8-CH_3, 6-OH, 7-OH, 6-C_6H_5, 8-C_6H_5
Py = 2-pyridyl, 4-pyridyl, 2-pyridyl-5-ethyl

The methiodides of II were also prepared.

The reaction apparently follows the reaction path suggested by Levine[5] with attack by the imide nitrogen of III on the electron-deficient terminal carbon atom of the vinyl groups in the 2- and 4-positions of the pyridine ring. Similar electron deficiency of the terminal carbon atom of the vinyl group in the 3-position[6] is impossible and no pyridylethylated products were obtained on attempted condensation of III with 2-methyl-5-vinylpyridine.

Yields of II ranged from 75% to quantitative as crude product and from 45–87% after recrystallization. The compounds prepared are described in Table I.

Two compounds related to type II were also prepared. In both of these, R = H. In one, the pyridyl group was replaced by the phenyl radical and in the other it was replaced by the 3,4-dimethoxyphenyl radical.

The required III was prepared by the sequence of reactions: substituted salicylic acid → methyl ester → amide. Reaction of the salicylamide with ethyl chlorocarbonate in pyridine–acetonitrile resulted in cyclization of the initially formed carbonic esters directly to III. Yields ranging from 84–100% as crude and 63–91% as recrystallized product were obtained and these findings are summarized in Table II. The compounds III (R = 6-OH, and 7-OH) were isolated under these conditions with unesterified hydroxyl groups. Evidently, the pyridine hydrochloride which is formed is sufficiently acidic to hydrolyze any carbonic ester which may have formed at the 6- or 7-hydroxyl group during the course of the reaction. Hydrolysis of the pyridylethylated benzoxazinediones with aqueous alkali at room temperature provided a convenient synthesis for the N-pyridylethylated salicylamides. The amides prepared are described in Table III.

The salicylamides (R = H, X = 2-pyridyl) upon hydrolysis with hydrochloric acid afforded 2-(2-aminoethyl)-pyridine (IV) as the dihydrochloride confirming the site of attack of III on the 2-carbon of the vinyl side chain of the pyridine.

Hot aqueous alkaline hydrolysis of II also afforded IV.

While these hydrolyses are synthetic pathways to these hitherto difficultly accessible amines, the reported synthesis[7] of IV and allied amines affords a much more convenient route.

Pyridylethylation also was studied and effected with theophylline and the imides, succinimide, saccharin and phenobarbital, and the results are described in Table IV.

Broad spectrum pharmacology did not show any regular structure–activity trends, although a variety of interesting responses were obtained in individual compounds for anticonvulsant, analgesic and anti-inflammatory effects in animal experiments. Thus the compounds (Table I) where R = H, Py = X and R = H, Py = Z showed anticonvulsant activity comparable to tridione. Analgesic activity two to three times that of salicylamide was noted with the compounds where R = 8-CH_3, Py = Y and R = 8-CH_3, Py = Z. The methiodides of the structures where R = 6-OH, Py = Y and R = 7-OH, Py = Y yielded anti-inflammatory activity superior to but were more toxic than butazolidin.

Experimental[8]

6-Bromo-1,3-benzoxazine-2,4-dione.—A suspension of 43.2 g. (0.2 mole) of 5-bromosalicylamide in 100 ml. of pyridine and 60 ml. of acetonitrile was maintained at 5° during addition of 22 ml. (0.22 mole) of ethyl chlorocarbonate over 20 minutes. The solution so obtained was concentrated until the internal temperature reached 122° (120 ml. of distillate collected) and then refluxed for 1 hr. Cooling and treating with 300 ml. of water and 10 ml. of concentrated hydrochloric acid yielded 46.2 g. (95.3%) of product.

6-Chloro-3-(2-(4-pyridyl)-ethyl)-1,3-benzoxazine-2,4-dione.—To 6.59 g. (0.033 mole) of 6-chloro-1,3-benzoxazine-2,4-dione was added 25 ml. of 4-vinylpyridine and the reaction mixture heated under a nitrogen atmosphere for 2 hr. at 100° and then for 2 additional hr. at 150°. On cooling, the product separated, the excess 4-vinylpyridine was decanted and the crystalline mat of product ground under hexane and separated, giving 9.79 g. (97%).

[a] The symbols have the same significance as shown in Table I. [ab] The compound used for pyridylethylation less its acidic hydrogen. [ac] These compounds were prepared by Mr. Harold Soloway of these laboratories using basic catalysis and the method of F. K. Kirchner and C. J. Cavallito, U. S. Patent 2,498,497, Feb. 21, 1950.

N-(β-Phenethyl)-salicylamide.—A solution of 15.2 g. (0.1 mole) of methyl salicylate and 20 ml. (excess) of β-phenethylamine was refluxed until a minimum internal temperature (104°) was reached. Volatiles were removed and 22.3 g. (92.5%) of product crystallized on cooling. Recrystallization from ether (51%) gave a product which melted at 94–95°.

Anal. Calcd. for $C_{15}H_{15}NO_2$: C, 74.7; H, 6.3. Found: C, 75.1; H, 6.3.

This product was cyclized with ethyl chlorocarbonate as described above to yield the 3-(β-phenethyl)-1,3-benzoxazine-2,4-dione.

N-(β-[3,4-Dimethoxyphenyl]-ethyl)-salicylamide.—This was prepared from methyl salicylate and β-(3,4-dimethoxyphenyl)-ethylamine as described above in 19% yield; m.p. 110–111° (acetonitrile–ether).

Anal. Calcd. for $C_{17}H_{19}NO_4$: C, 67.8; H, 6.4; N, 4.7. Found: C, 67.6; H, 6.2; N, 4.8.

N-2-(4-Pyridylethyl)-3-phenylsalicylamide.—A suspension of 1.8 g. (0.0053 mole) of 3-(2-[4-pyridylethyl])-8-phenyl-1,3-benzoxazine-2,4-dione in 50 ml. of 5% sodium hydroxide dissolved after stirring for 2 hr. Acidification with hydrochloric acid, followed by addition of excess sodium bicarbonate, gave 1.55 g. (93.2%) of crude amide, m.p. 174–179°.

2-(2-Aminoethyl)-pyridine (from Acid Hydrolysis of Pyridylethylsalicylamide).—A solution of 2.92 g. (0.012 mole) of N-(2-[2-pyridyl]-ethyl)-salicylamide in 11 ml. of 20% hydrochloric acid was refluxed for 8 hr. The formed salicylic acid was removed, the filtrate refluxed an additional 8 hr. and salicylic acid again removed, total 1.01 g. After washing with ether, the filtrate was evaporated and the residue recrystallized from ethanol. There was obtained 1.25 g. (56%) of 2-(2-aminoethyl)-pyridine dihydrochloride, m.p. 182–188°.

Anal. Calcd. for $C_{17}H_{12}Cl_2N_2$: N, 14.4. Found: N, 14.3.

The dipicrate melted at 227–228° (ethanol) and when mixed with the dipicrate prepared from authentic 2-(2-aminoethyl)-pyridine,[7] m.p. 224–225°, showed no depression, mixed m.p. 225–226°.

2-(2-Aminoethyl)-pyridine (from Basic Hydrolysis of Pyridylethylated Oxazinedione).—A solution of 6.0 g. of II, R = H, Py = X (0.0223 mole) and 65 ml. of 8% sodium hydroxide was refluxed for 12 hr. Sodium hydroxide (30 g.) was added and the reaction mixture steam distilled.

Acidification of the pot residue with hydrochloric acid and addition of excess sodium bicarbonate yielded 2.92 g. (53.3%) of the product of incomplete hydrolysis, N-(2-[2-pyridyl]-ethyl)-salicylamide, m.p. 102–104°.

Acidification of the distillate with hydrochloric acid, evaporation to dryness and recrystallization from ethanol yielded 1.07 g. (24.5%) of 2-(2-aminoethyl)-pyridine dihydrochloride, m.p. 182–189°.

Acknowledgment.—The authors are indebted to Dr. G. Ungar and his staff for the physiological screening of the compounds and to Mr. J. Hinchen for his technical assistance.

Pyrolysis of 3-Nitroso-5,5-disubstituted-2-oxazolidones

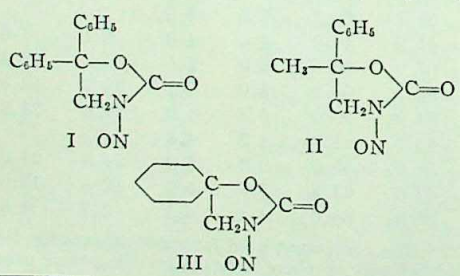
BY MELVIN S. NEWMAN AND ALAN E. WEINBERG[1]

RECEIVED DECEMBER 12, 1956

The pyrolyses of 3-nitroso-5,5-diphenyl-2-oxazolidone (I), 3-nitroso-5-methyl-5-phenyl-2-oxazolidone (II) and 3-nitroso-1-oxaazaspiro[4,5]decane-2-one (III) in the presence and absence of solvents is described.

Relatively little work has been reported on the pyrolysis of compounds containing the nitrosoamide group. Perhaps the earliest example is the pyrolysis of nitrosoacetanilide to yield biphenyl.[2] Recently, the pyrolysis of nitrosoamides has been used as an effective step in the series of reactions by which a primary aliphatic amine may be converted into the corresponding alcohol.[3] The mechanism of this reaction has been studied by Huisgen[4] and by White.[5]

We have been interested in the reactions which occur when nitrosoöxazolidones are treated with alkali.[6] Because of the thermal instability of certain of these nitrosoöxazolidones, we decided to study the pyrolysis of selected nitrosoöxazolidones. For this purpose we chose 3-nitroso-5,5-diphenyl-2-oxazolidone (I), 3-nitroso-5-methyl-5-phenyl-2-oxazolidone (II) and 3-nitroso-1-oxaazaspiro[4,5]decane-2-one (III), all of which had been prepared previously.[6b]



I II III

The pyrolysis of I in the absence of solvent yielded the parent oxazolidone, diphenylacetylene, 1,1-diphenylethylene and benzophenone in proportions which changed as the pyrolysis temperature was varied. The results are summarized in Table I.

TABLE I

PYROLYSIS OF 3-NITROSO-5,5-DIPHENYL-2-OXAZOLIDONE (I) AT VARIOUS TEMPERATURES

Yields[a] of	Temperature 120°	153°	168°	185°
Parent oxazolidone	57	51	40	18
$C_6H_5C{\equiv}CC_6H_5$[b,c]	16	20	23	32
$(C_6H_5)_2C{=}CH_2$[c,d]	15	21	26	40
$C_6H_5COC_6H_5$[e]	5	5	6	6
Residues[f]	7	3	5	4
Av. time of pyrolysis	13.5 hr.	2 hr.	2 hr.	40 min.

[a] % yield based on I originally decomposed. [b] Estimated as 2,4-dinitrophenylhydrazone of benzyl phenyl ketone after hydration of hydrocarbon fraction of products with sulfuric acid and mercuric sulfate. [c] Estimated by ultraviolet spectrophotometric analysis. [d] Estimated as 2,4-dinitrophenylhydrazone of benzophenone after ozonolysis. [e] Estimated as 2,4-dinitrophenylhydrazone. [f] The difference between products accounted for and 100% recovery was tarry residue.

Since the formation of parent oxazolidone in high yield in the absence of solvent and, hence, of any hydrogen donor other than the reacting molecule was surprising,[7] we also carried out the pyrolysis of I in eight solvents at the same tempera-

ture (153°). The results are summarized in Table II.

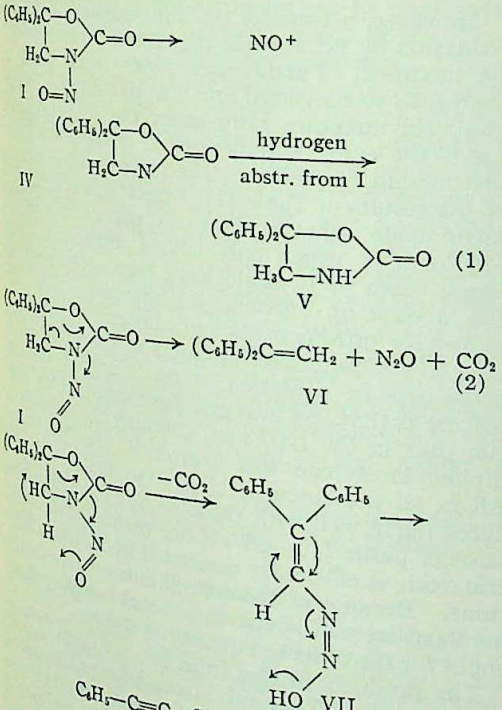
TABLE II

PYROLYSIS OF 3-NITROSO-5,5-DIPHENYL-2-OXAZOLIDONE (I) IN SOLVENTS AT 153°

Solvent	Products	Yield,[a] %
None, *t*-butylbenzene, Nitrobenzene, naphthalene, Methyl benzoate, Perchloropropylene, Bromobenzene	Oxazolidone	48–54
	$C_6H_5C{\equiv}CC_6H_5$	18–20[b,c]
	$(C_6H_5)_2C{=}CH_2$	21–22[c]
	$C_6H_5COC_6H_5$	5–6[d]
p-Xylene	Oxazolidone	80
	p-Toluic acid	18
Cumene	Oxazolidone	80
	$C_6H_5COCH_3$	22[d,e]
$(C_6H_5)_2C{=}CH_2$[f]	Oxazolidone	87
	$C_6H_5COC_6H_5$	10[d]

[a] Based on I originally decomposed. [b] Estimated as 2,4-dinitrophenylhydrazone of benzyl phenyl ketone after hydration of hydrocarbon fraction of products with sulfuric acid and mercuric sulfate. [c] Estimated by ultraviolet spectrophotometric analysis. [d] Estimated as 2,4-dinitrophenylhydrazone. [e] Average of five determinations. [f] This experiment was run at 185° for 40 minutes. No diphenylacetylene was found.

We believe that the results summarized in Table I may be explained by the following three decomposition paths.[8]



I IV V VI VII VIII

Decomposition by path 1 is favored (competitively) by a low temperature. The oxazolidyl free radical IV abstracts a hydrogen atom from some substrate to yield oxazolidone V. In the pyrolyses in the absence of added solvent the only sources of hydrogen atoms are starting compound I and the products VI and VIII, arising from decomposition by paths 2 and 3. From the results of pyrolyses in solvents (see Table II), it seemed unlikely that diphenylacetylene would act as a hydrogen-providing substrate and hence no separate run was made in diphenylacetylene as a solvent to check this point. However, diphenylethylene VI proved a ready source for hydrogen (see last experiment, Table II). Therefore, the amount of VI isolated in various runs undoubtedly is not a true measure of the amount of decomposition occurring *via* path 2 because some of the VI provides hydrogen to the free radical IV. The fate of the diphenylethylene which provides the hydrogen to the radical IV is unknown. However, since no diphenylacetylene VIII is formed in the pyrolysis of I in diphenylethylene VI it is obvious that VI cannot be the precursor of VIII.

Decomposition by path 2 involves a single concerted electron shift as shown. The same result might be pictured in other multistage ways, but the single process illustrated has the advantage of simplicity.

Decomposition by path 3 involves two concerted steps as shown. The same result might also be pictured in multistage processes, but the steps illustrated seem logical. Interestingly the hypothetical azo intermediate VII has a *cis* structure since the nitroso group in I undoubtedly is oriented as shown because of the dipole interactions of the carbonyl and nitroso groups.[9] As a general rule, *cis*-azo compounds are more labile than *trans*-azo compounds.[10]

As will be shown below, however, the results obtained from pyrolyses in cumene, *p*-xylene and 1,1-diphenylethylene, show that there is undoubtedly attack on the starting nitroso compound I by free radicals (either IV or nitric oxide) when the pyrolyses are carried out in the absence of these solvents (*e.g.*, alone or in the other solvents).

In all of the pyrolyses of I, alone and in most of the solvents used, there are formed small amounts of benzophenone and tar. The benzophenone undoubtedly arises mainly from oxidation of diphenylethylene by the nitric oxide formed in decomposition *via* path 1. This hypothesis is strengthened by the fact that the amount of benzophenone formed, although constant in many experiments (see Table II), was significantly increased when diphenylethylene was present in excess (last experiment, Table II). The oxidizing action of nitric oxide on organic substrates has been observed previously.[11] In a recent study of the oxidizing action of nitric oxide at 80° and 250 p.s.i. on cumene and other substrates, the phenyl ring was generally stable but alkyl substituents, particularly the iso-

(8) Decomposition by a path involving ring expansion to a seven-membered diazo carbonate structure was considered as a possibility. However, in view of the work of Huisgen and Reinertshofer[4] with nitrosopyrrolidone this mode of decomposition is estimated to occur to a very minor extent.

(9) The situation is analogous to that in the case of nitrosopyrrolidone, see ref. 4.

propyl groups, were attacked.[12] Before our knowledge of this work,[12] we had shown that the oxidation of cumene at 153° by nitric oxide at atmospheric pressure yielded acetophenone and small amounts of methanol and acetone.

The pyrolyses in solvents are interesting in that the products in the first six solvents noted in Table II are the same as those formed when the pyrolysis is performed in the absence of solvent. However, when a solvent which has a hydrogen particularly easily attacked by the free radical IV is used, markedly different results are obtained. For example, at 153° in the absence of solvent, or in the presence of the first six solvents mentioned, about 50% of oxazolidone V is formed, whereas in *p*-xylene and cumene 80% of V is formed. In diphenylethylene VIII at 185°, 87% of V is formed. Two explanations for these facts seem possible.

A. *p*-Xylene, cumene and 1,1-diphenylethylene assist decomposition by path 1 rather than hinder decompositions by paths 2 and 3. This explanation implies that the activation energy of decomposition by path 1 is lowered by a solvent which can lose a hydrogen atom easily, probably by incorporation of a suitably oriented solvent molecule in the transition state.

B. Decompositions by paths 2 and 3 do not occur as shown but rather by attack of a free radical produced by path 1 on unchanged starting material I. Thus, in solvents which are more easily attacked by the free radicals than I, the free radical IV formed by path 1 attacks solvents (rather than I) to form oxazolidone. However, if explanation B were correct, it is difficult to see how diphenylethylene could arise from attack of the free radical IV on I since both hydrogens in the heterocyclic ring are needed if diphenylethylene is to be the end product of reaction.

In the pyrolysis run in cymene, a careful search for 2,3-dimethyl-2,3-diphenylbutane was made, as this compound would result from dimerization of the radical formed from cymene. However, no trace of this dimer was found. Probably this radical is attacked readily by nitric oxide or actually is not formed in a free condition. The cumene may solvate the N–NO bond prior to rupture in such a way that $C_6H_5C(CH_3)_2NO$ and oxazolidone V are formed directly. Such a four-center reaction would account for the solvent effect above noted for cumene, *p*-xylene and diphenylethylene.

The behavior of the oxazolidyl free radical IV stands in marked contrast to the pyrrolidyl radical, formed on pyrolysis from nitrosopyrrolidone, which attacks the benzene ring to give N-substituted pyrrolidones.[4] We found no N-substituted oxazolidones in all of the experiments summarized in Table II.

The pyrolysis of I in α-methylstyrene was carried out at 100° for 24 hr. in order to see if polymerization would be enhanced by any of the radicals formed. However, less polymer was obtained than in the blank run for control. Probably the nitric oxide formed acted as an inhibitor.

In order to obtain a more nearly complete picture of the pyrolysis of I alone, gas analyses were run at 120 and 185° on the products. The results are listed in Table III. According to the three paths pictured the following results should be observed: A. The amount of nitric oxide should correspond to the yield of oxazolidone V. B. The amount of nitrous oxide should correspond to the yield of diphenylethylene VI. C. The amount of nitrogen should correspond to the yield of diphenylacetylene VIII. D. The amount of carbon dioxide should correspond to the sum of the yields of VI and VIII.

TABLE III

GASEOUS AND OTHER DECOMPOSITION PRODUCTS FROM PYROLYSIS OF 3-NITROSO-5,5-DIPHENYL-2-OXAZOLIDONE (I)

Product	Mole prod./mole I at 120°	Mole prod./mole I at 185°
H_2O	0.08	0.25
N_2	.40	.35
NO	.04	.05
N_2O	.31	.53
CO_2	.53	.87
Oxazolidone	.57	.18
$(C_6H_5)_2C{=}CH_2$	.15	.40
$C_6H_5C{\equiv}CC_6H_5$	.16	.30
$C_6H_5COC_6H_5$	.05	.06
Tar	.07	.04

However, because of the side reactions involving oxidation by nitric oxide the expected results must be modified. Furthermore, since nitric oxide is known to be converted into nitrous oxide and nitrogen[13] (in unknown ratio under the conditions we used) the expected amounts of nitrogenous gases are difficult to predict. The most striking feature of the results in Table III is the low percentage of nitric oxide found in the gases, particularly in the 120° run in which only 4% of nitric oxide was found when 57% would have been expected from the amount of oxazolidone I obtained. The high values for nitrous oxide and nitrogen are attributable to the reduction products of the nitric oxide consumed in oxidation steps. Another striking feature is that less nitrogen was formed in the 185° run than in the 120° run, although the amount of diphenylacetylene was greater in the 185° run. All in all the amounts of gaseous products found agree fairly well with those to be expected on the basis of paths 1, 2 and 3 if one realizes that the nitric oxide is efficiently consumed in oxidation reactions. Because of the several unknown quantities involved we will not go into detail in trying to account for the observed quantities of gases.

The products arising from the pyrolyses of 3-nitroso-5-methyl-5-phenyl-2-oxazolidone (II) and of 3-nitroso-1-oxaazaspiro[4,5]decane-2-one (III) are listed in Table IV. In the case of II, more tar was formed than during comparable pyrolyses of I, whereas when III was pyrolyzed the only substance that could be identified was the parent oxazolidone.

The formation of parent oxazolidone, α-methylstyrene, acetophenone and methylphenylacetylene from pyrolysis of II may be explained by the decomposition paths 1, 2 and 3 previously discussed.

[a] Average time, 2 hr. [b] Average time, 35 min. [c] Isolated as crystalline solid. [d] Estimated as 2,4-DNPH derivative. [e] Estimated as 2,4-DNPH of propiophenone. [f] Estimated as 2,4-DNPH of acetophenone after ozonization. [g] Estimated as 2,4-dinitrophenylosazone of 1-phenyl-1,2-propanedione. [h] Estimated as 2,4-DNPH derivative.

However, the formation of phenylallene is difficult to explain. Actually phenylallene was not isolated as such. Its presence was deduced from the fact that the 2,4-dinitrophenylosazone of 1-phenyl-1,2-propanedione was obtained from the hydrocarbon fraction remaining after removal of acetophenone as its 2,4-dinitrophenylhydrazone by treatment with sulfuric acid and mercuric sulfate in the presence of excess 2,4-dinitrophenylhydrazine. Other possible precursors of the osazone were examined but were ruled out as follows: 2-phenyl-1,2-propanediol yielded 2-phenylpropanal[14]; propiophenone gave too small a yield of osazone to account for the amount obtained and furthermore would have been removed by the treatment with 2,4-dinitrophenylhydrazine prior to the mercuric sulfate catalyzed reaction; 1-phenyl-2-propanone afforded a good yield of 1-phenyl-1,2-propanedione on treatment with mercuric sulfate and sulfuric acid but would have been removed along with acetophenone in the original treatment with 2,4-dinitrophenylhydrazine; and methylphenylacetylene gave too small a yield of diketone on treatment with mercuric sulfate and sulfuric acid to account for the amount of osazone formed.

The phenylallene formed is probably the result of a free radical attack on II prior to its thermal decomposition by path 1.

Experimental

General Procedures.—All melting points up to 200° are corrected. The petroleum ethers used were Skellysolve F (b.p. 30–60°) and Skellysolve B (b.p. 55–70°). For chromatographic procedures, silicic acid (Mallinckrodt chromatographic grade) and alumina (Fisher chromatographic grade) were used after previous heating to 200° for 12 hr. The analysis was run by Galbraith Microanalytical Laboratories, Knoxville, Tenn.

Freshly prepared 2,4-dinitrophenylhydrazine solution[15] (DNPH) was used to analyze for aldehydes and ketones. A small excess of this reagent was refluxed for a few minutes with an ethanolic solution of the carbonyl compound and the mixture cooled for at least 4 hr. The precipitate was chromatographed on a short column packed with alumina and developed with benzene.

All solid compounds were compared to an authentic sample by mixed melting point and by infrared spectra of the Nujol mulls. Unless otherwise stated, all percentage yields are based on the nitroso compound used.

Pyrolysis of 3-Nitroso-5,5-diphenyl-2-oxazolidone (I) in the Absence of a Solvent at 185°.—In a dried flask connected to a gas collecting device, 10.33 g. of I was decomposed at 185°, this temperature being maintained with a salt-bath or by the immersion of the reaction flask in refluxing *p*-bromotoluene. The decomposition was active but never violent. Gas evolution ceased after 40 minutes; the dry gas collected (1559 ml., S.T.P.) represented 1.80 moles per mole of I. A sample of this gas when shaken with ammoniacal silver hydroxide gave no metallic silver,[16] denoting the absence of carbon monoxide.

After cooling, 12 ml. of Skellysolve F and 2.5 ml. of ethanol were added. The solid obtained was recrystallized from ethanol to yield 0.89 g. of 5,5-diphenyl-2-oxazolidone (V), m.p. 199–201° (reported[6b] m.p. 199.6–200.4°). The filtrate was evaporated to give 6.38 g. of a yellow oil, A. To 0.52 g. of A was added excess DNPH reagent. There was obtained 0.069 g. (6.1%) of the 2,4-dinitrophenylhydrazone of benzophenone, m.p. 238–239°.[17] The filtrate when refluxed for 1 hr. with 2 g. of mercuric sulfate and 5 ml. of sulfuric acid and cooled, afforded 0.331 g. (28.1%) of desoxybenzoin 2,4-dinitrophenylhydrazone,[18] m.p. 202–203°. Analogously, pure diphenylacetylene was converted to the same derivative in 85% yield.

A solution of 5.38 g. of oil A in 3 ml. of chloroform and 3 ml. of Skellysolve B was chromatographed on a 5.6 × 19 cm. column packed with silicic acid and developed with 5% ether in Skellysolve B. The first fraction eluted, oil B (4.66 g.), was shown by infrared spectrum to be a mixture of hydrocarbons and benzophenone. The second fraction, 0.64 g., was found to be V; when this was combined with the oxazolidone V obtained from the original reaction mixture, the total yield was 1.65 g. (17.9%). The third fraction (0.06 g.) was a black tar. Oil B was rechromatographed to yield 4.30 g. of a colorless oil C, whose infrared spectrum showed it to be solely hydrocarbon, and 0.35 g. of a pale yellow oil D, whose infrared spectrum was identical with that of an authentic sample of benzophenone. From D was obtained 0.69 g. (5.9%) of benzophenone 2,4-dinitrophenylhydrazone, m.p. 238–239°.

Oil C was treated in four ways: (a) No derivatives were obtained when 0.482 g. of C was treated with excess DNPH; however, when this solution was refluxed with 2 g. of mercuric sulfate and 5 ml. of sulfuric acid and cooled, 0.377 g. (27.5%) of desoxybenzoin 2,4-dinitrophenylhydrazone, m.p. 202–203°, was obtained. (b) During the early stages of

the ozonolysis[19a,b] of 0.632 g. of oil C, 0.0216 g. of formaldehyde 2,4-dinitrophenylhydrazone, m.p. 164–165° (reported[20] m.p. 166°), was obtained by passing the exit gases through DNPH reagent. When the ozonized material was treated with zinc and acetic acid and worked up in the usual manner, benzophenone and 0.107 g. of benzoic acid, m.p. 120–121° (reported[21] m.p. 121.4°), were obtained. The benzophenone was converted to 0.547 g. of its 2,4-dinitrophenylhydrazone, m.p. 239–240°. This showed that at least 43% of the hydrocarbon mixture was unsymmetrically substituted. (c) Treatment of 0.263 g. of oil C with excess 2,4-dinitrobenzenesulfenyl chloride yielded 0.179 g., 15% based on I, of 1,1-diphenyl-2-(2,4-dinitrobenzenesulfenyl)-ethylene, m.p. 135.5–136.5° (reported[22] m.p. 135.5–136.5°). No acetylenic derivative was obtained.[23] (d) Oil C was submitted to multicomponent ultraviolet spectrophotometric analysis similar to that used by Tunnicliff, *et al.*[24] Pure samples of diphenylacetylene[25] ($c = 7.00 \times 10^{-4}$ g./100 ml. ethanol, 250 mμ, $E^{1\%}_{1cm.}$ 634; 270 mμ, $E^{1\%}_{1cm.}$ 1225) and 1,1-diphenylethylene[26] ($c = 7.00 \times 10^{-4}$ g./100 ml. ethanol, 250 mμ, $E^{1\%}_{1cm.}$ 808; 270 mμ, $E^{1\%}_{1cm.}$ 336) were used as reference compounds. The equations were

$$\text{absorbance}_{250m\mu} = 634X + 808Y$$
$$\text{absorbance}_{270m\mu} = 1225X + 336Y$$

where

X = concn. of diphenylacetylene
Y = concn. of 1,1-diphenylethylene
$A_{250m\mu} = 0.766$
$A_{270m\mu} = 0.765$

The solution of these equations showed that 2.23 g. (32.4%) of diphenylacetylene and 2.81 g. (40.3%) of 1,1-diphenylethylene were obtained from nitroso compound I.

Pyrolysis of I in Absence of Solvent at 120, 153 and 168°.—Decomposition and recovery of the decomposition products were described above. The temperature was maintained at 120° by immersing the reaction flask in refluxing 2-pentanol. This decomposition required 13.5 hr. Refluxing cumene was used at 153° and refluxing *t*-butylbenzene was used at 168°. Decomposition at these temperatures required 2 hr. The results are listed in Table I.

Pyrolysis of 3-Nitroso-5,5-diphenyl-2-oxazolidone (I) in Cumene. (A) **In Air.**—In a 250-ml. flask connected through a condenser to a cold trap were placed 4.08 g. of I and 52.0 g. of peroxide-free cumene. After 2 hr. at 153°, the mixture was cooled. Filtration yielded 2.69 g. (74.1%) of 5,5-diphenyl-2-oxazolidone (V) and 59 ml. of solution E.

A portion of E (44 ml.) was carefully fractionated to remove solvent to give oil F. A small forerun (0.68 g.) was found to contain methanol and acetone. The methanol was characterized as methyl 3,5-dinitrobenzoate (1.3%), m.p. 107.7–108.2° (reported[27] m.p. 108°). Oil F was chromatographed to yield four fractions: (1) cumene, (2) acetophenone, (3) V (0.129 g., 4.4%) and (4) 0.353 g. of tar.

When 5 ml. of solution E was treated with DNPH reagent, the resulting derivatives (0.169 g.) melted over a range, 227–249°. The solids were separated by chromatography on silicic acid using 10% ether in Skellysolve B as the developer. Two 2,4-dinitrophenylhydrazones were obtained, the acetophenone derivative (0.165 g., 42.7%), m.p. 249–250° (reported[28] m.p. 249–250°), and the acetone derivative (0.0033 g., 1.1%), m.p. 127.9–128.6° (reported[29] m.p. 128°). When a similar decomposition of nitroso compound I was run in the presence of 2,3-dimethyl-2,3-diphenylbutane (the cumene dimer), 91% of the dimer was recovered in addition to the other products of the decomposition.

(B) **In the Absence of Air.**—The experiment was repeated in a nitrogen atmosphere. Oxygen-free, water-free nitrogen was prepared from oil-pumped nitrogen using a Fieser type[30] absorption train modified by using cumene instead of xylene as the solvent for the metal ketyl. Nitrogen was pumped into the system for 4 hr. before the decomposition was begun. The products were isolated as described above: V (79%), acetophenone (30%), acetone (1%) and methanol (1%).

Pyrolysis of I in the Presence of α-Methylstyrene.—The polymerization of 50 ml. of freshly distilled α-methylstyrene was inhibited at 100° when 0.692 g. of I was added. The pyrolysis products were recovered as previously described: V, 84%; acetophenone, 42%; and 2.86 g. of polymer. The blank yielded 7.70 g. of polymer. The infrared spectra of the two polymers were identical.

Pyrolysis of I in the Presence of 1,1-Diphenylethylene.—The pyrolysis products obtained at 185° from 2.78 g. of I and 5.42 g. of 1,1-diphenylethylene were worked up as previously described. The products were 1.72 g. (87%) of V, 10.1% of benzophenone and unreacted 1,1-diphenylethylene. No diphenylacetylene was found.

Stability of 5,5-Diphenyl-2-oxazolidone (V) to Heat.—When 7.47 g. of V was heated in a salt-bath at 220–225° for 26 hr., 7.37 g. of V was recovered unchanged.

Gas Analyses of Decomposition Products from the Pyrolysis of I.[31]—A General Electrical analytical mass spectrometer was used for the analyses which employed the pressure sensitivity technique.[32] The sampling device was an all-glass system employing a 50-ml. decomposition bulb, a 50-ml. gas sample bulb adapted for direct attachment to the mass spectrometer. The decompositions were run under a low helium pressure (1 mm.) since helium is inert and has a mass number low enough not to interfere with the analysis. Carbon dioxide was the only carbon containing gas present since carbon monoxide was previously shown to be absent. The pressure sensitivities of pure gas samples and distilled water were run. It was found necessary to use an Ascarite[33] tube in order to separate carbon dioxide from nitrous oxide since the two gases had the same mass numbers (44). It was shown experimentally that this treatment had no effect on any of the gases except carbon dioxide and water, both of which were removed.

Decompositions of nitroso compound I were carried out at both 120 and 185°. Duplicate samples showed a 3% variation. The average results are found in Table III.

Pyrolysis of 3-Nitroso-5-methyl-5-phenyl-2-oxazolidone (II).—In a dried flask connected to a gas collecting device, 22.10 g. of III was decomposed at 185° in the manner previously described. The decomposition was vigorous but never violent. Gas evolution ceased after 40 minutes; the dry gas collected (2615 ml. S.T.P) represented 1.09 moles per mole of II. As in the case of the pyrolysis of I, no carbon monoxide was detected.

After cooling, the brown, mushy solid was mixed with four portions of Skellysolve F and filtered. The filtrate was concentrated to give 6.67 g. of oil G. Recrystallization of the 8.75 g. of solid from 15 ml. of toluene yielded 7.16 g. (37.7%) of 5-methyl-5-phenyl-2-oxazolidone (IX), m.p. 146–147° (reported[6b] m.p. 146.2–147.2°). The filtrate was chromatographed on alumina and developed with benzene to yield 0.11 g. (0.6%) of additional IX and 1.49 g. of tar.

When 0.46 g. of oil G was treated with DNPH reagent and the derivative worked up, 0.180 g. (8.1%) of the acetophenone derivative, m.p. 248–249°, was obtained. This filtrate was refluxed with 2 g. of mercuric sulfate and 5 ml. of sulfuric acid and then cooled. Workup as usual yielded two derivatives: 0.171 g. (7.4%) of propiophenone 2,4-dinitrophenylhydrazone, m.p. 190–191° (reported[34] m.p.

Digitized by Arya Samaj Foundation Chennai and eGangotri

190–191°), and 0.282 g. (7.5%) of 1-phenylpropane-1,2-dione 2,4-dinitrophenylosazone,[35] m.p. 263–264°.

Anal. Calcd. for $C_{21}H_{16}N_8O_8$: C, 49.6; H, 3.2; N, 22.0 Found: C, 49.4; H, 3.1; N, 21.9.

Propiophenone, when treated with mercuric sulfate and sulfuric acid in the presence of excess DNPH reagent, yielded 81% of the normal derivative and 12% of the osazone. After similar treatment, 1-phenyl-2-propanone yielded 89% of the osazone and none of the normal derivative, while 1-phenylpropyne yielded 74% of propiophenone 2,4-dinitrophenylhydrazone and 11% of the osazone.

When 1.54 g. of oil G was chromatographed on silicic acid and developed with Skellysolve B, four fractions were obtained: the first fraction, H (0.521 g.), was shown by infrared spectrum to be solely hydrocarbon. The second fraction was treated with DNPH reagent to yield 0.579 g. (7.8%) of the acetophenone derivative, m.p. 248–249°. The third fraction was 0.525 g. (12.8%) of additional IX. The fourth fraction was 0.211 g. of tar.

When 0.403 g. of H was ozonized[19a,b] and worked up as previously described, 0.606 g. (10.5%) of the acetophenone 2,4-dinitrophenylhydrazone, m.p. 248–249°, was obtained. When a portion of H was treated with DNPH reagent before ozonolysis, no carbonyl derivative was obtained.

Pyrolysis of 3-Nitroso-1-oxa-3-azaspiro[4.5]decan-2-one (III).—In a dried flask connected to a gas collecting device, 8.20 g. of III was decomposed at 185° in the manner previously described. The decomposition was moderate initially but became violent as the reaction proceeded. Gas evolution ceased after 40 minutes: the dry gas collected (963 ml., S.T.P.) represented 0.965 mole per mole of III. As in the case of the pyrolysis of I, no carbon monoxide was detected.

After cooling, the brown-black, tarry mass was made up to 10 ml. with chloroform to give solution J. When 5 ml. of J was treated with excess DNPH reagent, no derivative was obtained. When 5 ml. of J was chromatographed on a column packed with alumina and developed with 10% ether in Skellysolve B, two fractions were obtained. One fraction, a tar, remained on the column. The other fraction, concentrated and cooled, yielded 1.96 g. (56.8%) of 1-oxa-3-azaspiro[4.5]decan-2-one (X), m.p. 101–102° (reported[6a] m.p. 101.0–102.4°).

Pyrolyses of Nitroso Compounds I, II and III in the Presence of Solvents.—A typical reaction is described: a 25 × 200 mm. test-tube, which contained the nitroso compound (3.5–5.0 g.) and redistilled solvent (15–25 g.), was provided with an air condenser and maintained at 153 or 168° for 2 hr. or at 185° for 40 minutes.

Recovery of Decomposition Products. A. Nitroso Compound I.—After cooling, solid oxazolidone V was removed by filtration and the solvent carefully removed by distillation to yield an oil. Benzophenone was determined as the 2,4-dinitrophenylhydrazone and diphenylacetylene as desoxybenzoin 2,4-dinitrophenylhydrazone. When the solvent was adsorbed strongly enough on alumina so that the diphenylacetylene-1,1-diphenylethylene mixture could be selectively removed, multicomponent ultraviolet spectrophotometric analysis was used. The results are listed in Table II.

B. Nitroso Compounds II and III.—The recovery of the decomposition products was carried out as was previously described for II and III at 185°. In some cases in the decomposition of nitroso compound III, treatment of an aliquot of the reaction mixture with DNPH reagent yielded the cyclohexanone derivative, m.p. 161–162° (reported[36] m.p. 162°).

(35) 1-Phenylpropane-1,2-dione was prepared according to J. Wegmann and H. Dann, *Helv. Chim. Acta*, **29**, 1248 (1946).

The Reaction of Substituted Indoles with Methyl Vinyl Ketone. New Synthesis of 2-Methylcarbazole

BY J. SZMUSZKOVICZ

RECEIVED JANUARY 21, 1957

The reactions of indole, 2-methylindole and skatole with methyl vinyl ketone were investigated and the products characterized.

There are a number of examples in the literature which illustrate the behavior of the indole nucleus toward electrophilic components in the Michael-type reaction.

In the case of C_3-unsubstituted indoles, *under acidic conditions*, the negatively polarized C_3 undergoes reaction, *e.g.*, with acetamidoacrylic acid in acetic acid solution containing acetic anhydride,[1] with nitroethylene in benzene solution,[2] with propiolactone in the absence of solvent,[3] with diketene in the absence of solvent[4] and with acrylonitrile in acetic acid solution in the presence of copper borate.[5]

On the other hand, *the base-catalyzed* Michael-type reaction occurs at the 1-position. Thus, in a benzene solution containing potassium hydroxide, indole and acrylonitrile react to give 1-(β-cyano)-ethylindole,[6] 2-phenylindole reacts with acrylonitrile in the presence of trimethylbenzylammonium hydroxide to give 1-(β-cyano)-ethyl-2-phenylindole,[7] indole and methacrylonitrile in ethanolic sodium ethoxide solution gives rise to 1-(β-cyano-β-methyl)-ethylindole,[8] ethyl α-(3-indolyl)-isobutyrate afforded 1-(β-carboxypropyl)-3-indoleisobutyric acid on reaction with methacrylonitrile in ethanolic sodium methoxide and subsequent hydrolysis,[8] 2,3-dimethylindole reacts with acrylonitrile and sodium methoxide to give 1-(β-cyano)-ethyl-2,3-dimethylindole[9]; in some cases 1,3-dicyanoethylindoles are obtained as by-products

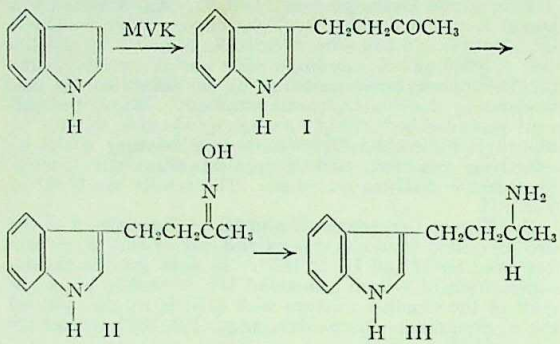
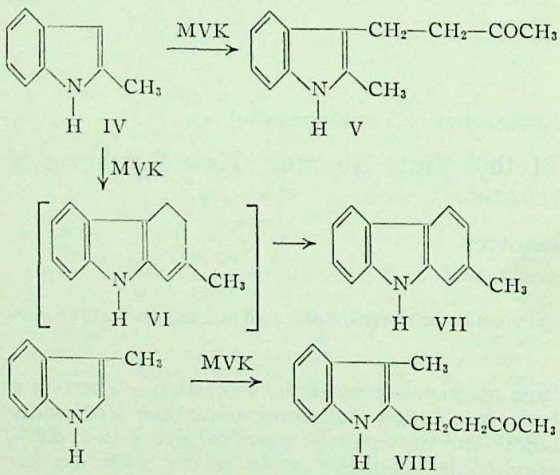
from the reaction of 2-substituted indoles with acrylonitrile.[10,11]

It has now been found that indole reacts with methyl vinyl ketone (MVK) in acetic acid medium with or without anhydride to give 75 and 69% yield, respectively, of 1-(3′-indolyl)-butanone-3 (I). The reaction also proceeds in the absence of solvent to give I in 22% yield.

Compound I was converted in a quantitative yield to a mixture of isomeric oximes (II) which was reduced with lithium aluminum hydride to 3-(3′-indolyl)-1-methylpropylamine (III), characterized as the creatinine sulfate complex.



Holland and Nayler[12] prepared I by treatment of gramine methosulfate with ethyl sodioacetoacetate in ethanol, the product subsequently being hydrolyzed with sodium hydroxide.



2-Methylindole (IV) reacted with MVK at 160° (5 hr. reaction time) in the absence of solvent to give a 28.6% yield of 1-[3′-(2′-methyl)-indolyl)]-butanone-3 (V). In acetic acid solution containing acetic anhydride the yield advanced to 84%. When hydroquinone was added to the two reactants and the temperature raised to 280°, 2-methylcarbazole (VII)[13] was isolated in 10% yield.[14] The reaction probably proceeded through an intermediate (VI) which was not isolated.

Skatole did not react with MVK in the absence of solvent even on prolonged heating (19 hr.). On the other hand, in acetic acid solution containing *acetic anhydride*[15,16] a moderate yield of 1-[2′-(3′-methyl)-indolyl]-butanone-3 (VIII) was obtained. When the reaction was conducted in acetic acid alone, the product VIII could not be isolated.

Experimental[17,18]

Preparation of 1-(3′-Indolyl)-butanone-3 (I).—Indole (2.34 g., 0.02 mole) was dissolved in glacial acetic acid (12 ml.), 4 ml. of acetic anhydride was added, then 4.2 g. (0.06 mole) of commercial methyl vinyl ketone. The solution was allowed to stand at room temperature for 5 minutes and then heated on the steam-bath (condenser, Drierite tube) for 25 minutes. The initial yellow solution turned dark brown. It was cooled in ice, 100 ml. of water was added and, after standing for a few minutes, the precipitate was filtered and washed with water. The crude product was recrystallized from benzene–petroleum ether (30–60°) as pale yellow needles, m.p. 93–94°, yield 2.8 g. (75%).

Anal. Calcd. for $C_{12}H_{13}NO$: C, 76.97; H, 7.00; N, 7.48. Found: C, 77.25; H, 7.13; N, 7.43.

Infrared spectrum: NH (3305 cm.$^{-1}$), C=O (1699), C=C (1621, 1572, 1555, 1492), *o*-disubstituted benzene (734, 725). **Ultraviolet spectrum:** λ_{max} 223 mμ (36,675), 275 (5,475), 283 (5,900), 291.5 (5,050).

When acetic anhydride was omitted[15] from the above procedure, the product I was obtained in 69.6% yield (m.p. 93–94°).

Preparation of the Oxime II.—One gram of I was dissolved in 10 ml. of 95% ethanol by warming. A solution of 2 g. of hydroxylamine hydrochloride and 3 g. of anhydrous sodium acetate in 10 ml. of water was added and the resulting solution refluxed for 15 minutes. It was then allowed to stand at room temperature for 45 hr., diluted with water and induced to crystallize by scratching. After cooling in ice for 1 hr., the crystals were filtered and washed with water; m.p. 89–115° (97% yield). Recrystallization from benzene–petroleum ether (30–60°) gave clusters, m.p. 89–111°.

Anal. Calcd. for $C_{12}H_{14}N_2O$: C, 71.26; H, 6.98; N, 13.85. Found: C, 71.34; H, 7.14; N, 13.58.

Lithium Aluminum Hydride Reduction of the Oxime II. Synthesis of III.—A solution of II (0.9 g.) in 10 ml. of anhydrous ether was added dropwise with ice-cooling and swirling to a solution of 1.2 g. of lithium aluminum hydride in 70 ml. of ether. The resulting mixture was refluxed for 2 hr. and then allowed to stand overnight at room tempera-

(11) The more drastic conditions used in these base-catalyzed Michael-type reactions suggest that thermodynamic control of products applies and that the 1-substituted product is the more thermodynamically stable isomer under the conditions of its formation. The milder acid conditions might favor kinetic control of products which result in 3-substitution. A test of this idea would involve submitting the adduct to the conditions under which the 1-adduct is prepared to see if 3-adduct yields 1-adduct [see also I. M. Bassett, R. D. Brown and A. Penfold in *Chemistry & Industry*, 892 (1956)].

(12) D. O. Holland and J. C. Nayler, J. Chem. Soc., 1461 (1955).

(13) For a review of carbazole syntheses see R. C. Elderfield, "Heterocyclic Compounds," Vol. III, John Wiley and Sons, Inc., New York, N. Y., 1952, p. 296.

(14) This yield very likely could be improved on further experimentation.

(15) It is interesting that acetic anhydride seems to be essential for the reaction of skatole with MVK, especially in view of a similar observation of Snyder and MacDonald[1] in the case of indole and α-acetamidoacrylic acid.

(16) The crude product showed a weak band in the infrared at 1747 cm.$^{-1}$ and a strong band at 1662 cm.$^{-1}$. The 1747 cm.$^{-1}$ band could be eliminated by mild alkaline treatment (see Experimental). The 1662 cm.$^{-1}$ band persisted after this alkaline treatment and may be due to either the N-acetyl compound being present or, less likely, to the amidic character of the carbonyl imposed by interaction with the indolic nitrogen.

(17) All melting points are uncorrected. Ultraviolet spectra were determined in 95% ethanol using Cary spectrophotometers, models 11 and 14. Infrared spectra were determined in Nujol (except when otherwise specified) using a Perkin–Elmer recording infrared spectrophotometer, model 21.

(18) The author is indebted to Prof. D. J. Cram for an interesting discussion, to Dr. J. L. Johnson and his staff for spectral data, to Mr. W. A. Struck and his associates for microanalyses, and to Mr. L. G. [illegible] for faithful assistance.

ture. Water was added, cautiously at first, then excess of 10% potassium hydroxide solution, and the mixture was extracted four times with ether. The ethereal extracts were washed once with water and then extracted three times with 10% hydrochloric acid. The acidic solution was reëxtracted with ether and then basified with excess potassium hydroxide. The resulting oily mixture was extracted three times with ether, washed twice with saturated salt solution, dried over sodium sulfate and evaporated to give 0.8 g. (95% yield) of pale yellow oil which could not be crystallized.

The amine (0.253 g.) was dissolved in 1.45 ml. of 1 *N* sulfuric acid and 4 cc. of water by gentle warming, the solution was filtered and 0.210 g. of creatinine sulfate was added. The solution was warmed to *ca.* 60° and 45 ml. of acetone was added. After 2 hr., the crystalline precipitate was filtered and washed with acetone–water (6:1); yield 0.436 g. (80%), m.p. 150–153°. The complex was recrystallized by dissolving in 4 ml. of warm water and adding 50 ml. of acetone. The needles were filtered, washed with cold acetone–water solution (4:1), then acetone and finally ether; m.p. 153–156° (completely clear at 160°).

Anal. Calcd. for $C_{16}H_{25}N_5O_5S + 1.5H_2O$: C, 45.06; H, 6.77; N, 16.42; S, 7.52. Found: C, 44.90; H, 6.73; N, 16.16; S, 8.26.

Synthesis of 2-Methylcarbazole (VII).—A mixture of 2-methylindole (6.6 g., 0.05 mole), MVK (4.2 g., 0.06 mole) and 0.3 g. of hydroquinone was heated for 1.5 hr. (outside bath temperature 155–160°). The temperature was then raised to 280–290° and maintained for 20.5 hr. The resulting reaction mixture crystallized within 1 hr. on standing at room temperature. On treatment with 20 ml. of benzene a slightly oily material was obtained which was recrystallized from the same volume of benzene to give 0.6 g. of plates melting at 261.5–262.5°.[19]

Anal. Calcd. for $C_{13}H_{11}N$: C, 86.15; H, 6.12; N, 7.73. Found: C, 86.33; H, 6.20; N, 7.66.

Infrared spectrum: NH (3400), C=C (1627, 1608, 1486), *o*-disubstituted and trisubstituted benzene (806, 763, 744, 725). **Ultraviolet spectrum**: flex. 230 mμ, λ_{max} 235.5 (48,270), flex. 246, λ_{max} 259.5 (19,225), flex. 286, λ_{max} 297.5 (17,200), 323 (3,900), 335 (2,900).

The second crop amounted to 0.140 g. (m.p. 261–262°). The combined filtrates and washings were evaporated to dryness and the residual dark oil was distilled from an oil-jacketed flask at 0.1 mm. The first fraction, b.p. 120–160° (3.46 g.), was discarded. The second fraction, b.p. 180–270° (3.26 g.), solidified overnight and was crystallized from 5 ml. of benzene and 9 ml. of petroleum ether (30–60°) with seeding to give a third crop of VII (0.2 g., m.p. 252–255°). The fourth crop amounted to 14 mg. (m.p. 237–242°). The total yield of VII was 10.5% (0.954 g.). The picrate was formed in ethanol as orange-red needles, m.p. 168° (lit.[19] m.p. 168°).

Synthesis of 1-[3′-(2′-Methyl)-indolyl]-butanone-3 (V).—A mixture of 2-methylindole (13.1 g., 0.1 mole) and MVK (8.4 g., 0.12 mole) was heated under nitrogen at 155–162° for 5 hr. The resulting oil was allowed to stand overnight at room temperature. It was then distilled from an oil-jacketed flask at 0.05 mm. to give: (1) 5.97 g. of unchanged 2-methylindole, b.p. 120–160° (mainly 135–140°); (2) 10.82 g. of viscous yellow oil, b.p. 160–190°.

Fraction 2 was redistilled carefully at 0.05 mm. and material boiling at 180–190° was collected; 5.76 g. (28.6% yield), $n^{27.5}$D 1.5833. The analytical sample showed b.p. 185°, $n^{27.5}$D 1.5835.

Anal. Calcd. for $C_{13}H_{15}NO$: C, 77.58; H, 7.51; N, 6.96. Found: C, 77.74; H, 7.59; N, 6.70.

Infrared spectrum: NH (3340), C=O (1698), C=C (1617, 1582, 1565, 1487), *o*-disubstituted benzene (740). Quantitative infrared comparison with I in the NH region indicated the presence of 92.9% of NH absorption.

The trinitrofluorenone derivative was formed in acetic acid–ethanol as black plates, m.p. 139–142°.

Anal. Calcd. for $C_{26}H_{40}N_4O_8$: C, 60.46; H, 3.90; N, 10.85. Found: C, 60.11; H, 3.98; N, 10.87.

When the reaction was run in acetic acid containing acetic anhydride (as described above) and the product extracted with ether, washed and distilled, an 84.6% yield of a yellow oil was obtained, b.p. 170–195° (0.05 mm.).

Infrared spectrum: NH (3400), C=O (1710), extraneous band at 1676 (probably due to N-acetyl impurity), C=C (1636, 1607, 1593, 1571, 1561, 1536, 1480), *o*-disubstituted benzene (746).

Synthesis of 1-[2′-(3-Methyl)-indolyl]-butanone-3 (VIII).—A solution of skatole (10 g., 0.0765 mole), MVK (16.2 g., 0.232 mole), 46 ml. of acetic acid and 15.5 ml. of acetic anhydride was heated on the steam-bath for 25 minutes. The resulting dark green solution was cooled to room temperature, 400 ml. of water was added and the heating continued on the steam-bath for 2 hr. The cooled mixture was extracted with ether (4 × 150 ml.). The ethereal extracts were washed once with water, twice with saturated salt solution and dried over sodium sulfate. The product (brown oil, 12.52 g.) was distilled from an oil-jacketed flask to give: (1) 4.12 g. of recovered skatole, b.p. 120–135° (0.1 mm.); and (2) 4.72 g. of an oil boiling at 170–210° (0.1 mm.). Redistillation of fraction 2 afforded 2.76 g. of material which was collected at 170–190° (0.05 mm.), n^{25}D 1.5835.

Infrared spectrum: NH (3380), weak band at 1747, C=O (1702), strong band at 1662, C=C (1600, 1537, 1477), *o*-disubstituted benzene (757).

The product (0.641 g.) was dissolved in 10 ml. of methanol, a solution of 1.0 g. of potassium hydroxide in 10 ml. of water was added and the solution heated on the steam-bath for 5 minutes. It was then cooled and extracted with ether (4 × 30 ml.). The ethereal extracts were washed twice with saturated salt solution, dried over sodium sulfate and evaporated. The resulting oil (0.4868 g.) was distilled from an oil-jacketed flask; b.p. 170–175° (0.05 mm.), 0.3296 g.

Anal. Calcd. for $C_{13}H_{15}NO$: C, 77.58; H, 7.51; N, 6.96. Found: C, 76.81; H, 7.49; N, 5.98.

Infrared spectrum: essentially the same as above, but the band at 1747 no longer was present.

Apparently this product represents a mixture of the desired material VIII and the corresponding N-acetyl derivative. Quantitative infrared comparison with I in the NH region indicated 21.5% NH absorption.

The Mechanisms of Permanganate Oxidation. IV. Hydroxylation of Olefins and Related Reactions

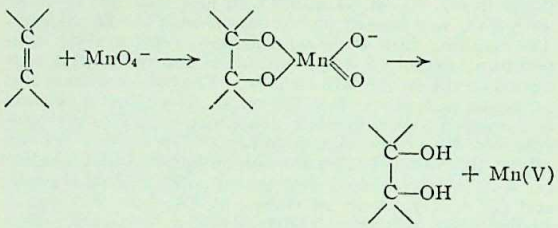
BY KENNETH B. WIBERG AND KLAUS A. SAEGEBARTH

RECEIVED OCTOBER 27, 1956

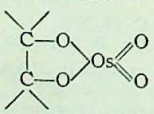
The oxygen introduced into oleic acid in its conversion to 9,10-dihydroxystearic acid by permanganate has been found to arise from the oxidizing agent. The reaction of bicyclo[2.2.1]-2-heptene with permanganate in neutral solution led to a new type of reaction, cleavage to a dialdehyde. The mechanisms for the formation of the diol, ketol and dialdehyde from a common intermediate are discussed.

Introduction

The hydroxylation of olefins by potassium permanganate has been known for many years and has proved a useful method for this conversion. Wagner, who did much of the early work on this reaction, proposed that it involved the formation of a cyclic ester between the permanganate ion and the olefin.[1] Decomposition of the intermediate with cleavage of the manganese–oxygen bonds would lead to the formation of the glycol.



This hypothesis received strong support from the careful stereochemical investigations of Böeseken and his co-workers[2] who determined that the reaction invariably gave the glycol formed by *cis*-addition of the hydroxyl groups. The formation of a cyclic ester intermediate has been well accepted, particularly since osmium tetroxide, which also gives *cis*-hydroxylation, has been shown by Criegee[3] to give an isolable intermediate which almost certainly has the structure



The most important evidence which now could be obtained would be a demonstration that the oxygens introduced into the olefin did arise from the permanganate. Since an excellent method for analyzing for O^{18} in organic molecules is now available,[4] we have studied the oxidation of an olefin with O^{18}-labeled permanganate. The olefin chosen was oleic acid since it gives an excellent yield of the diol and since the product is easily isolated.[5]

It was also of interest to study the effect of reaction conditions on the oxidation of other olefins, since whereas oleic acid gives quantitatively 9,10-dihydroxystearic acid in alkaline solution, the main product in a neutral solution is a mixture of 9,10- and 10,9-ketohydroxystearic acids.[6]

Results and Discussion

In studying the oxygen transfer from permanganate to oleic acid, it is desirable to effect the reaction under conditions which will minimize oxidation of the double bond by manganate, since it is known that manganate will exchange oxygens with water whereas permanganate will not,[7] and since the rate of oxidation by manganate is considerably lower than that for permanganate. Thus, if a large part of the oxidation were effected by manganate, the extent of oxygen transfer would be quite low Even with a large excess of permanganate, incomplete oxygen transfer would be expected since it is known that the rate of electron transfer between manganate and permanganate is very rapid,[8] permitting some exchange of O^{18} with the solvent to occur as the reaction proceeds.

The oxidation of oleic acid was effected at about *p*H 12 using the conditions of Lapworth and Mottram[5] (1.45 $KMnO_4$:1 oleic acid) and also using a larger excess of permanganate (2 $KMnO_4$:1 oleic acid). The large excess of permanganate is permissible since it is known that the oxidation of the diol under these conditions is very slow relative to the rate of oxidation[6] and since a nearly quantitative yield of diol was obtained in each case. The results are shown in Table I.

TABLE I

OXYGEN TRANSFER IN THE OXIDATION OF OLEIC ACID

Excess atom % O^{18} in $KMnO_4$[a]	[$KMnO_4$]/[oleic acid]	Excess atom % O^{18} in CO_2[a,b]	No. of oxygens from $KMnO_4$
0.910	1.45:1	0.117	1.03
.910	2.00:1	.176	1.55

[a] Excess over normal abundance, 0.204%. The precision of the results is ±0.002%. [b] Carbon dioxide from the oxygen analysis. In calculating the oxygen transfer, a dilution factor of four is used, two for the conversion of carbon monoxide to carbon dioxide and two for the oxygens in the carboxylate group of the acid.

It is clear from these results that over 1.5 atoms of oxygen are transferred from the oxidizing agent to the oleic acid in the course of the hydroxylation. A consideration of the effect of the permanganate–oleic acid ratio on the extent of oxygen transfer leads to the conclusion that the true extent of trans-

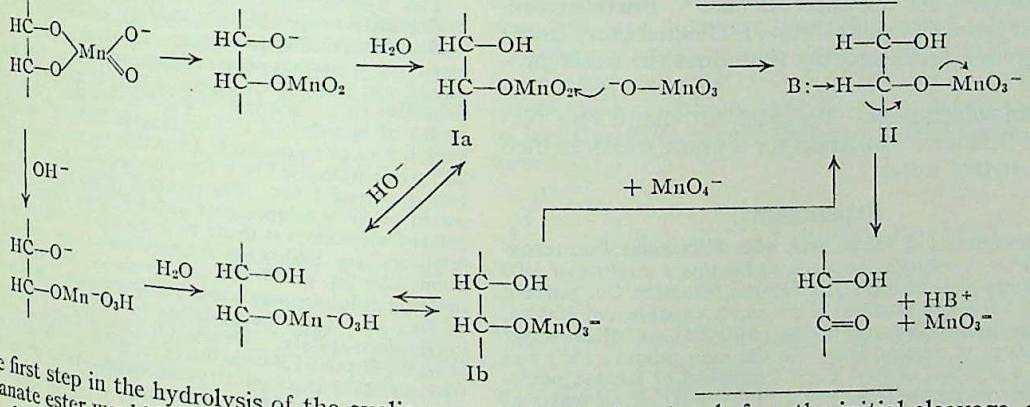
fer is close to 2. These results are then a confirmation of the proposal of Wagner and Böeseken.

As was mentioned previously, the high yield of diol from oleic acid is obtained only in basic solution, and a mixture of 9,10- and 10,9-ketohydroxystearic acids is obtained in neutral solution. That oleic acid is not an isolated case is shown by the observations of Lemieux and von Rudloff[9] that other olefins probably give ketols as intermediates in the permanganate–periodate oxidation at *p*H 7–8. It may also be noted that the hydroxylation of 2,3-dimethylbicyclo[2.2.2]-5-octene-2,3-dicarboxylic anhydride was best effected in 2 *N* sodium hydroxide (80% yield)[10] and that the hydroxylation of oleyl and elaidyl hydrogen phthalates were also best effected in basic solution.[11]

Since it is known that the ketol is not formed from the diol, it is reasonable to believe that the ketol and the diol are formed from a common intermediate which has two modes of reaction.[6] The formation of the ketol requires a four-electron oxidation. Since permanganate usually undergoes only a three electron change under the conditions used, two molecules of permanganate probably are involved in the formation of the ketol. Ketol formation is favored by low base concentration and relatively high permanganate concentration, and diol formation is favored by low permanganate and relatively high base concentration. Thus it appears that permanganate and hydroxyl ions compete for reaction with a common intermediate. A reasonable scheme for the reactions is

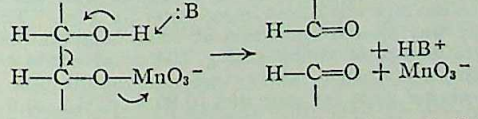


The first step in the hydrolysis of the cyclic permanganate ester would lead to the intermediates Ia or Ib depending on how the manganese–oxygen bond was broken. If both intermediates could be formed, one would expect that they could be interconverted, depending on reaction conditions. The intermediate (Ia or Ib) could be converted to the diol by reaction with hydroxyl ion and to the ketol by oxidation of the Mn(V) in the intermediate to Mn(VI) by permanganate, followed by cleavage of the remaining manganese–oxygen bond in such a way as to produce a carbonyl group. The oxidation would involve the transfer of either an electron or an oxygen ion-radical depending on which intermediate was involved.

The conclusions reached above apply only to oxidations carried out in aqueous solution. In no case has the isolation of a ketol been reported when a mixture of an organic solvent and water was employed as the reaction medium, and in no case has base been added when these conditions were used. In fact, the recent procedures usually employ a neutral medium.

Straus and Rohrbacher[12] appear to have been the first to use a neutral solution for the hydroxylation reaction. They added magnesium sulfate to precipitate hydroxyl ions as magnesium hydroxide, presumably to avoid oxidation of the ethanol they used as the solvent, for the permanganate oxidation of ethanol is strongly base catalyzed. Subsequent workers have for the most part continued to use this procedure with either ethanol or acetone as the solvent. It is interesting to note that Straus and Rohrbacher reported the hydroxylation of 1,2-dihydronaphthalene to give, in addition to the diol, an unidentified non-crystalline neutral compound, which may have been a ketol.

In order to see whether a ketol might be obtained in a neutral permanganate oxidation, the reaction of bicyclo[2.2.1]-2-heptene was studied and was found to give a small amount of diol and cyclopentane-1,3-dicarboxaldehyde in 54–66% of the theoretical amount. There are two paths which might lead to this product. First, the intermediate II which led to the ketol could also give the dialdehyde by attack of base on a different position (reaction (A)). Second, further oxidation of the original cyclic permanganate ester, before the initial cleavage, might occur. This would lead to an intermediate similar



to that in the periodic acid oxidation of diols to carbonyl compounds.

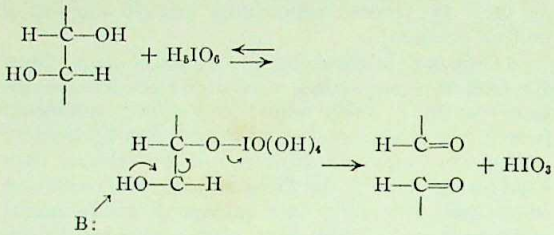
If the first of these possibilities were correct, one might expect that the first-formed intermediate in the periodate cleavage of diols (the periodate ester of one of the hydroxyl groups) should also be able to undergo this type of reaction, in which case the *trans*-glycol should react as fast or faster than the



cis-glycol. However, the opposite order of reactivity is found[13] and thus the cleavage cannot occur in this manner. The possible similarity between the permanganate and periodate reactions therefore leads us to favor the second path at this time. Further work on the effect of solvent and structure on this reaction is now in progress.

It was also of interest to determine whether alkaline permanganate would have any advantages over neutral permanganate for the hydroxylation reaction in mixed solvents. The oxidations of cyclopentene, cyclohexene and cycloheptene were effected in *t*-butyl alcohol–water solution at about *p*H 13 giving 55, 38 and 38% of the theoretical amounts of diol, respectively. The maximum yields reported for the oxidation in neutral solution are 34, 33 and 35% for the three olefins.[14] Furthermore, the oxidation in basic solution is effected more easily and gives a purer product than does the other procedure.

Experimental[15]

Hydroxylation of Oleic Acid with Potassium Permanganate O^{18}.—A solution prepared by heating a mixture of 1.00 g. (3.5 mmoles) of oleic acid (Fisher Scientific Co. purified grade), 1.0 g. (25 mmoles) of sodium hydroxide and 100 ml. of water was cooled and diluted with 800 ml. of ice-water and 100 g. of crushed ice. To the cold mixture (5°) was added a solution of 0.80 g. (5.1 mmoles) of labeled potassium permanganate ($\%O^{18} = 1.114$)[16] in 80 ml. of water as rapidly as possible with vigorous stirring. After five minutes, the reaction mixture was decolorized with sulfur dioxide, 30 ml. of concentrated hydrochloric acid was added and the mixture was cooled in ice-water for 1 hr. The precipitate was filtered and dried at room temperature in a vacuum desiccator giving 1.05 g. (94%) of crude *erythro*-9,10-dihydroxystearic acid. One recrystallization from 95% ethanol gave the pure diol (0.90 g. 81%), m.p. 130–131°.[17]

The reaction was repeated using 1.10 g. (7 mmoles) of labeled potassium permanganate in 110 ml. of water. The solution was decolorized after one minute, and the diol was obtained as above (1.10 g. (98%) crude; 0.88 g. (79%) pure, m.p. 130–131°).

Oxygen-18 Analysis.—The apparatus and procedure was essentially that described by Doering and Dorfman,[4] except that the bubbler containing 2–3% bromine in 1:1 chloroform–carbon tetrachloride was not used. The high temperature furnace (1120°) consisted of a heating coil enclosed in a cylindrical sheet nickel housing which was constructed in two halves which were hinged together. The coil was approximately 15 mm. i.d. and 280 mm. long (73 turns spaced 2 mm. apart) of 12 gage Kanthal A-1 wire, having a resistance of 1.5 ohms. The electrical connections were made using pure nickel machine screws and nuts. The heating current was supplied from an 18 amp. Powerstat followed by a 2:1 stepdown transformer. At 1120°, the coil draws approximately 27 amp. at 50 volts.

The analyses were conducted in quadruplicate, and in each case the third and fourth analyses agreed to ±0.002%.

Oxidation of Bicyclo[2.2.1]-2-heptene with Potassium Permanganate. A. Dilute Basic Permanganate.—A solution of 23.4 g. (0.148 mole) of potassium permanganate and 5 g. (0.125 mole) of sodium hydroxide in 800 ml. of water, cooled to 0°, was added quickly with vigorous stirring to a cold mixture (−10°) of 1 l. of *t*-butyl alcohol, 200 ml. of water and 500 g. of cracked ice containing 9.42 g. (0.1 mole) of bicyclo[2.2.1]-2-heptene.[18] After 3–5 min., most of the permanganate color had been discharged, and sulfur dioxide was added to ensure complete reduction of the permanganate. The precipitate of manganese dioxide was filtered through a layer of Filter-Aid, most of the *t*-butyl alcohol was removed by distillation at atmospheric pressure, and the resultant solution was concentrated to about 250 ml. under reduced pressure with steam-bath heating. The solution was continuously extracted with ether for 48 hr., and the ether solution was dried over anhydrous sodium sulfate. Evaporation of the solvent gave 5.77 g. (45%) of a white crystalline solid which was purified by sublimation at 105–110° at 18 mm. giving 5.38 g. (40%) of *exo-cis*-bicyclo[2.2.1]heptane-2,3-diol, m.p. 139.5–140.5°.[19] The infrared spectrum (carbon tetrachloride solution) of the crude reaction product and of the purified material were identical and showed no absorption in the 6 μ region.

The hydroxylations of cyclopentene, cyclohexene and cycloheptene were effected using this procedure.

B. Neutral Permanganate.—A solution of 12.6 g. (0.08 mole) of potassium permanganate and 9.6 g. (0.08 mole) of anhydrous magnesium sulfate in 300 ml. of water was added dropwise to a vigorously stirred suspension of 9.42 g. (0.1 mole) of bicyclo[2.2.1]-2-heptene in 200 ml. of acetone at such a rate as to maintain a reaction temperature of −15 to 20° while immersed in a Dry Ice–acetone-bath. The addition required 1 hr. The reaction mixture was allowed to warm to room temperature and was then filtered. The resultant solution was made basic by the addition of 5 ml. of 40% sodium hydroxide solution and then evaporated to about 250 ml. at 60–70° under reduced pressure. The remaining solution was continuously extracted with ether for 48 hr., and the ether solution was dried over anhydrous magnesium sulfate. Distillation gave 4.1–5.0 g. (54–66%) of cyclopentane-1,3-dicarboxaldehyde, b.p. 80–87° at 2 mm. Redistillation through a 15-inch twisted wire gauze column gave the pure dialdehyde, b.p. 74–75° at 1.5 mm., $n^{25}D$ 1.4759, with good recovery.

Anal. Calcd. for $C_7H_{10}O_2$: C, 66.6; H, 8.0. Found: C, 66.2; H, 8.3.

The phenylhydrazone (m.p. 121–122°), dinitrophenylhydrazone (m.p. 225.5–226°) and the semicarbazone (m.p. 203–203.5°) were prepared.

Anal. Calcd. for $C_{19}H_{18}N_8O_8$ (2,4-dinitrophenylhydrazone): C, 46.9; H, 3.7. Found: C, 46.7; H, 3.8. Calcd. for $C_9H_{16}N_6O_2$ (semicarbazone): C, 45.0; H, 6.7. Found: C, 45.1; H, 6.8.

The above 2,4-dinitrophenylhydrazone did not on admixture depress the m.p. of the dinitrophenylhydrazone of cyclopentane-1,3-dicarboxaldehyde prepared by the lead tetraacetate cleavage of *exo-cis*-bicyclo[2.2.1]heptane-2,3-diol.

The Preparation of 2-Methyloxazolidines and 2-Methyltetrahydro-1,3-oxazines from Acetylene and Aminoalcohols

BY WARREN H. WATANABE AND LAWRENCE E. CONLON

RECEIVED NOVEMBER 2, 1956

In the absence of any added catalyst acetylene reacts with aminoalcohols, $RNH(CR_2)_nOH$, where R is H or an alkyl group and n is 2 or 3, at pressures of 400–500 p.s.i. and temperatures of 100 to 200°, to form 2-methyloxazolidines (I, $n = 2$) and 2-methyltetrahydro-1,3-oxazines (I, $n = 3$). No vinyl ether is formed in this reaction. Owing to the instability of these products at reaction temperatures, the reactions are best carried out to 10–30% conversions. Yields based on unrecovered aminoalcohol then range from 30 to 75%. The theoretical implications of this new reaction are discussed and a possible mechanism proposed.

When acetylene is treated with an alcohol in the presence of a strong base, there is formed in good yield a vinyl ether. As one example, aminoalcohols are thus readily converted to aminoalkyl vinyl ethers.[1] Reppe has reported, moreover, that when N-phenylethanolamine is treated with acetylene, with zinc and cadmium acetates as catalyst, the isolated product is N-phenyloxazolidine[2] (whether exclusively or in mixture with the vinyl ether is not stated)

$$C_6H_5NHCH_2CH_2OH + HC{\equiv}CH \xrightarrow{Zn(OAc)_2\text{-}Cd(OAc)_2} \text{2-phenyloxazolidine} \quad (1)$$

We now have found that even in the absence of any added catalyst, aminoalcohols containing primary or secondary amino groups beta or gamma to the hydroxyl group are converted by acetylene exclusively to 2-methyloxazolidines and 2-methyltetrahydro-1,3-oxazines

$$R'NH(CR_2)_nOH + HC{\equiv}CH \longrightarrow \text{2-methyl-3-R'-tetrahydro-1,3-oxazine} \quad (2)$$

I, $n = 2,3$

Under these new conditions, aminoalcohols in which R′ is H, alkyl or substituted alkyl, but not aryl (N-phenyl ethanolamine does not undergo this reaction), are transformed to compounds I in yields ranging from about 5 to 75%, with conversions on the order of 13–30%.

A short study of reaction variables showed that yields were determined by a balance of reaction conditions, the major factors being the opposing ones of stability of the products and the reactivity of the aminoalcohols in the acetylene–aminoalcohol reaction. Calculations of very crude rate "constants" from weight gain and time of reaction data, assuming a first-order consumption of aminoalcohol, showed that the highest rate was obtained with N-methylethanolamine. Less rapid were the reactions of ethanolamine and 3-aminopropanol-1, both aminoalcohols with primary amino groups but with no substituents on the carbon chain, and least reactive were the aminoalcohols containing primary amino groups and alkyl substituents alpha or beta to the amino group.

Identification and Stability of Products.—Boiling points, physical constants, analyses and chemical reactions were not sufficient to provide clear-cut characterizations of the products. It was particularly desirable to show that these were actually the cyclic compounds and not the isomeric vinyl ethers. Fortunately there is in the infrared spectra of vinyl ethers a multiplicity of quite characteristic bands (1637, 1615, 960 and 810 $cm.^{-1}$)[3] which makes it possible to determine with certainty the presence or absence of vinyl ether. In none of the compounds prepared was any vinyl ether detected. Positive identification of the ring structure was, however, less satisfactory, although a pattern of peaks at longer wave lengths is claimed to be associated with O–C–N of the ring.[4] In those compounds (I) which have R′ = H, a further aid to identification is provided in the ring-chain tautomerism

$$\text{2-methyl-tetrahydro-1,3-oxazine} \rightleftharpoons HO(CR_2)_nN{=}CHCH_3 \quad (3)$$

$n = 2,3$

The Schiff base form could be characterized by —C=N— absorption at 1650–1680 $cm.^{-1}$ and, after dilution with a non-polar solvent, non-bonded –OH at 3570 $cm.^{-1}$.[5] All compounds prepared in this work capable of existing in the Schiff base form, except one, showed —C=N— absorption, indicating that at least some Schiff base was present. The exception was 2,4,4-trimethyloxazolidine, which had no absorption at all in the double bond region, thus unambiguously eliminating the vinyl ether form as well as the Schiff base.

The products, immediately after purification by fractional distillation, gave molecular refraction values only slightly lower than those calculated for the cyclic structure but higher by about 1.8

units than values calculated for the Schiff base form. In the case of 2,4,4,-trimethyloxazolidine, which is, from infrared measurements, entirely in the cyclic form, the difference [M_D (theor. cyclic) $-M_D$ (exptl.)] was 0.27. This difference for three of the other four products ranged from 0.21 to 0.31. Thus if there is any validity to the claim that the proportion of the two forms in equilibrium 3 can be determined from the M_D value of the mixture, it must be concluded that these three products initially contained very little, if any, Schiff base. On subsequent warming of these compounds to room temperature there were rapid but measurable increases in both refractive index and density, which may have reflected the approach to an equilibrium state. Infrared curves were taken at least a day after the compounds were prepared, and it is thus not surprising that absorption bands for the Schiff base forms were found in these measurements.

There was also observed a non-reversible condensation of all our products to higher-boiling materials upon standing at room temperature, or upon short heating at higher temperatures. For those compounds (I) with R′ = H, Nace and Goldberg[6] have suggested that this conversion is most probably an aldol condensation proceeding through the Schiff base form

$$2CH_3CH{=}NR \longrightarrow CH_3CHCH_2CH{=}NR \longrightarrow \underset{\text{NHR}}{|}$$

$$CH_3CH{=}CHCH{=}NR + RNH_2 \quad (4)$$

$$R = (CR_2)_nOH,\ n = 2 \text{ or } 3$$

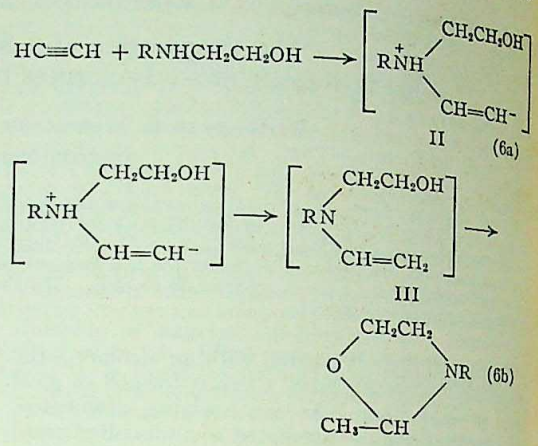
This condensation also contributes to changes in refractive index, density and infrared spectrum, measurements of which therefore must be used with caution if it is intended to draw conclusions as to proportions of oxazolidine and Schiff base. Since 2,3-dimethyloxazolidine cannot exist in Schiff base form, its mode of conversion to higher-boiling compounds is considerably more obscure.

Possible Mechanism.—It is probable that the present reaction is a special instance of vinylation, in which the reaction of acetylene is on the amine nitrogen rather than on the oxygen. It would then be analogous to the reaction of tertiary amines in aqueous solution with acetylene to form vinyl trialkylammonium hydroxide.[7] The general mechanism for such nucleophilic reactions on acetylene has been written as[8]

$$HC{\equiv}CH + N{:}^- \longrightarrow [HC{=}CHN]^- \text{ rate determining} \quad (5a)$$

$$[HC{=}CHN]^- + HN \longrightarrow CH_2{=}CHN + N{:}^- \text{ fast} \quad (5b)$$

where N:$^-$ is a nucleophilic species. The present reaction could then proceed in the steps



The intermediate II may go directly to product or proceed through a transitory N-vinylamine III, which then cyclizes. We have no positive proof of the existence of III, and since there are a number of other likely paths through which II may cyclize, we wish only to emphasize the probability of (6a) as the first step in the mechanism of reaction 2. Evidence supporting (6a) is our observation that acid reduces the rate of reaction 2.[9]

The possibility that (2) proceeds by O-vinylation to a vinyl ether, followed by cyclization, is excluded since O-vinylation requires a strongly basic catalyst. Moreover, it was not found possible to cyclize a representative aminoalkyl vinyl ether, obtained by base-catalyzed O-vinylation, to an oxazolidine under conditions in which reaction 2 occurs readily. A further possibility is that water acts as a catalyst, generating OH$^-$ by hydrolysis of the amine, which reacts with acetylene to form acetaldehyde. The acetaldehyde would then form the oxazolidine from the aminoalcohol, regenerating water. However, deliberately added water neither increased the rate of reaction nor improved the conversion to product; the reverse was rather the case.

Since reaction 1 is catalyzed by metal salts, it might be conceived that the apparently uncatalyzed reaction 2 was actually catalyzed by trace amounts of metal salts dissolved from the metal reactor. We do not believe this to be the case since sulfur, a mercaptan and a sequestering agent, all effective poisons for metal-catalyzed reactions, do not inhibit reaction 2. If, however, reaction 2 is indeed catalyzed by metal salts, then it no longer becomes possible to eliminate a two-step mechanism in which a vinyl ether is first formed, then cyclized. This is so since each step is independently known. Zinc and cadmium salts are stated to be catalysts for the vinylation of alcohols,[10] and we have shown that these same salts will catalyze

(6) H. R. Nace and E. P. Goldberg, THIS JOURNAL, **75**, 3646 (1953); the adlol condensation of an aldimine has been demonstrated by W. S. Emerson, S. H. Hess and F. G. Uhle, *ibid.*, **63**, 872 (1941).

(8) R. Rigamonti and L. Bernardi, *Chimica e industria*, **34**, 561 (1952); S. I. Miller and G. Shkapenko, THIS JOURNAL, **77**, 5038 (1955).

(9) *Cf.* W. H. Watanabe and L. R. DeFonso, *ibid.*, **78**, 4542 (1956), in which it is shown that acid sharply reduces the rate of an aminolysis reaction. The aminolysis is therefore proposed to proceed largely through the amine anion, RNH$^-$. Since aminolysis and reaction 6a are both nucleophilic reactions of amines, it could be considered that the retarding action of acid on (6a) argues for HOCH$_2$CH$_2$NR as the actual reacting species.

the cyclization of aminoalkyl vinyl ethers to 2-methyloxazolidines.[11]

Acknowledgments.—We thank Mr. O. H. Loeffler for his constant advice and encouragement during the course of this work and acknowledge with pleasure many stimulating discussions held with Dr. H. J. Schneider. Mr. Benjamin C. Wilbur provided technical assistance in a portion of this work.

Experimental

Materials, Apparatus and General Procedure.—The aminoalcohols were all commercially available compounds and were redistilled before use. As reactors there were used a 250-ml. magnetically-stirred stainless steel autoclave, heated with high-pressure steam, and a 300-ml. stainless steel rocking bomb, heated with a liquid heat transfer agent. The general procedure for all runs was as follows: The aminoalcohol was charged to the reactor, the reactor then sealed and pressure-tested, swept twice with nitrogen and twice with acetylene and finally cut off under about 50 p.s.i. acetylene. Heat was then applied to bring the reactor up to reaction temperature and the temperature maintained by suitable controls. Temperatures were in the range 100–180°. Acetylene was then pressed in to 400–600 p.s.i. and this pressure maintained by replenishing the acetylene as required. At the end of the reaction period the reactor was cooled, vented and drained. The raw product was in most instances directly fractionated under nitrogen to obtain the pure material. The product fractions were collected in receivers cooled with ice-water and every attempt was made to measure the density and refractive index of these materials within 5 min. of the time when the product was removed from the distilling column. It should nevertheless again be emphasized that some of the products, notably those with R′ = H in I, increased rapidly in these constants as the compounds aged, and our values may therefore not be entirely reliable. The neutralization equivalents of the products, as reported below, were obtained from potentiometric titration of the compounds in water with standard hydrochloric acid. Yield and conversion data for the reactions studied are given in Table I.

Preparation of 2-Methyloxazolidine.—About 175 g. of ethanolamine was dissolved in 60 g. of benzene and the solution distilled to remove any benzene–water azeotrope. Most of the benzene was then boiled off and the residue (169.0 g.) was charged to the magnetically-stirred autoclave. Since 10 g. of benzene was recovered later from the products, the charge therefore consisted of 159 g. (2.60 moles) of ethanolamine. Reaction with acetylene was then carried out according to the above general procedure at 145–150° for 2.5 hr. The material drained from the reactor weighed 180 g., the gain in weight of 11 g. corresponding to an acetylene uptake of 0.42 mole. Fractionation of this reaction mixture gave 26.0 g. of crude 2-methyloxazolidine, b.p. 50–56° (60 mm.), and 107.0 g. of recovered ethanolamine, b.p. 100° (90 mm.) –92° (40 mm.). The crude oxazolidine was therefore obtained in 12% conversion and 36% yield, based on unrecovered aminoalcohol. This material was sealed in an ampoule under nitrogen and immediately stored in the refrigerator. After storage for 13 days, it was found to have yellowed and become quite viscous. It was, however, combined with the crude product from another preparation of 2-methyloxazolidine and refractionated. Since the residue from this distillation amounted to 17.2 g. (largely column hold-up), it was clear that a large proportion of the 26 g. of apparently polymerized 2-methyloxazolidine had been regenerated in the distillation. The pure compound had b.p. 51–52° (60 mm.), $n^{25}D$ 1.4338, d^{25}_4 0.9651, M_D 23.50 (theor. 23.71), neut. equiv. 90.13 (theor. 87.12). These constants do not agree with those reported by Knorr and Matthes[12] and Doughty, *et al.*[13]

Anal.[14] Calcd. for C_4H_9ON: C, 55.14; H, 10.41; N, 16.08. Found: C, 55.29; H, 10.38; N, 15.92.

[a] Per cent. (by mole) of total aminoalcohol converted to pure product. [b] Per cent. (by mole) of unrecovered aminoalcohol converted to pure product.

Preparation of 2,5-Dimethyloxazolidine.—A charge of 141.0 g. (1.88 moles) of 1-aminopropanol-1 was treated with acetylene in the magnetically-stirred autoclave for 2.6 hr. at 136–152°. Fractionation of the reaction mixture gave 27.5 g. of 2,5-dimethyloxazolidine (14% conversion, 50% yield) b.p. 68–69° (120 mm.), $n^{25}D$ 1.4304, d^{25}_4 0.9246, M_D 28.28 (theor. 28.33), neut. equiv. 101.3 (theor. 101.15), and 100 g. of recovered 1-aminopropanol-2, b.p. 97–100° (80 mm.).

Anal. Calcd. for $C_5H_{11}ON$: C, 59.37; H, 10.96; N, 13.85. Found: C, 59.63; H, 10.99; N, 13.90.

Preparation of 2-Methyl-4-ethyloxazolidine.—2-Aminobutanol-1 (139.0 g., 1.56 moles) was treated in a similar fashion with acetylene. Fractional distillation of the product gave 41.5 g. of 2-methyl-4-ethyloxazolidine, b.p. 83° (105 mm.) to 81° (86 mm.) (mainly at 81.5° (86 mm.)), and 82.0 g. of recovered 2-aminobutanol-1, b.p. 113–115° (76–72 mm.) (23% conversion, 56% yield). Redistillation of this product gave pure 2-methyl-4-ethyloxazolidine, b.p. 84° (100 mm.), $n^{25}D$ 1.4302, d^{25}_4 0.9119, M_D 32.64 (theor. 32.95), neut. equiv. 115.7 (theor. 115.17).

Anal. Calcd. for $C_6H_{13}ON$: C, 62.57; N, 12.16; H, 11.38. Found: C, 62.80; N, 11.94; H, 11.22.

Preparation of 2,4,4-Trimethyloxazolidine.—2-Amino-2-methylpropanol-1 was dried by azeotropic distillation with benzene, and 122 g. of a mixture consisting of 114 g. (1.28 moles) of the aminoalcohol and 8 g. of benzene was allowed to react at 175° for 10.5 hr. The reaction mixture was fractionated into 46.0 g. of crude 2,4,4-trimethyloxazolidine, b.p. 62–75° (120 mm.), and 66.0 g. of recovered 2-amino-2-methylpropanol-1, b.p. 102° (120 mm.) to 97° (55 mm.) (31% conversion, 73% yield). This product was redistilled to give the pure oxazolidine, b.p. 72° (125 mm.), $n^{25}D$ 1.4215, d^{25}_4 0.8946, M_D 32.68 (theor. 32.95), neut. equiv., 118.6 (theor. 115.2).

Anal. Calcd. for $C_6H_{13}ON$: C, 62.57; H, 11.38; N, 12.16. Found: C, 62.59; H, 11.20; N, 11.91.

Another reaction carried out at 150° for 5.7 hr. gave a 10% conversion and 72% yield. When 3% by weight of water was added to the aminoalcohol before reaction, the conversion dropped to 4% and the yield to 22%.

Preparation of 2,3-Dimethyloxazolidine.—A solution of 93 g. (1.24 moles) of N-methylethanolamine in 50 g. of benzene was distilled to remove the benzene–water azeotrope, most of the excess benzene distilled off and the residue (101.5 g.) charged to a 250-ml. magnetically-stirred autoclave. Reaction with acetylene was carried out at an average temperature of 144° for 2.5 hr. Fractional distillation of the reaction product yielded 43.5 g. of 2,3-dimethyloxazolidine, b.p. 50–58° (120 mm.), and 36.0 g. of recovered N-methylethanolamine, b.p. 100–102° (100 mm.) (35% conversion, 57% yield). The pure oxazolidine was obtained by redistillation, b.p. 54.5–55° (120 mm.), 109–110° (760 mm.) (lit.[12] 109° (758 mm.)), $n^{25}D$ 1.4200, d^{25}_4 0.8991, M_D 28.47 (theor. 28.67), neut. equiv. 100.9 (theor. 101.2).

Anal. Calcd. for $C_5H_{11}ON$: C, 59.37; H, 10.96; N, 13.85. Found: C, 59.46; H, 10.73; N, 13.48.

Preparation of 2-Methyltetrahydro-1,3-oxazine.—3-Aminopropanol-1 (161 g., 2.14 moles) was treated with acetylene at an average temperature of 152° for 3.9 hr. to give a product which, after fractionation, yielded 27.0 g. of 2-methyltetrahydro-1,3-oxazine, b.p. 68–70° (100 mm.), $n^{25}D$ 1.4382, d^{25}_4 0.9480, M_D 28.02 (theor. 28.33), neut. eqiv. 101.3 (theor. 101.2).

Anal. Calcd. for $C_5H_{11}ON$: N, 13.85. Found: N, 13.60.

Recovered 3-aminopropanol-1, b.p. 95° (25 mm.), amounted to 97.0 g. The conversion to product was therefore 12% and the yield 31%.

Preparation of 2-Methyltetrahydro-1,3-oxazine from Acetaldehyde.—A mixture of 75 g. (1.0 mole) of 3-aminopropanol-1 and 30 g. of anhydrous sodium carbonate in 200 ml. of anhydrous ether was placed in a three-neck flask equipped with a stirrer, reflux condenser and dropping funnel. The flask was cooled to 0° and 52 g. (1.2 moles) of acetaldehyde added slowly to the cooled (0–5°) and stirred mixture. After addition was complete, the reaction mixture was allowed to warm to room temperature during an additional 2 hr. of stirring. It was then filtered, most of the low-boiling material distilled from the filtrate under mild water-aspirator vacuum and the residue fractionally distilled. Product cuts were obtained as follows: 3.5 g., b.p. 63–65° (100 mm.), $n^{25}D$ 1.4390; 9.5 g., b.p. 65–68° (100 mm.), $n^{25}D$ 1.4389; 55.0 g., b.p. 68–70° (100 mm.), $n^{25}D$ 1.4389. The yield was therefore 67%. This product was identical in its physical constants with the product from the acetylene–aminoalcohol reaction.

Attempted Cyclization of N-Methylaminoethyl Vinyl Ether under Vinylation Conditions.—When N-methylethanolamine is treated, using strong base catalysis, with acetylene under 400–500 p.s.i. at 140–150° until reaction ceases, there is obtained a mixture containing approximately 25% 2,3-dimethyloxazolidine, b.p. 55–56° (120 mm.), and 50% N-methylaminoethyl vinyl ether, b.p. 65–67° (120 mm.). In order to test whether, under these conditions, the vinyl ether is first formed, then cyclizes to the oxazolidine, the following experiment was performed. A solution of 4.6 g. (0.2 mole) of sodium in 100 g. (1.33 moles) of N-methylethanolamine was mixed with 50 g. (0.49 mole) of N-methylaminoethyl vinyl ether and the resulting solution charged to a 300-ml. stainless steel rocking microbomb. The bomb was pressured to 195 p.s.i. with nitrogen at 23°, heated to 154°, with a resultant increase in pressure to 345–355 p.s.i., and kept at that temperature for 2.5 hr. The mixture was then fractionally distilled. There resulted a 92% recovery of the vinyl ether; no material identifiable as 2,3-dimethyloxazolidine was isolated.

Preparation of 2,3-Dimethyloxazolidine in the Presence of Metal Catalyst Poisons and Acid.—A mixture of 0.5 g. of powdered sulfur and 77.0 g. (1.0 mole) of N-methylethanolamine was treated with acetylene at an average temperature of 140° for 0.5 hr. Uptake of acetylene started immediately and continued vigorously. The crude product, which was homogeneous, had gained 16 g. in weight, corresponding to an acetylene uptake of 0.58 mole. Fractionation of this material gave 25.0 g. of 2,3-dimethyloxazolidine, b.p. 52–54° (120 mm.), and 39.9 g. of recovered N-methylethanolamine, b.p. 55–57° (10 mm.). The conversion to product was therefore 25% and the yield based on unrecovered aminoalcohol, 50%.

The reaction of 89.6 g. (1.2 moles) of N-methylethanolamine with acetylene, within the pressure range 470–460 p.s.i.g. at 117 ± 1° for 0.5 hr. was repeated four times. The first reaction charge (1) contained only the aminoalcohol, the second (2) contained in addition 7.5 g. of the dihydrate of ethylenediaminetetraacetic acid disodium salt, the third (3) contained in addition 2.4 g. of 1,5-pentanedithiol and the fourth (4) contained in addition 5.0 g. of 85% phosphoric acid. Crude rate measurements gave the following rates of absorption of acetylene in the first minute of reaction (in moles per minute): (1) 0.11, (2) 0.10, (3) 0.14, (4) 0.04. The rates during the next 10–20 minutes were: (1) 0.02, (2) 0.01, (3) 0.008, (4) 0.003. The experimental error was such that the rates of (1), (2) and (3) may be considered the same, but the rates in (4) were decidedly lower. Work-up of the reaction products resulted in 14.6 g. of 2,3-dimethyloxazolidine from (1) and 13.7 g. from (3). Most of the product obtained in (2) and (4) polymerized during reaction.

Homogeneous Metal Salt Catalysis in Organic Reactions. I. The Preparation of Vinyl Ethers by Vinyl Transetherification

BY WARREN H. WATANABE AND LAWRENCE E. CONLON

RECEIVED NOVEMBER 2, 1956

The interchange reaction $ROCH{=}CH_2 + R'OH \rightleftarrows ROH + R'OCH{=}CH_2$, which is catalyzed by mercuric salts of weak acids, has been studied and found to be of wide scope and utility. It has been found that mercuric salts are specific catalysts for this reaction. A large number of other metal salts, as well as acid and base, were found to be without catalytic activity under conditions in which catalysis by mercuric salts of weak acids was rapid and efficient. As presently developed, the reaction gives yields ranging from relatively poor to excellent, but is nevertheless advantageous in that it provides a simple one-step synthesis of vinyl ethers from alcohols. Some attention has been given to the mechanism of this and related catalytic reactions, and a scheme involving acetoxymercuriacetals as intermediates is proposed.

Among the number of reactions which are specifically catalyzed by mercuric salts, there is an important group in which an olefinic function bonded to oxygen in an ester or ether is transferred to another oxygen atom in another ester or ether. For example, mercuric salts of strong acids catalyze the transfer to carboxylic acids of vinyl[1] or isopropenyl groups[2] from vinyl or isopropenyl esters to form new vinyl or isopropenyl esters. The same type of catalyst has been shown to cause transfer of vinyl groups from vinyl esters to alcohols to form, at low temperatures, vinyl ethers,[3] and to effect transfer of vinyl groups from vinyl ethers to alcohols to give new vinyl ethers, again at low

temperatures.[4] More recently mercuric salts of weak carboxylic acids have been reported to be particularly effective in catalyzing the transfer of vinyl groups from vinyl ethers to alcohols.[5]

This last reaction, in which weak acid salts of mercury are used to effect vinyl transetherification

$$ROCH{=}CH_2 + R'OH \rightleftarrows ROH + R'OCH{=}CH_2 \quad (1)$$

also was encountered independently in these laboratories several years ago, and it is the purpose of this report to describe our development of this reaction, as well as to suggest a general mechanism for this and the other transfer reactions mentioned above.

Reaction Procedures.—Equation 1 states that vinyl transetherification is reversible, and we have demonstrated that reactions may be made to proceed in either direction by appropriate choice of method. Thus we have prepared *n*-octyl vinyl ether from ethyl vinyl ether and *n*-octyl alcohol, and ethyl vinyl ether from *n*-octyl vinyl ether and ethyl alcohol. The procedure used throughout by the British workers in their disclosure of this new reaction[5] was one in which the desired vinyl ether is directly fractionated out of a solution of catalyst, a high-boiling vinyl ether, and a lower-boiling alcohol which it is desired to vinylate. This is feasible since vinyl ethers generally have boiling points about 10 to 30° below those of the alcohols from which they are derived.[7] We have found this method (method A in Table I) to lead to uniformly good yields of product since the equilibrium in (1) is shifted continuously toward the products, and the newly-formed vinyl ether remains only for a short time in contact with the reaction mixture, thereby minimizing side reactions. Nine examples utilizing this procedure are listed in Table I.

A more general and flexible method, but one in which lower yields are obtained, is the equilibration of a mixture of a vinyl ether, in excess, catalyst and an alcohol which it is desired to vinylate (method B in Table I). The equilibrium is then frozen by flash-stripping the volatile components from the catalyst or by inactivating the catalyst, and the mixture separated. Special advantages of this method are that no restrictions as to boiling point are placed on the vinyl ether serving as vinylating agent (except, of course, that it must ultimately be separable from the product vinyl ether) and that low reaction temperatures may be used, allowing the reaction of thermally-labile materials. The major disadvantage is that low yields (20–40%) are obtained, owing to the occurrence of a side reaction in which acetals are formed by acid-catalyzed addition of alcohol to vinyl ether.[8]

$$ROCH{=}CH_2 + R'OH \xrightarrow{H^+} \begin{matrix} RO \\ \diagdown \\ CHCH_3 \\ \diagup \\ R'O \end{matrix} \quad (2)$$

This side reaction reduces yields to less than half the amount of product to be expected on the basis of an equilibrium constant of one for reaction 1. Table I lists eleven vinyl ethers prepared by method B.

It should be noted that vinyl transetherification provides a one-step synthesis of vinyl ethers directly from alcohols and, thus, in spite of the low yields obtained in reactions carried out by method B, is generally preferable to the common

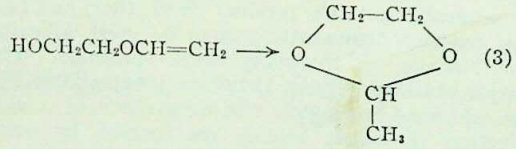
multi-step procedures (*e.g.*, by cracking of acetals,[10] by dehydrohalogenation of β-haloethyl ethers[11] or by reduction of haloacetals[12]). Base-catalyzed vinylation of alcohols by high pressure acetylene is an alternative one-step method,[13] but vinyl transetherification is of wider application in that it may be used with base-sensitive alcohols which cannot be vinylated with acetylene. Examples of such alcohols which have been converted to vinyl ethers in this work are ethylene chlorohydrin, ethylene cyanohydrin, 1-methyl-1-hydroxy-3-butanone, 2-nitro-1-butanol, 2-methyl-2-nitro-1-propanol, 2-chloroallyl alcohol and 2-(β-hydroxyethyl)-pyridine. Allyl and methallyl alcohols, which are vinylated with difficulty by acetylene,[14] are vinylated by the present method in good yield.

The alcohols listed in Table I indicate a reasonably broad scope for this reaction. Most of these compounds reacted smoothly, but several presented some special aspects which should be mentioned here. Acetal formation was marked in the reaction of ethylene chlorohydrin, even in method A, possibly due to splitting off of HCl with consequent strong acid catalysis of the acetal-forming reaction (2). Some improvement was observed when a salt of a weak acid was added to reduce acidity during the reaction. *t*-Butyl alcohol, ethylene cyanohydrin and N,N-dimethylaminoethanol all reacted very slowly, requiring long reaction times, with resulting losses in yield.[15] A number of other vinyl ethers were tried as vinylating agents for ethylene cyanohydrin, but only with the difunctional 1,2-divinoxyethane was it possible to obtain as high as 40% yield. The vinylation of ethylene glycol also was attempted, but while small amounts of both the monovinyl and divinyl ethers were isolated, the yields were in general low and variable. This is due to the competitive cyclization of 2-hydroxyethyl vinyl ether to 2-methyl-1,3-dioxolane,[12b] which also was isolated from among the



(3)

reaction products. When amino-alcohols containing primary and secondary amino groups were tried, the reaction was found not to proceed as in (1) but in another direction, which is described in the second paper of this series.[16]

(16) W. H. Watanabe, THIS JOURNAL, **79**, 2833 (1957).

Catalysts and Catalyst Systems.—Tests made on a variety of metal salts showed that mercuric salts are highly specific catalysts for reaction 1. Inactive salts included those of cobalt, cadmium, copper (cuprous and cupric), iron (ferrous and ferric), lead, silver, nickel and zinc. Of these inactive materials, a number effected the formation of high-boiling products (probably acetals); these salts were mainly halides, although several nitrates also led to this type of reaction.[17]

Adelman already has shown that strong acid salts of mercury will catalyze (1), although vinyl ethers can be isolated only when the reaction is carried out at low temperatures (−10° or lower).[4] We postulate that in the course of the catalysis the acid derived from the anion of the mercuric salt is set free, and it is therefore probable that the strength of this acid will determine the extent of side reaction 2. Our finding that mercuric salts of weak acids, particularly mercuric acetate and mercuric benzoate, are effective catalysts which can be used advantageously at higher temperatures supports this aspect of the catalysis. Thus the specific activity resides in the cation; the acid derived from the anion must take part in some later step of the catalysis but may also be the agent promoting side reactions.

Exceptions to our general observation that strong acid salts of mercury gave acetals at room temperature and above were found in mercuric iodide, mercuric fluoride and chloromercuriacetaldehyde, all of which gave vinyl ether products. These results imply that the extent of dissociation of the mercury salts is also a determining factor in establishing the balance of reactions 1 and 2.

Mechanism of the Reaction.—For those reactions catalyzed by strong acid salts of mercury (*e.g.*, mercuric sulfate), Adelman has postulated a mechanism wherein the vinyl compound first dissociates into an acetylene–mercuric salt complex, which then reacts with alcohol or carboxylic acid to form the product.[3] This mechanism requires that the catalyst for vinyl interchange also be a catalyst for the reaction of acetylene with alcohol or carboxylic acid to give vinyl ether or vinyl ester, and while this is true with mercuric salts of strong acids, it is not the case with mercuric salts of weak acids.[18] We agree with Adelman's proposal that the several mercuric salt-catalyzed vinyl interchange reactions probably proceed through the same general type of mechanism. We consider it more probable, however, that the actual reaction path will more closely correspond to the following scheme, which is written for vinyl transetherification. This mechanism is, in essence, a reversible alkoxymercuration. One of its important aspects is the formation of an intermediate or intermediates which are essentially symmetrical, so that the reverse reactions can lead either to the starting reactants or to the desired products. The anal-

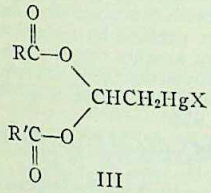
ogous intermediate for vinyl transesterification (III) should also possess the property of reverting either to starting reactants or products, thus explaining the equilibrium character of this reaction.



III

The possibility that intermediates of the structure (I) may in fact be involved in the over-all path of vinyl transetherification is lent some credence by our finding that compounds of structure I readily can be prepared and isolated. Slow addition of sodium ethoxide in ethyl alcohol to mercuric acetate dissolved in ethyl vinyl ether gives a good yield of 2-acetoxymercuri-1,1-diethoxyethane (IV), which can be recrystallized and stored unchanged in the cold for at least several weeks.[19] 2-Acetoxymercuri-1-methoxy-1-ethoxyethane (V) was prepared similarly from sodium methoxide, mercuric acetate and ethyl vinyl ether.

$$R'O^- + ROCH{=}CH_2 + Hg(OAc)_2 \longrightarrow$$

$$\begin{matrix} R'O \\ \diagdown \\ CHCH_2HgOAc \\ \diagup \\ RO \end{matrix} + AcO^- \quad (5)$$

IV, $R = R' = C_2H_5$
V, $R' = CH_3$ $R = C_2H_5$

Compound V was kept refrigerated for several months and after this period was found to have decomposed largely into metallic mercury, ethyl vinyl ether and some acetaldehyde.

(19) A. N. Nesmeyanov, I. F. Lutsenko and N. I. Vereschagina, *Bull. acad. sci. U.R.S.S., Classe sci. chim.*, 63 (1947); *C. A.*, **41**, 4148i (1948), have prepared chloro- and bromomercuriacetaldehyde in good yield by reaction of an alkyl vinyl ether and mercuric acetate in aqueous solution, followed by addition of KCl or KBr.

The 2-acetoxymercuri-1,1-diethoxyethane was found to be decomposed readily by acetic acid to ethyl vinyl ether and ethyl alcohol, thus establishing that such a structure is indeed labile to weak acid. This demonstration is a necessary although not a sufficient condition that structure I be an intermediate in vinyl transetherification. We are led to the proposal of step 4c, in which I reacts further with vinyl ether to give the diacetal II, by our observation that the 2-acetoxymercuriacetals in the absence of added acetic acid (as well as phenyl mercuric acetate, both mercury compounds with a single acid anion) are quite efficient catalysts for vinyl transetherification. This implies that structures $RHgCH_2CH(OR)_2$, where R is phenyl or $(RO)_2CHCH_2-$, may be formed, liberating acetic acid, and may subsequently be decomposed by this acid. As expected, di-*p*-tolylmercury, which is relatively stable to cleavage at the C–Hg bond, has no catalytic activity.

Acknowledgment.—We wish to thank Mr. O. H. Loeffler for much helpful advice and encouragement during the course of this work.

Experimental

Materials.—All vinyl ethers used as vinylating agents, except ethyl vinyl ether and 2-ethylhexyl vinyl ether, which were commercially available, were prepared by base-catalyzed high-pressure vinylation of the alcohols with acetylene[13] and were used either pure or as azeotropes with their precursor alcohols. The commercially obtained vinyl ethers were fractionated before use to remove polymerization inhibitors, which, being amines, inactivate the mercuric salt catalysts. No special effort was made to remove peroxides from the vinyl ethers, other than by distillation; however, these materials were never distilled to less than one-fifth the original pot charge. The alcohols were also purified by distillation. Dr. P. L. deBenneville and his associates kindly supplied the 1-methyl-1-hydroxy-3-butanone; all other alcohols were commercially available. All mercuric salts used were the best grade obtainable.

Analytical Methods.—A qualitative test for vinyl ethers which we found most useful in assessing the results of our experiments was as follows: several drops of the compound are placed on a spot plate and a drop of boron trifluoride etherate added with care. If the compound is a vinyl ether, there is an immediate, often violent, reaction with formation of black viscous or solid tars and evolution of fumes. Certain alcohols which are themselves polymerized by acid, such as furfuryl alcohol, also react in this manner to boron trifluoride. Azeotropes of vinyl ethers and alcohols react less violently but still rapidly. Acetals react very slowly, but do darken on standing for several minutes.

Quantitative analyses for the vinyl group were carried out by the method of Siggia, in which the vinyl ether is hydrolyzed in aqueous hydroxylamine hydrochloride, the acetaldehyde thereupon forming the oxime and liberating HCl, and the free HCl then determined by titration.[20]

Catalyst Testing.—The possible catalytic activity of metal salts in effecting reaction 1 was tested by determining whether these salts would convert a solution of ethyl alcohol and *n*-butyl vinyl ether to ethyl vinyl ether and *n*-butyl alcohol, under reflux. By this test the following compounds were found to be active catalysts: mercuric acetate, mercuric benzoate, phenyl mercuric acetate, mercuric citrate, mercuric chromate, mercuric oxalate, mercuric linoleate, mercuric fluoride, mercuric iodide, mercuric lactate, 2-acetoxymercuri-1,1-diethoxyethane, 2-acetoxymercuri-1-ethoxy-1-methoxyethane and chloromercuriacetaldehyde. The fluoride, iodide and lactate were relatively poor catalysts, giving acetals as well as transetherification product. The following compounds led to the formation of high-boiling products, presumably acetals: mercuric sulfate, mercuric nitrate, mercuric chloride, mercuric thiocyanate, mer-

curous sulfate, cuprous chloride, nickel bromide, nickel nitrate, nickel iodide, cobalt chloride, antimony trichloride, ferric chloride, bismuth nitrate, arsenic trichloride and sodium bisulfate. Compounds which gave no apparent reaction were mercuric cyanide, mercuric oxide, mercuric sulfide, mercurous chloride, cobalt acetate, cobalt carbonate, cadmium acetate, cadmium carbonate, cadmium oxide, cuprous thiocyanate, cuprous cyanide, cupric carbonate, ferrous sulfate, lead acetate, nickel acetate, nickel cyanide, nickel carbonate, nickel formate, nickel sulfate, thallous bromide, thallous malonate, zinc acetate, zinc bromide, zinc oxide, silver nitrate, silver acetate, ammonium chloride, sodium ethoxide and sodium hydroxide.

Preparation of Ethyl Vinyl Ether. Method A.—This and the following procedure are representative examples of method A. Mercuric acetate (5 g., 0.016 mole) was dissolved in a mixture of dry ethyl alcohol (50 g., 1.08 moles) and *n*-butyl vinyl ether (100 g., 1.0 mole) and the resulting solution placed on a short distilling column fitted with a total condensation partial take-off head. The distillation was first kept at total reflux until the vapor temperature settled at 36–37°, and the rate of distillation was thereafter adjusted so as to keep the boiling point within this range. There was distilled off 71 g. (0.98 mole) pure ethyl vinyl ether, b.p. 36–37°, a yield on the vinyl ether of 98%. Water was then added to the distilling flask, and an azeotrope of *n*-butyl alcohol and water, b.p. 93°, was distilled off and separated to give 71.2 g. (0.97 mole) of *n*-butyl alcohol.

Preparation of Allyl Vinyl Ether. Method A.—A solution of 5 g. of mercuric acetate in 602 g. of *n*-butyl alcohol–*n*-butyl vinyl ether azeotrope (90% vinyl ether, 5.4 moles) and 231 g. (3.98 moles) of dry allyl alcohol was distilled slowly through an efficient distilling column. The reflux ratio was so controlled as to remove distillate at 66–68°. After 6 hr., an additional 5 g. of mercuric acetate was added and distillation continued. An additional 14 hr. of distillation was required to carry the reaction to completion. The pot residue was distilled to recover excess *n*-butyl vinyl ether and the *n*-butyl alcohol formed. The product, 282.5 g., b.p. 66–68°, was an azeotrope of allyl alcohol with allyl vinyl ether, containing about 90% by weight of allyl vinyl ether. This azeotrope was stripped of allyl alcohol by washing with water and redistilling, giving allyl vinyl ether of greater than 98% purity, b.p. 67.5°, $n^{20}D$ 1.4109. *n*-Butyl vinyl ether (azeotrope with *n*-butyl alcohol) recovered amounted to 125 g.; *n*-butyl alcohol formed amounted to 339.5 g. The yield of pure allyl vinyl ether based on total alcohol was therefore 75%.

Removal of the last traces of allyl alcohol should not be attempted by distillation out of sodium since allyl vinyl ether reacts with sodium and, to an appreciable degree, rearranges to propenyl vinyl ether, $CH_3CH{=}CHOCH{=}CH_2$, b.p. 61–62°, which is very difficult to remove from allyl vinyl ether.[14]

Preparation of *n*-Octyl Vinyl Ether. Method B.—This and the following three procedures are representative of method B. A solution of 3 g. of mercuric acetate in 65 g. (0.5 mole) of *n*-octyl alcohol and 216 g. (3.0 moles) of ethyl vinyl ether was refluxed for 6 hr. During this period, the liquid temperature of the refluxing solution rose from 39.5 to 42°. Several grams of anhydrous potassium carbonate were then added to the cooled reaction mixture and excess ethyl vinyl ether and ethyl alcohol formed in the reaction were removed at reduced pressure. Distillation of this residue directly out of the carbonate gave 28 g. of crude product, b.p. 64–65° (5 mm.), and 30 g. of recovered *n*-octyl alcohol, b.p. 75–77° (5 mm.). The product, which by analysis was shown to contain 83% by weight of *n*-octyl vinyl ether, was distilled out of sodium to give the pure vinyl ether, b.p. 63–64° (5 mm.), $n^{20}D$ 1.4268. The yield based on total alcohol was 30%, the yield on unrecovered alcohol, 64%.

Preparation of 2-Nitro-2-methylpropyl Vinyl Ether. Method B.—A solution of 5 g. of mercuric acetate and 59.6 g. (0.5 mole) of 2-methyl-2-nitro-1-propanol in 146.2 g. (2.0 moles) of ethyl vinyl ether was heated under reflux for 6 hr. The reaction mixture was then cooled and washed with five 100-cc. portions of water, dried over anhydrous sodium sulfate and flash-distilled at less than 1 mm. pressure into a receiver chilled with Dry Ice until the distillate began to crystallize on the sides of the distilling apparatus. This distillate was fractionated and three cuts totaling 24.9 g., boiling over the range 71–80° (10 mm.), $n^{20}D$ 1.4404–1.4403, were obtained. These cuts were combined and by analysis found to contain 91.4% 2-nitro-2-methylpropyl vinyl ether. The yield was therefore 32%. Purification of the crude product was carried out by heating it with 50% aqueous sodium hydroxide on the steam-bath, diluting with ether, separating and redistilling to give 99.7% pure vinyl ether, b.p. 77–78° (10 mm.), $n^{20}D$ 1.4400.

Anal.[21] Calcd. for $C_6H_{11}O_3N$: C, 49.64; H, 7.64; N, 9.65. Found: C, 49.85; H, 7.55; N, 9.52.

Preparation of 2-(β-Vinoxyethyl)-pyridine. Method B.—A solution of 5 g. of mercuric acetate in 61.5 g. (0.5 mole) of 2-(β-hydroxyethyl)-pyridine (redistilled, b.p. 72° (0.35 mm.)) and 288 g. (4.0 moles) of ethyl vinyl ether was refluxed for 7 hr. The reaction mixture was freed of volatile material at 1 mm. pressure at room temperature and the residue from this process then fractionated to give 29.5 g. of crude product, b.p. 98–110° (22 mm.), active to boron trifluoride. Analysis showed this fraction to contain 80% by weight of 2-(β-vinoxyethyl)-pyridine, representing a 32% yield. This material was dissolved in 50 cc. of ether, washed with seven 10-cc. portions of water, dried and redistilled. The pure vinyl ether distilled at 87–89.5° (10 mm.), $n^{25}D$ 1.5118, d^{25}_4 1.0035, and was 98.4% pure by analysis.

Anal. Calcd. for $C_9H_{11}ON$: C, 72.45; H, 7.43; N, 9.39. Found: C, 72.84; H, 7.44; N, 9.25.

Preparation of 2-Cyanoethyl Vinyl Ether. Method B.—A mixture of 114.1 g. (1.0 mole) of 1,2-divinoxyethane, 35.5 g. (0.5 mole) of ethylene cyanohydrin, 2.0 g. of sodium acetate and 5.0 g. of mercuric acetate was heated under reflux for 2.5 hr. The reaction mixture was cooled and flash-distilled and the distillate fractionated to give several major fractions: 2-methyl-1,3-dioxolane, b.p. 43–44° (18 mm.), 15 g.; recovered 1,2-divinoxyethane, b.p. 71–85° (120 mm.), 42.5 g.; 2-cyanoethyl vinyl ether (95% pure), b.p. 75–85° (20 mm.), 20.5 g. (40% yield). There is no azeotrope formed with this vinyl ether and the alcohol, and it can therefore be purified by refractionation. The 95% crude product from another run in which ethyl vinyl ether was used as the vinylating agent was refractionated to give 100% 2-cyanoethyl vinyl ether, b.p. 79–80° (20 mm.), $n^{20}D$ 1.4335, d^{22}_4 0.9540.

Anal. Calcd. for C_5H_7ON: C, 61.83; H, 7.27; N, 14.44. Found: C, 61.75; H, 7.23; N, 14.37.

A sample of this product was hydrogenated in heptane with Raney nickel catalyst for 3 hr. under 1500 p.s.i. hydrogen at 100–105°.[22] Approximately three moles of hydrogen was absorbed per mole of compound. Fractionation gave material, b.p. 79° (120 mm.), neutralization equivalent by potentiometric titration with standard base, 103.4 (calculated as 3-ethoxypropylamine, 103.2). To purify this product, it was dissolved in 5% hydrochloric acid, extracted with ether, the acid solution made basic with 5% sodium hydroxide and again extracted with ether. The ether extract of the basic solution was dried over anhydrous sodium sulfate, calcium hydride and calcium oxide added and ether distilled off. The residue was put over fresh calcium hydride and fractionated, yielding material, b.p. 74–75° (120 mm.), $n^{20}D$ 1.4186, $n^{25}D$ 1.4166, d^{25}_4 0.8516 (lit.[23] for 3-ethoxypropylamine, $n^{20}D$ 1.4201, d^{20}_{20} 0.8613).

Anal. Calcd. for $C_5H_{13}ON$: C, 58.21; H, 12.70; N, 13.58. Found: C, 58.11; H, 12.65; N, 13.45.

Preparation of 2-Acetoxymercuri-1,1-diethoxyethane.—A slurry of 180 g. (0.565 mole) of mercuric acetate in 550 cc. of absolute ethyl alcohol was prepared, and to this was added 40 g. (0.538 mole) of ethyl vinyl ether with vigorous stirring. The mercuric acetate dissolved immediately, with an accompanying temperature rise to 40°. The solution was cooled to 20°, and a solution of 0.565 mole of sodium ethoxide in 200 cc. of absolute ethyl alcohol was added at such a rate as to keep the reaction temperature below 21°. The reaction mixture was stirred for 1 hr. and filtered and evaporated to dryness under a nitrogen atmosphere. The residue was then taken up in chloroform, filtered and again evaporated, leaving a mass of white fibrous crystals. Recrystallization from hot 30–60° petroleum ether gave 130 g. of product, m.p. 151–154° dec., a yield of 64% based on ethyl vinyl ether and 61% based on mercuric acetate. This

material was stored in a vacuum desiccator over potassium hydroxide pellets.

Anal. Calcd. for $C_5H_{10}O_4Hg$: C, 25.50; H, 4.28; Hg, 53.24. Found: C, 25.3; H, 4.5; Hg, 54.0.

Preparation of 2-Acetoxymercuri-1-methoxy-1-ethoxyethane.—A solution of 4 g. (0.174 mole) of sodium in 100 cc. of dry methyl alcohol was added dropwise to a solution of 20 g. (0.063 mole) of mercuric acetate in 250 cc. of dry methyl alcohol until a reddish-orange precipitate of the basic salt began to appear. Ethyl vinyl ether was then added dropwise until this precipitate just dissolved. Alternate additions of sodium methoxide and ethyl vinyl ether were made in this manner until further addition of sodium methoxide failed to precipitate the basic salt. The solution was then evaporated to dryness under vacuum. The residue was taken up in chloroform, filtered to remove sodium acetate and the chloroform solution again evaporated under vacuum. The crystalline residue was recrystallized from 30–60° petroleum ether. About 0.5 g. of this product was tested for catalytic activity, and another small portion was dried in vacuum over phosphoric anhydride, m.p. 56–57°.

Anal. Calcd. for $C_7H_{14}O_4Hg$: Hg, 55.30. Found: Hg, 55.97.

The remainder of the product was stored in a tightly-capped bottle in the refrigerator. Examination of this material after about 7 months showed that it had decomposed largely into free mercury and a colorless two-phase liquid. Fractionation of the liquid gave 2 g., b.p. 31–36°, which had a slight odor of acetaldehyde but was mostly wet ethyl vinyl ether, and 6 g., b.p. 46.5–62°, which probably contained dimethyl acetal.

Decomposition of 2-Acetoxymercuri-1,1-diethoxyethane.—A slurry of 60 g. (0.16 mole) of this compound in 300 cc. of *n*-heptane was brought to gentle reflux on an efficient distilling column. An equimolar amount of glacial acetic acid was then added dropwise to this refluxing slurry over a 45-minute period. The solids in the pot turned from a white to a cream color after this addition, and after 1.5 hr. of reflux, the vapor temperature settled at 36°. Slow fractionation gave 3 g. of 94% pure ethyl vinyl ether. Further fractionation gave 22 g. over the range 40–98°, containing 16.5% ethyl vinyl ether and including a large amount of distillate, b.p. 69–70°, which was the azeotrope of ethyl alcohol with *n*-heptane. The total yield of ethyl vinyl ether was therefore 56%. No free mercury appeared during this distillation until the vapor temperature had reached 70°. All attempts to determine the form in which mercury was present in the distillation residue were unsuccessful, but it appeared that no simple salts of mercury were formed.

Homogeneous Metal Salt Catalysis in Organic Reactions. II. The Reaction of Vinyl Ethers with Aminoalcohols and 1,2-Diamines

BY WARREN H. WATANABE

RECEIVED NOVEMBER 2, 1956

When aminoalcohols, $RNH(CR_2)_nOH$, in which R is H, alkyl or aryl and n is 2 or 3, are treated with alkyl vinyl ethers in the presence of mercuric salts of weak acids or silver salts such as silver nitrate or silver acetate, there are formed in good yield 2-methyloxazolidines (I, n = 2) or 2-methyltetrahydro-1,3-oxazines (I, n = 3). Similarly, 1,2-diamines, treated with alkyl vinyl ethers with the same catalysts, give 2-methylimidazolidines (II). These new reactions are improved methods of preparation of these relatively unstable compounds. The relation of these reactions to vinyl transetherification[1] is discussed and a mechanism is proposed.

In a previous publication we have described a method of preparation of vinyl ethers by the reaction

$$ROCH{=}CH_2 + R'OH \rightleftarrows ROH + R'OCH{=}CH_2 \quad (1)$$

which is catalyzed by mercuric salts of weak acids.[1] We have now found that when the alcohol R′OH is an aminoalcohol, $RNH(CR_2)_nOH$, in which R is H, alkyl or aryl group and n is 2 or 3, reaction 1 takes a quite different course. The products in these instances are 2-methyloxazolidines (I, n = 2) or 2-methyltetrahydro-1,3-oxazines (I, n = 3) rather than the vinyl ethers

$$ROCH{=}CH_2 + R'NH(CR_2)_nOH \;(n = 2,3) \longrightarrow \text{I} + ROH \quad (2)$$

We have been able also to extend this reaction to 1,2-diamines, whereby 2-methylimidazolidines are formed

$$ROCH{=}CH_2 + R'NHCH_2CH_2NHR'' \longrightarrow \text{II} + ROH \quad (3)$$

The yields of the cyclic compounds prepared by this method range from about 40 to greater than 80% and are limited largely by the stability of these compounds. This new reaction thus is a simple, useful and generally preferable alternative to the standard method of preparation of I and II, which is by reaction of the aminoalcohols[2] or diamines[3] with acetaldehyde.

Catalysts.—The same catalysts found to be effective in our previous study of vinyl transetherification (*i.e.*, mercuric salts of carboxylic acids[1]) were also the most efficient catalysts for the present reaction. It was of interest that mercuric sulfate, which is a very active catalyst for vinyl transetherification at very low temperatures,[4] had no activity for reaction 2 and, probably due to the strongly basic nature of the reaction mixture, had no effect at all on the vinyl ether. Moreover, in contrast to the vinyl transfer reaction 1, for which mercuric salts are highly specific catalysts, the present reaction also was found to be catalyzed by silver nitrate and silver acetate. Zinc acetate,

cadmium acetate, cuprous chloride and ammonium chloride were found, under our testing conditions, to be without activity. The mercury salts were, however, preferable to the silver salts, because the latter underwent more extensive decomposition, accompanied by rapid loss in catalyst activity.

Reaction Procedures.—In Table I there are listed the compounds which have been prepared by reactions 2 and 3. The alkyl vinyl ethers used were those conveniently available and readily separable from the products of reaction. Catalysts generally used were mercuric acetate or mercuric benzoate; silver acetate and silver nitrate were tested in single reactions solely to demonstrate their activity.

Of the two methods used to carry out reaction 2, the more useful was the one in which the product was removed by distillation from the reaction mixture as rapidly as it was formed. Continuous removal was of particular advantage in that 2-methyloxazolidines (or the tautomeric Schiff bases, in the case of compounds I where R′ = H) are rapidly converted to condensation products at elevated temperatures.[5] This procedure (method A in Table I) is possible since 2-methyloxazolidines and 2-methyltetrahydro-1,3-oxazines have boiling points lower than their parent aminoalcohols. By choice of a high-boiling vinyl ether as the vinyl ether component, a system usually can be devised such that the lowest-boiling component will be the product, which can then be removed rapidly by distillation. Yields by this method are indeed to a large extent determined by the efficiency and speed at which this separation can be effected. It is certainly this possibility of continuous rapid removal of product which results in higher yields by this reaction than from the alternative method of preparation from acetaldehyde, in which the product cannot be removed until reaction is complete.

This distillation method loses its utility, however, when the product is very high-boiling (*e.g.*, 2-methyl-3-phenyloxazolidine), since an even higher-boiling vinyl ether would have to be employed. Fortunately, the phenyl compound proved to be relatively stable and could thus be obtained in good yield by heating the reactants under reflux (method B in Table I). The reflux procedure also was used in the preparation of 2-methylimidazolidines since the boiling points of these compounds are almost identical with those of the starting diamines, and the products cannot therefore be separated by distillation. Separation by crystallization could, however, be effected, since the imidazolidines had melting points higher than those of the starting diamines.

Discussion

A point of particular interest in the present work is the problem of whether reactions 2 and 3 proceed in a single step, or in two discrete steps, with a vinyl compound as an intermediate. There are substantial arguments for both hypotheses, but we believe that the preponderance of present evidence is in favor of a single-step mechanism. In support of a two-step mechanism are these points: (1) It already has been shown that mercuric salts of weak acids will catalyze vinyl transetherification.[1] It also has been found that aminoalkyl vinyl ethers can be cyclized by both mercuric and silver salts to oxazolidines and tetrahydro-1,3-oxazines.[6] Thus the two possible separate steps of a two-step mechanism (vinyl transetherification, followed by cyclization) are known reactions. (2) We moreover estimate, from the relative amounts of catalyst required for a sensible rate of reaction at room temperature, that cyclization proceeds much more rapidly than vinyl transetherification. Thus the exclusive isolation of the cyclic product is consistent with the probable relative rates of the presumed two steps.

Arguing against a two-step mechanism, however, are the following points: (1) the rate of the over-all reaction 2 or 3 is estimated, again purely on the basis of relative amounts of catalyst required for reasonable rates at room temperature, to be greater by at least a factor of five than vinyl trans-

(5) W. S. Emerson, S. M. Hess and F. C. Uhle, THIS JOURNAL, **63**, 872 (1941), have shown that aliphatic Schiff bases undergo aldol-type condensations, splitting off amine. H. R. Nace and E. P. Goldberg, *ibid.*, **75**, 3646 (1953), conclude from infrared evidence that 2-propyl-4-ethyloxazolidine, which polymerizes and changes rapidly in refractive index on standing, does so through an aldol-type condensation.

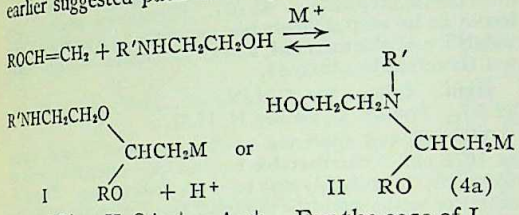
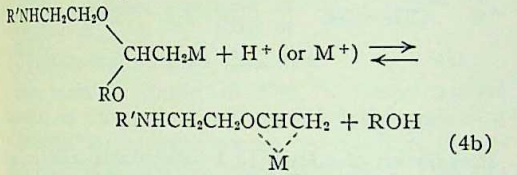
etherification. If this is the case, the transetherification cannot then be an intermediate step. (2) The two-step mechanism does not accommodate the 1,2-diamine reaction (3), unless an –O–vinyl to –NH transfer can occur. There is no reported reaction of such a type. (3) The two-step mechanism does not accommodate silver salt catalysis, since it has been found that silver salts do not catalyze vinyl transetherification.[1]

A possible one-step mechanism would be the following, which is patterned closely after our earlier suggested path for vinyl transetherification

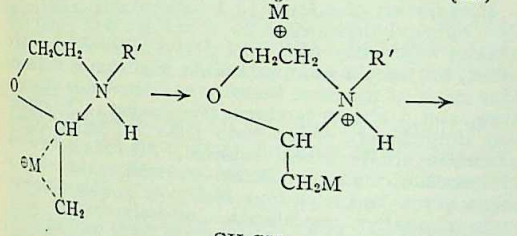


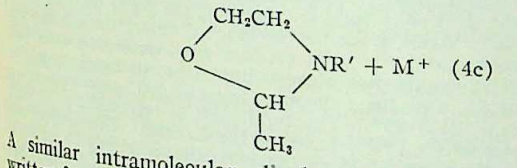
(4a)

where $M^+ = HgOAc^+$ or Ag^+. For the case of I



(4b)





(4c)

A similar intramolecular displacement can be written for II. We are, however, much less satisfied with the above postulate of a stable intermediate I or II in this reaction than in the case of vinyl transetherification where a similar intermediate was proposed, since essentially all of the metal salt should be complexed with the amine, leaving little available for covalent metal–carbon bond formation. It is nevertheless necessary that the metal salt in some manner activate the formation of a new O–C bond and, in lieu of a more sturdy alternative, we suggest reaction through such intermediates as I or II. It is, of course, possible that the steps (4a-c) take place simultaneously, in a single concerted process, obviating the necessity for the formation of any long-lived intermediates.

Experimental

Materials.—The aminoalcohols and diamines used were commercially available materials and were redistilled or recrystallized before use. 1,2-Divinoxyethane was prepared by the base-catalyzed reaction of acetylene with ethylene glycol.[7] The other vinyl ethers were commercially available and were purified by distillation. The metal salts were reagent grade chemicals, used as received.

General Comments.—Those compounds prepared where R = H and $n = 2$ in I (no substitution on the nitrogen of the 2-methyloxazolidines) were, with the exception of 2,4,4-trimethyloxazolidine, relatively unstable substances which became viscous upon standing, even in the cold.[5,8] There was thus an unavoidable loss upon the redistillation of the first crude product, and yields are therefore given for both the crude and redistilled product. As one consequence of the instability of these compounds, both $n^{25}D$ and d^{25}_4 values changed rapidly with time, and while every attempt was made to measure these values as quickly as possible, not too much reliance should be placed on these constants. Those compounds with N-substitution, or when $n = 3$, were much more stable, and the constants reported for them are more reliable. However, these substances will also darken and decompose slowly if left at room temperature.

Catalyst Testing.—The reaction of N-methylethanolamine and 1,2-divinoxyethane, which with mercuric acetate as catalyst gives about a 70% yield of 2,3-dimethyloxazolidine, was used as the standard reaction for the testing of various metal salts for catalytic activity. By this test mercuric acetate, mercuric benzoate, silver nitrate and silver acetate were found to be active, and mercuric sulfate, cuprous chloride, zinc acetate, cadmium acetate and ammonium chloride were found to be inactive. Recoveries of 1,2-divinoxyethane from tests on inactive substances ranged from 89 to 99% (recovery from the mercuric sulfate run, 99%).

Preparation of 2,5-Dimethyloxazolidine.—A cloudy, two-phase mixture resulted when 1-aminopropanol-2 (77.1 g., 1.03 moles) was mixed with 2-butoxyethyl vinyl ether (171.9 g., 1.19 moles). When 1 g. of mercuric benzoate was added, however, and dissolved by vigorous shaking, the mixture became homogeneous and an exotherm resulted which quickly brought the temperature of the solution to about 50°. The solution was therefore cooled and placed on a distillation column. An initial product cut, b.p. 55–68.5° (100 mm.), was taken, the distilling flask cooled and 1 g. of mercuric benzoate added to the reaction mixture; a second product cut taken at 65.5–70° (100 mm.) and the flask again cooled and another 1 g. of mercuric benzoate added; and a final product cut taken at 66–67°/100 mm. The weight of combined crude product was 55.1 g., a crude yield of 53%. Continued distillation of the reaction mixture yielded 117.6 g. of 2-butoxyethanol, b.p. 72–75° (20 mm.), 61–61.5° (10 mm.), a yield based on the aminoalcohol of 97%. The crude product was redistilled, giving 34.0 g. of pure 2,5-dimethyloxazolidine, b.p. 62.5–64.5° (100 mm.), $n^{25}D$ 1.4366, d^{25}_4 0.9371, which was thus obtained in 33% yield.

Anal. Calcd. for $C_5H_{11}ON$: C, 59.37; H, 10.96; N, 13.85. Found: C, 59.94; H, 11.36; N, 13.75.

2-Methyl-4-ethyloxazolidine was prepared by essentially the same method: $n^{25}D$ 1.4407, d^{25}_4 0.9219. *Anal.* Calcd. for $C_6H_{13}ON$: C, 62.57; H, 11.37; N, 12.16. Found: C, 62.70; H, 11.28; N, 11.85.

2,3-Dimethyloxazolidine was also prepared in a similar manner: $n^{25}D$ 1.4200, d^{25}_4 0.9001. *Anal.* Calcd. for $C_5H_{11}ON$: C, 59.37; H, 10.96; N, 13.85. Found: C, 59.38; H, 10.74; N, 13.77.

2,4,4-Trimethyloxazolidine.—This was prepared by both methods A and B: $n^{25}D$ 1.4240, d^{25}_4 0.8904. *Anal.* Calcd. for $C_6H_{13}ON$: C, 62.57; H, 11.37; N, 12.16. Found: C, 62.82; H, 11.49; N, 12.04.

The infrared spectrum of the product was determined and showed that this material was identical with 2,4,4-trimethyloxazolidine, prepared otherwise by the reaction of acetylene with 2-amino-2-methylpropanol-1.[9] There was no absorption in the double bond region, indicating first, that there was less than 0.5% of a vinyl ether present and, second, that this compound must exist entirely in the cyclic form and not as a Schiff base. This lack of any appreciable amount of a Schiff base tautomer is probably the reason why this compound is so much more stable than the other oxazolidines (I), with R = H, which we have prepared, and which all show evidence of existing at least partially in the Schiff base form.[9] The lack of vinyl ether is particularly signifi-

cant, since both the oxazolidine and the isomeric vinyl ether have identical boiling points[9] and no fractionation could have occurred by distillation if both these compounds had been formed in the reaction. Moreover, if the reaction proceeds in two steps, then the presumed first step (vinyl transetherification) would not be appreciably hindered sterically, whereas the presumed second step (cyclization) should be seriously hindered. Thus, this example is a particularly favorable case for isolation of the vinyl ether if any had formed.

2-Methyltetrahydro-1,3-oxazine was prepared by both methods A and B: $n^{25}D$ 1.4407, d^{25}_4 0.9459. *Anal.* Calcd. for $C_5H_{11}ON$: C, 59.37; H, 10.96; N, 13.85. Found: C, 59.57; H, 11.00; N, 13.59.

Preparation of 2-Methyl-3-phenyloxazolidine.—N-Phenylethanolamine (141.5 g., 1.03 moles) was dissolved in 86.3 g. (1.20 moles) of ethyl vinyl ether and 1 g. of mercuric acetate added to this solution. The solution warmed spontaneously and began to boil before all the mercuric salt had gone into solution. It was immediately placed under a reflux condenser and heated under reflux for 2 hr. During this period, the reaction temperature rose from 45 to 78°. The reaction mixture was then poured into a beaker and chilled in ice, whereupon it set to a crystalline mass. The solid was removed by filtration and recrystallized from ethyl alcohol, giving 143.8 g. of 2-methyl-3-phenyloxazolidine, m.p. 58–59°, a yield of 85.5%. This product was recrystallized again from 30–60° petroleum ether, resulting in 107.5 g. of pure product (64% yield), m.p. 58.5–59°. A final recrystallization from 85–100° petroleum ether gave an analytical sample, m.p. 59–59.5° (lit.[20] 60.5–61°).

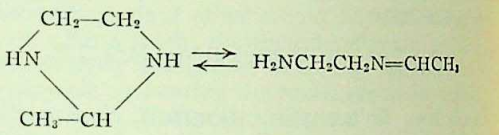
Anal. Calcd. for $C_{10}H_{13}ON$: C, 73.59; H, 8.03; N, 8.58. Found: C, 73.62; H, 7.89; N, 8.54.

Preparation of 2-Methylimidazolidine.—Ethylenediamine (65.5 g., 1.09 moles) was dissolved in 133.5 g. (1.85 moles) of ethyl vinyl ether and 1 g. of mercuric benzoate added to this solution. The mercuric salt dissolved only partially even with vigorous shaking; there was no immediate exotherm. The mixture was then heated under reflux for 8 hr. During this period the pot temperature rose from 42 to 51°, and almost all of the mercuric salt went into solution, accompanied by the formation of some globules of mercury. The solution was cooled and left overnight at room temperature. On the following day another 1 g. of mercuric benzoate was added. This time the mercuric salt went rapidly and completely into solution. Reflux was resumed, and over a 1-hr. period the pot temperature rose from 51.5 to 60°. The solution was then cooled and flash-distilled at about 0.5 mm. pressure into a receiver cooled with Dry Ice–acetone. The first cut of this flash-distillation, 66.9 g., was obtained without heating the distilling flask; this cut was terminated when a solid material started to plug the outlet of the take-off tube. A wide-bore outlet was then utilized, and a second cut was taken by heating the distilling flask to a maximum liquid temperature of 73°. This second fraction, 107.7 g., was partly solid at room temperature, but the solid soon dissolved in the liquid portion. The residue weighed 18.1 g.

The second fraction was overlaid with about twice its volume of 100–140° petroleum ether, well shaken, and chilled in Dry Ice–acetone to induce crystallization. The crystals were filtered under nitrogen from the resultant two-phase liquid mixture. The filtrate was again chilled, and the solid which formed again filtered off under nitrogen. This procedure was repeated about six times until no further crystallization occurred. The combined solid product was dried under vacuum at room temperature. The yield of this once-crystallized product, m.p. 46–49°, was 38.4 g., 41% based on the diamine. This material was recrystallized out of 30–60° petroleum ether to obtain an analytical sample, which was a white, very volatile, hygroscopic solid, m.p. 47.5–48.5°. Potentiometric titration of this sample with standard 0.1 *N* HCl gave replicate values of 43.39 and 42.91 for the neutralization equivalent (theor. for 2-methylimidazolidine, 43.07). Elementary analysis was found to be very difficult because of the hygroscopicity and volatility of the material, and an analysis for nitrogen could not therefore be obtained.

Anal. Calcd. for $C_4H_{10}N_2$: C, 55.77; H, 11.70; N, 32.53. Found: C, 56.36; H, 11.57.

The infrared spectrum of this compound showed bands at 1670 cm.$^{-1}$ attributable to —C=N— stretching, and at 1595 cm.$^{-1}$, probably due to $-NH_2$ deformation. These results are consistent with the Schiff base form of the imidazolidine



Preparation of 2-Methyl-1,3-diphenylimidazolidine.—N,N′-Diphenylethylenediamine (100.9 g., 0.48 mole) was shaken vigorously with 72.0 g. (1.0 mole) of ethyl vinyl ether, but only a small part of the solid diamine dissolved. One gram of mercuric benzoate was dissolved in this mixture, and a strong exotherm then resulted. The mixture was immediately placed under reflux and heating applied when the initial exotherm subsided. After 21 min. of reflux almost all of the solid had gone into solution and the liquid temperature had risen from 35.5 to 49°. Almost immediately thereafter crystallization suddenly occurred, filling the flask with solid and lowering the liquid temperature to 42°. After a further 40 min. of reflux, the mixture was cooled and the solid product dried under vacuum. Part of this solid was recrystallized from methanol, m.p. 90–91.5°, and the remainder from 85–100° petroleum ether, m.p. 91.5–95°. The total yield of recrystallized product was 93.4 g., 82% based on the diamine. This product was further recrystallized out of methanol, giving 75 g. (66% yield) of pure 2-methyl-1,3-diphenylimidazolidine, m.p. 92–93.5° (lit.[20] 98–100°), ebulliometric molecular weight, 226 (theor. 238).

Anal. Calcd. for $C_{16}H_{18}N_2$: C, 80.63; H, 7.61; N, 11.76. Found: C, 80.40; H, 7.47; N, 11.76.

Synthetic Hypotensive Agents. V. 4-(2′-Aminoethyl)-piperidine Derivatives

BY ARTHUR P. PHILLIPS

RECEIVED DECEMBER 19, 1956

A series of 4-(2′-aminoethyl)-piperidines has been prepared for testing for hypotensive ganglionic blocking activity. The most active compound in the series was comparable in activity to hexamethonium.

Following the discovery[1,2] of ganglionic blocking activity in 1-methyl-3-(4′-dimethylaminobutyl)-piperidine (I) and its bis-quaternary ammonium salts, several series of compounds[3] modelled after I have been prepared and tested for this kind of activity. The present paper reports the preparation and properties of another series of compounds structurally related to I. These are some 4-(2′-aminoethyl)-piperidine derivatives which can be represented by the general formula II. The products were made by the sequence of reactions shown

R = H or CH_3; N(R′)(R′) = $(CH_3)_2N$, $(C_4H_9)_2N$, pyrrolidine, piperidine or morpholine; R″X = HCl, CH_3I or C_2H_5I, etc.

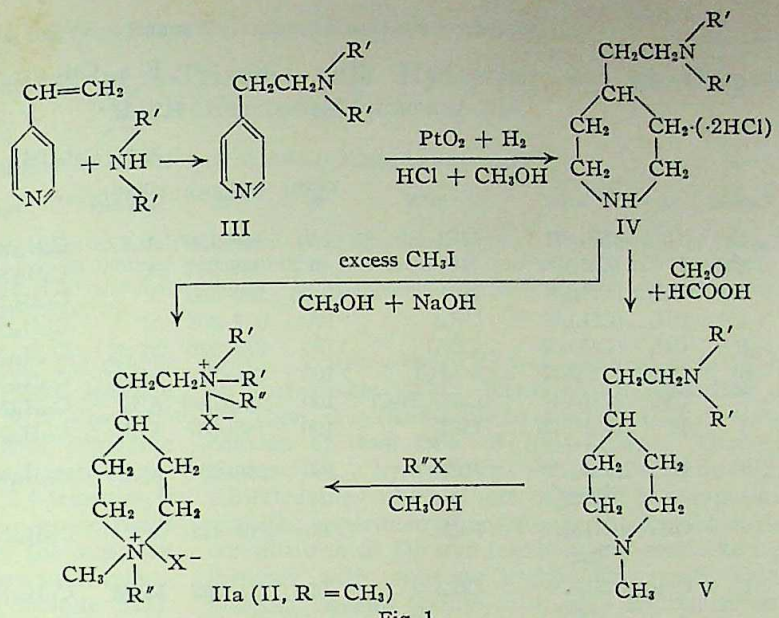

Fig. 1.

The reactions shown in Fig. 1 were carried through on the products obtained by the addition of dimethylamine, diethylamine, pyrrolidine, piperidine and morpholine to 4-vinylpyridine. The addition of amines to 4-vinylpyridine has been described in some detail earlier[4] and needs no further comment here.

The dihydrochlorides of the 4-(2′-aminoethyl)-pyridines (III) were hydrogenated in methanol solution using Adams catalyst, at about three to four atmospheres of hydrogen pressure and room temperature. Hydrogen uptake was usually slow, but high yields of the 4-(2′-aminoethyl)-piperidines (IV) were obtained.

Methylation of the 4-(2′-aminoethyl)-piperidines (IV) by the well-known Eschweiler[5]–Clarke[6] procedure gave the N-methyl-bis-tertiary amines V. The latter, V, were quaternized by refluxing with excess of the appropriate alkyl halide in methanol solution and gave the products IIa. When the products IIa were to be quaternized with methyl iodide, they could be obtained by an alternative route, the direct methylation of the compounds IV using excess methyl iodide in methanol in the presence of at least one equivalent of alkali.

The physical and analytical data for all the compounds are listed in Table I.

Pharmacology.—These 4-(2′-aminoethyl)-piperidines resemble the 3-(4′-dimethylaminobutyl)-piperidines (such as I) structurally. The new compounds differ in the point of attachment and the length of the side chain on the piperidine ring. With an inter-nitrogen chain of five carbons they are pentamethonium rather than hexamethonium analogs. Both the bis-tertiary amines and the derived bis-quaternary salts showed ganglionic blocking activity in cats; usually, however, the hypotensive effects were of a low order and of brief duration. Only the diethiodide and dimethiodide of the 4-(2′-pyrrolidinoethyl)-piperidine (compounds 12 and 11 of Table I) approached I and hexamethonium in potency. Thus the diethiodide (compound 12) at 2 mg./kg. gave a 50% lowering of blood pressure lasting for 1 hr.

The best of the bis-tertiary amines, 1-methyl-4-(2′-pyrrolidinoethyl)-piperidine (compound 10, Table I) gave a comparable blood pressure lowering but of shorter duration only at 8 mg./kg.

A more detailed report on the pharmacology of these compounds will appear elsewhere.

Acknowledgment.—The author is indebted to S. W. Blackman for the microanalyses included.

Experimental

Typical procedures for each of the general types of reactions are described below.

The addition of amines to 4-vinylpyridine proceeded very well in most cases and the details of these reactions have been described fully elsewhere.[4]

Catalytic Hydrogenation of 4-(2′-Pyrrolidinoethyl)-pyridine Dihydrochloride (Compound 9, Table I).—A solution containing 5 g. (0.02 mole) of 4-(2′-pyrrolidinoethyl)-pyridine dihydrochloride (m.p. 214–216°) in 150 cc. of methanol and 0.2 g. of Adams catalyst was shaken in a Burgess–Parr type machine at 3–4 atmospheres of hydrogen pressure and room temperature. The theoretical amount of hydrogen (0.06 mole) was absorbed over 5 hr. After removal of the platinum the filtrate was concentrated by evaporation and the product was crystallized by the addition of ethyl acetate. After several recrystallizations from ethanol–ethyl acetate mixtures, 5 g. (>95%) of white crystalline product was obtained, m.p. 266–267°.

Eschweiler–Clarke Methylation of 4-(2′-Dimethylaminoethyl)-piperidine (Compound 3, Table I).—After liberation of the oily base from its dihydrochloride, 8 g. (0.05 mole) of 4-(2′-dimethylaminoethyl)-piperidine was carefully neutralized by and dissolved in 10 cc. of 98–100% formic acid with cooling. About 10 cc. of 35–37% formalin was added at once and the mixture was heated for 2 hr. on a steam-bath. Another 5 cc. each of formic acid and formaldehyde solution was added and heating was continued for 2 hr. longer. An excess (15 cc.) of concentrated hydrochloric acid was added and the solution was evaporated to dryness. The residual solid was purified by several recrystallizations from hot ethanol and then gave 10 g. (85%) of white crystals, m.p. 299–300°. This was the dihydrochloride of 1-methyl-4-(2′-dimethylaminoethyl)-piperidine.

[a] A = ethanol; Ac = acetone; Aq = water; Æ = ethyl acetate; E = ether; M = methanol. [b] Made by catalytic hydrogenation of the 4-(2′-aminoethyl)-pyridine dihydrochloride. [c] From the secondary amine with formic acid and formalin. [d] From the secondary amine, excess methyl iodide and sodium hydroxide. [e] From the ditertiary amine and alkyl halide. [f] $(CH_2)_4N$ is the pyrrolidino group. [g] $(CH_2)_5N$ is the piperidino group. [h] $O(C_2H_4)_2N$ is the morpholino group.

1-Methyl-4-(2′-dimethylaminoethyl)-piperidine Bis-*n*-propiodide (Compound 6, Table I).—The oily base was liberated from the dihydrochloride described above. A solution of 1.7 g. (0.01 mole) of this base was refluxed with 5 cc. of *n*-propyl iodide in 50 cc. of methanol for 18 hr. (overnight). Evaporation of part of the methanol and addition of acetone gave 5.1 g. (100%) of white crystalline product. After recrystallization from ethanol the purified product melted at 214–215°.

1-Methyl-4-(2′-piperidinoethyl)-piperidine Bis-methiodide (Compound 15, Table I). By Alkylation of the Secondary Amine with Excess Methyl Iodide.—A solution of 2 g. (0.01 mole) of the base, 4-(2′-piperidinoethyl)-piperidine, in 50 cc. of methanol with 5 cc. of methyl iodide was refluxed for 2 hr. Another 5 cc. of methyl iodide and a solution of 1 g. of sodium hydroxide in 50 cc. of methanol were added and refluxing was continued for 3 hr. The reaction mixture was evaporated to dryness *in vacuo* and sodium iodide was removed by washing the solid residue with several 25-cc. portions of acetone. This procedure left 5 g. (100%) of white crystals. These were purified by crystallization from methanol and melted at 290–291°.

Triazines. XIX. Some Reactions of s-Triazine with Hydrazine and its Organic Derivatives

BY CHRISTOPH GRUNDMANN AND ALFRED KREUTZBERGER[1,2]

RECEIVED JANUARY 7, 1957

s-Triazine (I) is cleaved by anhydrous hydrazine to 1,2-diformylhydrazine dihydrazone (IV). The reactions of IV with carbonyl compounds and acetic anhydride, and its thermal decomposition to 4-amino-1,2,4-triazole and 1,2,4-triazole are described. I and aromatic hydrazines yield N,N′-diaryl-formazans. Semicarbazide, thio-semicarbazide and aminoguanidine lead to the corresponding 1,2,4-triazole derivatives.

We recently reported that *s*-triazine (I) reacts easily with primary amines with complete cleavage of the ring forming ammonia and N,N′-disubstituted formamidines.[3a] The reaction of *s*-triazine with the hydrohalides of hydrazine and monoalkyl- or monoaryl hydrazines leads to 1,2,4-triazoles.[3b] It was anticipated that free hydrazine would react like primary amines. In this case, the reaction product should be the as yet unknown formhydrazide hydrazone (II) or formamide hydrazone (III). In fact, a mixture of *s*-triazine and anhydrous hydrazine reacts even at room temperature. The reaction becomes very vigorous on gentle heating and consequently is better performed in an inert diluent. The product, m.p. 122–123° dec., is formed in good yield and has been shown to be identical with a compound obtained long ago from hydrocyanic acid and hydrazine,[4] and not the expected II or III. The earlier procedure gave only very small yields, our reaction makes this interesting compound readily accessible. On the basis of their degradation experiments, Müller and Herrdegen assigned to this product the formula 1,2-diformylhydrazine dihydrazone (IV). Their findings, however, would also be compatible with the structures II and III. Since IV is, by elementary analysis, almost indistinguishable from III and since molecular weight determinations gave somewhat erratic results because of the instability of this compound, much effort was spent on proving its constitution. With picric acid under various conditions, only hydrazine picrate was isolated. Ethereal hydrogen chloride formed a dihydrochloride which was stable on storage in contrast to the parent compound IV. In water, however, the dihydrochloride was easily hydrolyzed and underwent extensive decomposition. Benzoylation of IV yielded only N,N′-dibenzoylhydrazine. The compound IV condensed readily with carbonyl compounds. The dibenzal derivative V already has been described,[4] but is not very suitable for the characterization of IV because of its instability. The product from acetone appears to be the best. The 1,2-diformylhydrazine bis-(isopropylidenehydrazone) (VI) is a fairly stable and recrystallizable compound which, however, is difficult to obtain analytically pure as is the dibenzal derivative. Contrary to V, VI was obtained from IV in an appreciable yield. Based on the formation of VI, then, it is reasonable to conclude that IV must contain at least two $-N-NH_2$ groups. This excludes IVa, a hydrazinium salt of 1,2-dihydro-1,2,-4,5-tetrazine,[5] which otherwise would be compatible with the experimental findings.[6] Final proof of the constitution of IV was found in the complete hydrolysis with aqueous hydrochloric acid which yielded, besides formic acid, only hydrazine and no ammonia. This result definitely excludes formula III for the primary reaction product from hydrazine and *s*-triazine.

The formation of 1,2-diformylhydrazine dihydrazone (IV) from *s*-triazine and hydrazine could be explained by the assumption that, at first, in a normal cleavage of the *s*-triazine ring, three moles of formhydrazide hydrazone (II) are formed

$$C_3H_3N_3\,(I) + 6N_2H_4 = 3C_6H_2H_4\,(II) + 3NH_3$$
$$2CH_6H_4\,(II) = C_2H_8N_6\,(IV) + N_2H_4$$

and then two moles of the unstable intermediate II condense with loss of hydrazine to IV.

The 1,2-diformylhydrazine dihydrazone (IV) is light sensitive , turning pink, especially in the presence of air. This color is due apparently to the formation of 1,2,4,5-tetrazine (VIII), since the coloring matter is readily soluble in ether and volatile with the vapors of this solvent.[5,7] The first stage of this light-induced decomposition of IV is presumably the formation of 1,2-dihydro-1,2,4,5-tetrazine (VII)—or an isomer thereof—which then suffers dehydrogenation either spontaneously or by air oxidation. That, in fact, VII can easily be formed from IV is demonstrated by the reaction of IV with acetic anhydride. This leads to a product to which we have assigned the structure 1,2-diacetyl-1,2-dihydro-1,2,4,5-tetrazine (IX). The other possible constitution, 4-diacetylamino-1,2,4-triazole (X), is excluded by the synthesis of X from 4-amino-1,2,4-triazole (XII) and acetic anhydride, which yields a compound quite different from IX. Furthermore, IX is hydrolyzed readily by methanolic potassium hydroxide and the resulting intense red-colored solution presents, by its reactions, strong evidence for the presence of 1,2,4,5-tetrazine. 1,2,4,5-Tetrazine has not yet been isolated from the light-induced degradation products of IV, however. This failure stems partly from the in-

herent difficulty in isolating small quantities of such a volatile and sensitive substance as VIII, and also from the presence of another route of spontaneous decomposition of IV.

This second route of decomposition proceeds even in the dark and in a vacuum. It converts the hydrazoformaldehyde dihydrazone within several days at room temperature into a brownish, viscous oil. By fractional vacuum sublimation, we were able to isolate hydrazine, 1,2,4-triazole (XI, 38%), and 4-amino-1,2,4-triazole (XII, 15%) from this oil. The latter compound already has been noticed by Müller and Herrdegen among the thermal degradation products of IV.

While the formation of XII is easily understandable as the result of a ring closure of IV with the loss of one molecule of hydrazine, an explanation of the formation of XI seems much more difficult because it demands a reductive step in one or another phase of the self-decomposition of IV. At first, we made certain that 1,2,4-triazole is not an artificial product resulting from our mode of isolating the reaction product. 4-Amino-1,2,4-triazole is not converted into 1,2,4-triazole under the conditions of our experiments, either thermally or by the reductive action of hydrazine. The assumption that IV itself is reduced to formamide hydrazone (III), either by hydrazine, always present in the decomposing mixture, or by an internal oxidation–reduction process,[8] seems to be the only way to explain our results. That such a process may occur during the spontaneous decomposition of IV is indicated by a constant evolution of ammonia from the decomposing mixture. This ammonia can only stem from the reaction $2N_2H_4 = 2NH_3 + N_2 + H_2$, which yields the necessary reductive equivalent for the conversion of IV into III. Two molecules of this hypothetical intermediate III could then decompose to 1,2,4-triazole (XI) by loss of one molecule of ammonia and one molecule of hydrazine. By loss of two molecules of ammonia III could also yield 4-amino-1,2,4-triazole (XII).

Substituted hydrazines, as the free bases, react quite differently from the parent compound. In the first step aromatic hydrazines, like phenylhydrazine, apparently form diaryl-formhydrazide hydrazones (XV), which are not isolable but undergo spontaneous oxidation, either by air or by excess arylhydrazine, to the stable, intensively colored N,N′-diphenylformazans (phenylazo-formaldehyde phenylhydrazones). This reaction was successfully carried out with phenylhydrazine, *p*-bromophenylhydrazine and *p*-nitrophenylhydrazine, to yield the formazans XVIa, XVIb and XVIc. While the cleavage of *s*-triazines by primary amines is restricted to the parent compound, aromatic hydrazines cleave besides the parent compound I also trialkyl- and triaryl-*s*-triazines in the same way. From 2,4,6-trimethyl-*s*-triazine (Ia) we obtained the N,N′-diphenyl-C-methyl-formazan (XVId) and from 2,4,6-triphenyl-*s*-triazine (Ib) the N,N′-diphenyl-C-phenylformazan (XVIe).

With disubstituted hydrazines, less clear results were obtained. *asym*-Dimethylhydrazine reacts with *s*-triazine in a manner strictly analogous to a primary amine, yielding in this case the 1-formyl-2,2-dimethylhydrazine 2,2-dimethylhydrazone (XIII), the parent compound of which II is not known. With 1-methyl-1-phenylhydrazine, how-

(8) Reduction of hydrazo compounds by hydrazine derivatives to the corresponding amino compounds has been observed on different occasions, *cf.* R. Walther, *J. prakt. Chem.*, [2] **52**, 141 (1895); H. Beyer and G. Wolter, *Chem. Ber.*, **85**, 1075 (1952).

ever, the reaction proceeds only half-way. Without elimination of ammonia, but with breakdown of the *s*-triazine ring the N^3-methylphenylformamidrazone (XIV) is formed as the sole product. Even with a large excess of 1-methyl-1-phenylhydrazine and elevated temperatures, it was impossible to force the reaction to the tetra-substituted hydrazine derivative analogous to XIII. No explanation can be given at present for this striking difference in reactivity between the *asym*-dimethyl- and the 1-methyl-1-phenylhydrazine. As expected, symmetrically disubstituted hydrazines which do not contain an NH_2 group do not react with *s*-triazine under these conditions.

Among other hydrazine derivatives we have investigated the reaction of semicarbazide (XVII), thiosemicarbazide (XIX) and aminoguanidine (XXI) with *s*-triazine. In all cases these derivatives react as described previously for *o*-substituted diamines,[3a] forming, with cleavage of the triazine ring and liberation of ammonia, the corresponding 3-substituted-1,2,4-triazoles, 3-hydroxy-1,2,4-triazole (XVIII), 3-mercapto-1,2,4-triazole (XX) and 3-amino-1,2,4-triazole (XXII). It is interesting to note that in the case of XVII and XIX no formation of other possible products of ring closure, namely, 2-amino-1,3,4-oxadiazole (XXIII) and 2-amino-1,3,4-thiadiazole (XXIV) could be detected.[9]

Acknowledgment.—We are very much indebted to the Olin Mathieson Chemical Corporation for their generous support of this work. Furthermore, we wish to thank Mr. A. C. Schulz for his valuable assistance in the experimental work.

Experimental[10]

1,2-Diformylhydrazine Dihydrazone (IV).—With exclusion of direct light 8 g. of anhydrous hydrazine was added dropwise to a solution of 4.5 g. of *s*-triazine in 50 ml. of anhydrous ether. After standing overnight at room temperature, the almost colorless solid was collected under nitrogen and washed with small amounts of ice-cold anhydrous ether and then dried in a vacuum desiccator in the dark for two hours over phosphorus pentoxide; yield 80%. This crude product was best purified by digesting the finely powdered material with 5 ml. of cold absolute alcohol for 30 minutes followed by rapid filtration under nitrogen. A repetition of this procedure yielded 4.8 g. of pure IV as a micro-crystalline yellowish powder melting at 122–123° dec. No solvent could be found for IV in which this compound is soluble without decomposition.

Anal. Calcd. for $C_2H_8N_6$: C, 20.68; H, 6.95; N, 72.37. Found: C, 21.00; H, 7.09; N, 72.20.

Within a few seconds of exposure to the atmosphere IV turned pink, later red, but such samples kept *in vacuo* over concentrated sulfuric acid soon regained their original color (evaporation of the formed 1,2,4,5-tetrazine). The coloring matter could also be extracted with ether. After evaporation of such extracts, practically nothing remained, the red substance being entrained with the ether vapors.

The dihydrochloride of 1,2-diformylhydrazine dihydrazone was formed from a suspension of 5.8 g. of IV in 100 ml. of dry carbon tetrachloride by passing through a stream of dry hydrogen chloride for 24 hours, followed by vacuum filtration of the suspension. The filter cake was washed with dry carbon tetrachloride and dried on a porous plate in a desiccator over calcium chloride and paraffin chips for three days; m.p. 74–76° dec. All the above operations should be carried out with exclusion of moisture. The hydrochloride is extremely hygroscopic and is easily decomposed by water, the only isolable product in such cases being hydrazine hydrochloride.

Anal. Calcd. for $C_2H_8N_6 \cdot 2HCl$: C, 12.71; H, 5.33; Cl, 37.51. Found: C, 12.72; H, 6.12; Cl, 37.00.

The dihydrochloride apparently is stable for an unlimited time sealed in a glass tube.

With picric acid in aqueous solution or in alcoholic suspension, IV yielded a yellow crystalline picrate which was identified by analysis and mixed melting point (187–188°) with **hydrazine picrate.**[11]

Anal. Calcd. for $C_6H_7N_9O_7$: N, 26.82. Found: N, 26.62, 26.40.

Benzoylation of IV was carried out with benzoyl chloride in anhydrous quinoline and also by Pinner's procedure for the benzoylation of amidrazones,[12] but the only isolable product proved to be **N,N′-dibenzoylhydrazine,** according to analysis and a mixed melting point (245–246°) with an authentic sample.

Anal. Calcd. for $C_{14}H_{12}N_2O_2$: C, 69.98; H, 5.04; N, 11.66. Found: C, 70.01; H, 5.07; N, 11.71.

Acid Hydrolysis of IV.—Upon addition of 15 ml. of concentrated hydrochloric acid to 1.5 g. of freshly prepared pure IV the mixture became hot and foamed. When the initial reaction had subsided, the solution was evaporated on the steam-bath to dryness. The residue was dissolved in 30 ml. of water and again evaporated to dryness. This procedure was repeated twice more in order to remove all formic acid. The remaining white crystalline salt was dried in a desiccator over calcium chloride and analyzed for hy-

(9) Compare in this respect the formation of benzoxazole and benzthiazole from *s*-triazine and *o*-aminophenol, resp., *o*-aminothiophenol, Ch. Grundmann and A. Kreutzberger.[3a]

(10) All melting points are corrected, microanalyses are from Galbraith Laboratories, Knoxville, Tenn., and Spang Microanalytical Laboratory, Ann Arbor, Michigan.

drazine and ammonia by the method of the Mathieson Chemical Corporation.[13]

Anal. Calcd. for $N_2H_4 \cdot 2HCl$: N_2H_4, 30.53. Found: N_2H_4, 32.34, 32.69; NH_3, 0.00, 0.00.

Synthetic mixtures of ammonium formate and hydrazine dihydrochloride, treated as described above, yielded the calculated values for hydrazine and ammonia.

1,2-Diformylhydrazine Bis-(isopropylidenehydrazone) (VI).—A suspension of 3.2 g. of IV in 70 ml. of dry acetone gave a clear solution after refluxing for three hours. From the reddish solution 2.4 g. of large white crystals of VI separated on cooling. These crystals were rapidly filtered off and washed with cold dry acetone. Upon exposure to air, the crystals tend to turn slightly pink, a color which is afterwards difficult to remove. For purification they were recrystallized from acetone, under exclusion of air and moisture, yielding white prisms which, after drying over phosphorus pentoxide *in vacuo*, melted at 113°.

Anal. Calcd. for $C_8H_{16}N_6$: C, 48.95; H, 8.22; N, 42.83. Found: C, 47.78; H, 8.07; N, 42.32.

Repeated recrystallization of VI from acetone as well as other attempts at further purification did not yield better analytical values.

Condensation of IV was also attempted with benzaldehyde,[14] anisaldehyde, *o*-nitrobenzaldehyde, methyl ethyl ketone and acetophenone, but this resulted only in the isolation of the corresponding azines, while diethyl ketone and phenylacetone yielded only resins, and benzophenone and phenanthrenequinone did not react at all.

1,2-Diacetyl-1,2-dihydro-1,2,4,5-tetrazine (IX).—An amount of 10.5 g. of IV was added portionwise to 40 ml. of acetic anhydride. Dissolution occurred immediately with evolution of heat, while the color of the solution changed to orange. The reaction mixture was heated for two hours on the steam-bath and then the excess acetic anhydride distilled off *in vacuo*. The distillate was colored red by a volatile by-product, probably 1,2,4,5-tetrazine. In the distillation flask there remained a yellowish transparent sirup which slowly crystallized upon standing. The crude product was freed from adhering resinous material by dissolving in 17 ml. of hot acetone and decolorizing with charcoal. After cooling and filtration, 3.9 g. of a yellowish micro-crystalline substance was obtained. Upon repeated vacuum sublimation of this crude material, pure IX was obtained as faintly yellowish needles melting at 149–150°.

Anal. Calcd. for $C_6H_8N_4O_2$: C, 42.86; H, 4.80; N, 33.32; mol. wt., 168. Found: C, 42.57; H, 4.84; N, 33.07; mol. wt. (Rast), 168, 174.

IX has neither basic nor acidic properties. When a small sample was heated with an excess of 10% methanolic potassium hydroxide for a half-minute on the water-bath, the solution became intensively red. The colored matter could be extracted with ether and was volatile with the vapors of that solvent.

4-Diacetylamino-1,2,4-triazole (X).—When 10 g. of 4-amino-1,2,4-triazole (XII) was added portionwise to 100 ml. of acetic anhydride, a colorless solution resulted with evolution of heat. After heating for two hours on the steam-bath, the excess of acetic anhydride was removed by vacuum distillation. The remaining faintly brownish sirup crystallized slowly upon standing in a refrigerator for two weeks. The crude material was recrystallized with addition of charcoal from 30 ml. of boiling acetone, yielding 9.2 g. of white sturdy prisms, m.p. 129–131°.

Anal. Calcd. for $C_6H_8N_4O_2$: C, 42.86; H, 4.80; N, 33.32. Found: C, 42.75; H, 5.13; N, 33.22.

1,2,4-Triazole (XI) and 4-Amino-1,2,4-triazole (XII) from 1,2-Diformylhydrazine Dihydrazone (IV).—After 10.5 g. of IV had undergone spontaneous decomposition by storage in a vacuum desiccator in the dark for five days at room temperature, the resulting transparent brownish viscous oil was subjected to a slow fractional vacuum sublimation in a cold finger apparatus. After 12 hours at 140° bath temperature and 1 mm. 2.4 g. (38.4%) of white sturdy needles of 1,2,4-triazole (XI) was obtained. After one recrystallization from ethanol, the product was analytically pure, m.p. 120–121°. A mixed melting point with an authentic sample of XI[15] was without depression.

Anal. Calcd. for $C_2H_3N_3$: C, 34.78; H, 4.37; N, 60.85. Found: C, 35.11; H, 4.75; N, 60.80.

The resinous remainder in the distillation apparatus largely crystallized on standing. The crystals were freed from the main amount of adhering resins on a porous plate and then purified by dissolving in 30 ml. of ethanol and boiling with charcoal. After filtration and removal of the solvent from the filtrate, a slightly colored oil remained. This oil solidified on cooling to fine needles (1.1 g., 14.5%) of 4-aminotriazole (XII), m.p. 82–83°, which showed no depression in a mixed melting point with an authentic sample of XII.[16] The substance was further identified by its picrate,[17] m.p. 197–198°.

Anal. Calcd. for $C_8H_7N_7O_7$: N, 31.31. Found: N, 31.60.

From a mixture of 4-amino-1,2,4-triazole and anhydrous hydrazine heated for 12 hours at 140° and 1 mm., XII could be recovered unchanged. No 1,2,4-triazole was found in this experiment. Likewise, XII, heated alone to 180°, yielded no triazole.

1-Formyl-2,2-dimethylhydrazine 2′,2′-Dimethylhydrazone (XIII).—A mixture of *s*-triazine and *asym*-dimethylhydrazine (mole ratio 1:6) reacted slowly at room temperature under evolution of ammonia. The reaction was completed by heating for one hour at 100–115°. Subsequent vacuum distillation gave an 85% yield of XIII as a colorless mobile oil with an unpleasant odor, b.p. 73° (9 mm.); $n^{21}D$ 1.4664.

Anal. Calcd. for $C_5H_{14}N_4$: C, 46.13; H, 10.83; N, 43.04. Found: C, 45.92; H, 11.02; N, 43.02.

In an analogous manner, from 1-methyl-1-phenylhydrazine and *s*-triazine there was obtained the **N³-methylphenylformamidrazone (XIV)**. In this case, the remaining solid reaction product (72%) was purified by repeated recrystallization from ethyl acetate, yielding beige-colored needles, m.p. 103–104°.

Anal. Calcd. for $C_8H_{11}N_3$: C, 64.40; H, 7.43; N, 28.17. Found: C, 64.55; H, 7.31; N, 28.12.

No definite product other than XIV could be obtained from a mixture of an excess of *asym*-methylphenylhydrazine and *s*-triazine at temperatures up to 190°.

Phenylazoformaldehyde Phenylhydrazone (XVIa).—Phenylhydrazine, either in alcoholic solution or undiluted, reacted slowly with *s*-triazine with evolution of ammonia at room temperature. The initial reaction product, presumably XV, was a viscous oil which could not be obtained crystalline by any means, and which very soon turned red, even in an atmosphere of nitrogen. Heating the mixture decomposed the primary product into unidentifiable resinous matters, but, when the primary product was poured in thin layers on flat disks and kept there for about 14 days in contact with the air, the color increased to deep red and gradually the mass crystallized to red needles of XVIa, yield 83.6%. XVIa was purified by several recrystallizations, first from aqueous and then from absolute methanol, m.p. 119–120°.

Anal. Calcd. for $C_{13}H_{12}N_4$: C, 69.63; H, 5.39; N, 24.98. Found: C, 69.60; H, 5.33; N, 24.69.

XVIa was identified by a mixed melting point with an authentic sample[18] and by conversion into the acetyl phenylazo-formaldehyde phenylhydrazone, m.p. 189°.[19]

Anal. Calcd. for $C_{15}H_{14}N_4O$: C, 67.64; H, 5.30; N, 21.04. Found: C, 67.84; H, 5.39; N, 20.85.

***p*-Bromophenylazo-formaldehyde *p*-bromophenylhydrazone (XIVb)** was obtained from *s*-triazine and freshly prepared free *p*-bromophenylhydrazine in 81% yield. In this case oxidation of the intermediate hydrazidine XV occurred spontaneously during the reaction. The remaining dark red microcrystalline mass yielded XIVb after recrystallization from glacial acetic acid as small reddish brown needles, m.p. 114–115°. These were identified by mixed melting

point with an authentic specimen.[20] In an analogous manner, the reaction of *s*-triazine with *p*-nitrophenylhydrazine resulted in *p*-nitrophenylazo-formaldehyde *p*-nitrophenylhydrazone (XIVc); yield 67%. After one recrystallization from benzene, reddish brown crystals, sintering at 94–95° and melting then slowly up to 104–105°, were obtained. They were identical with a sample prepared according to literature.[20]

A mixture of 2,4,6-trimethyl-*s*-triazine (Ia, 1.0 g.) and phenylhydrazine (5.3 g.) after heating for 30 minutes at 150–190° evolved ammonia and then turned deep red. From this crude product isolation of the N,N′-diphenyl-C-methylformazan, XVId (phenylazo-acetaldehyde phenylhydrazone) proceeded as described for XVIa. After recrystallization from ethanol the red, glittering needles of XVId (2.3 g.) melted at 122–123°. This melting point was not depressed upon mixing with an authentic sample.[21] With 2,4,6-triphenyl-*s*-triazine (Ib, 5.0 g.) and phenylhydrazine (10.5 g.) the reaction did not proceed to completion, even after two hours at 190°. After cooling the deep red solid obtained could be separated by extraction with boiling ethanol. The insoluble part (4.0 g.) was unreacted Ib, while the desired N,N′-diphenyl-C-methylformazan, XVIe, (phenylazo-benzaldehyde phenylhydrazone) crystallized from the concentrated alcoholic extracts (1.4 g.), m.p. 174–175°. The identity of XVIe was established by a mixed melting point with an authentic sample.[22]

(22) H. v. Pechmann, *ibid.*, **27**, 1690 (1894).

3-Hydroxy-1,2,4-triazole (XVIII).—A vigorous reaction with evolution of ammonia occurred when a mixture of *s*-triazine (2.9 g.) and semicarbazide (XVII) (8 g.) in a flask was immersed into an oil-bath preheated to 100°. The mixture thereafter was heated for five minutes more at 120° and then allowed to cool. The resulting yellowish resin was extracted with hot ethanol and decolorized with charcoal. After evaporation to dryness the remaining crystalline XVIII (1.7 g., 18.7%) was recrystallized from alcohol, m.p. 234–235°.

3-Mercapto-1,2,4-triazole (XX) was obtained analogously from thio-semicarbazide (XIX) and *s*-triazine at a reaction temperature of 190°. The crude material (63.4%) was recrystallized from water, m.p. 215–216°.

3-Amino-1,2,4-triazole (XXII).—Free aminoguanidine (XXI) was prepared from the sulfate with an equivalent amount of barium hydroxide in aqueous solution, filtering off the precipitated barium sulfate and evaporating the filtrate to dryness *in vacuo*. The remaining crystalline free base is not stable. It soon turned red and must be used immediately. Its reaction with *s*-triazine at 210° as described above yielded 3-amino-1,2,4-triazole (47.4%), m.p. 158–159°, after recrystallization from ethyl acetate.

The compounds XVIII, XX and XXII were identified by mixed melting points with authentic samples prepared according to the literature.[23]

Synthesis and Biological Activity of Some 6-(Substituted)-aminopurines

BY CHARLES G. SKINNER, PETE D. GARDNER AND WILLIAM SHIVE

RECEIVED JANUARY 7, 1957

Thirteen new 6-(substituted)-aminopurines have been synthesized and tested for biological activity in two assay systems. Some compounds which possessed the greatest activity in inhibition of hydra regeneration (*e.g.*, 6-(4-cyclohexylbutylaminopurine)) had relatively little effect on the rate of germination of lettuce seed (Early Curled Simpson); and those compounds (*e.g.*, 6-(α-naphthylmethyl)-aminopurine)) which possessed the greatest seed germination effect had relatively little activity in the hydra regeneration study.

The synthesis, and some biological activities, of several 6-(substituted)-purines has recently been reported from these laboratories.[1–4] In an effort to examine the relationship between biological activity and structure of the substituent group in the 6-positions of the purine nucleus, additional compounds have been prepared and are reported in this paper in conjunction with their biological activity in two assay systems.

6-(2-Furfuryl)-aminopurine (kinetin) has received considerable attention since it was reported by Miller, *et al.*,[5,6] to be a cell division factor in tobacco "wound" callus tissue. More recently, Miller has reported a stimulation of lettuce seed germination with kinetin, 6-benzylaminopurine and 6-hexylaminopurine,[7] and we have also observed such effects with various 6-(substituted)-thiopurine derivatives.[8] Liverman has observed an effect with both kinetin and several other adenine analogs in a leaf disk expansion type assay,[9] and the effects of some fifty 6-(substituted)-purines have been studied by Eakin, *et al.*, in these laboratories for their effect upon moss budding[10] and hydra tentacle regeneration.[2–4] More recently, a bacteriological assay for these purine analogs has been developed.[11] While it appears that no overall statement may be made with respect to most active compound(s) in the separate assay systems, a particular homolog is frequently the most active in more than one of the biological assays.

In the present study, differences in activity of some new 6-(substituted)aminopurines (Table I) in two different assay systems have been observed.

[a] This compound was a wax-like solid.

It is apparent from Table II that some compounds which possessed the greatest activity in inhibition of hydra regeneration (*e.g.*, 6-(4-cyclohexylbutyl)-aminopurine) had relatively little effect on the rate of germination of lettuce seed. Also, those compounds which possessed the greater seed germination effect (*e.g.*, 6-(α-naphthylmethyl)-aminopurine) had relatively little effect in the hydra regeneration study.

The preparations of these purine derivatives were accomplished through the general procedure of Elion, Burgi and Hitchings[12] which involves a thermal reaction between an amine and 6-methylthiopurine. Data concerning these compounds are reported in Table I. The intermediate amines usually were obtained through the corresponding nitrile by catalytic reduction. In an alternate procedure, the corresponding acid amide was reduced with lithium aluminum hydride.

In several instances, the acid required to prepare the desired amine was not available. These acids were prepared through the condensation of the appropriate aldehyde with ethyl ethylidenemalonate followed by reduction, hydrolysis and decarboxylation. Certain of the later condensation procedures did not yield the desired product. For example, the attempted condensation of 2-hydroxyl-1-naphthaldehyde with ethyl ethylidenemalonate failed, and an 81% recovery of starting material was obtained.

Experimental[13,14]

Starting Materials.—6-Methylthiopurine was prepared by the method of Elion, Burgi and Hitchings[12] from 6-mercaptopurine. The previously reported amines were synthesized by the catalytic reduction of the corresponding nitrile over Raney nickel in an alcohol–ammonium hydroxide solution: α-naphthylmethylamine, b.p. 153° (11 mm.)[15]; 2-phenoxyethylamine, b.p. 127° (27 mm.)[16]; 4-phenoxybutylamine, b.p. 145° (17 mm.), $n^{25}D$ 1.5235.[17]

Biological Testing.—The biological technique used to obtain the hydra regeneration data has been reported by Ham, Fitzgerald and Eakin.[18] The stimulation of lettuce seed germination was determined on a field variety of seed, Early Curled Simpson. The seeds were pre-soaked in the purine solutions for eight hours and then allowed to germinate in the dark at 30° on wet filter paper in covered Petri dishes. The percentage germination data recorded in Table II is based on 100 or more seeds per assay and the experimental technique will be presented elsewhere.[19]

7-Phenylheptylamine.—The amide of 7-phenylenanthic acid was prepared by a previously reported method[20] and used as the crude material, m.p. 82–85°.

A slurry of 10.0 g. of the amide in 150 ml. of anhydrous ether was added slowly with stirring to a suspension of 5.0 g. of lithium aluminum hydride in 100 ml. of ether. After addition was complete the mixture was stirred for an additional 10 hours. Upon the addition of dilute hydrochloric acid three layers resulted. The center one, presumably containing the hydrated amine-salt, was separated and made basic by the addition of dilute sodium hydroxide. The free amine was isolated by ether extraction and distilled to give 6.17 g. of colorless liquid, b.p. 157–160° (740 mm.). This amine did not form a solid picrate; however, a solid hydrochloride salt formed readily but was extremely hygroscopic. A sample of the amine which was redistilled for analysis boiled entirely at 157° (740 mm.).

Anal. Calcd. for $C_{13}H_2N$: N, 7.32. Found: N, 7.45.

11-Phenylundecylamine.—A sample of 50 g. of 11-phenylundecanoic acid (Eastman Organic Chemicals) was converted to the acid chloride *via* thionyl chloride, without purification, and transformed to 11-phenylundecylamide with concen-

[a] The seeds were pre-soaked in purine solutions of the noted concentrations for 8 hours, drained, and allowed to germinate on wet filter paper in the dark at 30°. [b] These data were furnished by Mr. R. G. Ham and Dr. R. E. Eakin of the Biochemical Institute, The University of Texas, by a previously reported technique, ref. 18.

trated ammonium hydroxide. The reaction mixture tended to gel and only 16 g. of crystalline material was easily obtained. This product was dried over phosphorus pentoxide under vacuum, m.p. 42–44°.

Anal. Calcd. for $C_{17}H_{27}NO$: N, 5.36. Found: N, 5.64.

A suspension of 12.0 g. of 11-phenylundecylamide in 250 ml. of ether was added, with efficient stirring, to a suspension of 5.0 g. of lithium aluminum hydride in 200 ml. of dry ether at such a rate that reflux was not too vigorous. After standing overnight, ethyl acetate was added dropwise to the well-stirred mixture until the vigorous reaction subsided. A few milliliters of water was then added dropwise, followed by enough 10% hydrochloric acid solution to break the emulsion. The ether phase was separated, and was found to contain the amine hydrochloride which was converted to the free amine by drying over sodium hydroxide for several days. After removal of the solvent, the residue was distilled under reduced pressure, b.p. 145–149° (2 mm.), to yield 10.0 g. of product, $n^{25}D$ 1.4970.

Anal. Calcd. for $C_{17}H_{29}N$: N, 5.66. Found: N, 5.59.

ω-Cyclohexylalkylamines.—Methyl-(I), ethyl-(II), propyl-(III), butyl-(IV), pentyl-(V) and hexyl-(VI): Compounds I, II, III, IV and VI were prepared by hydrogenation, under 50 lb./sq. in. pressure of hydrogen, of a mixture containing 1 part of the corresponding nitrile,[21] 1 part of ammonium hydroxide and 3 parts of 95% ethyl alcohol in the presence of Raney nickel catalyst. After the theoretical amount of hydrogen had been consumed, the reaction mixture was filtered and the catalyst washed with alcohol. The solvent was then removed, and the residue was distilled under reduced pressure.

Compound V was prepared by the interaction of 5-cyclohexylvaleramide (18.3 g.) and lithium aluminum hydride (11.1 g.) in the presence of ether (500 ml.); and the reaction product was isolated in the same manner as that previously described for this reduction technique.

I, b.p. 37° (4 mm.), $n^{25}D$ 1.4645[23]; III, b.p. 60–26° (1.2 mm.), $n^{25}D$ 1.4640, 44% yield. *Anal.* Calcd. for $C_9H_{19}N$: N, 9.92. Found: N, 9.97. IV, b.p. 73° (1 mm.); $n^{25}D$ 1.4651, 75% yield. *Anal.* Calcd. for $C_{10}H_{21}N$: N, 9.02. Found: N, 9.12. V, b.p. 108–113° (6 mm.), $n^{25}D$ 1.4659, 60% yield. *Anal.* Calcd. for $C_{11}H_{23}N$: N, 8.27. Found: N, 8.17. VI, 104–112° (3 mm.), $n^{25}D$ 1.4641, 69% yield. *Anal.* Calcd. for $C_{12}H_{25}N$: N, 7.64. Found: N, 7.99.

2-Carboxyl-5-(1-naphthyl)-2,4-pentadienoic Acid.—A solution was prepared comprised of 15.6 g. of 1-naphthaldehyde and 27.9 g. of ethyl ethylidenemalonate[24] and treated with a solution prepared from 21.7 g. of potassium hydroxide (85%) and 150 ml. of methanol. The flask and contents were cooled as required to maintain the temperature below 30°. After 20 hr. at 30° the solution was acidified by the addition of 100 ml. of concd. hydrochloric acid in 150 ml. of water (with cooling). The resulting semi-solid precipitate was collected by suction filtration and triturated with hot methanol. The suspension was cooled to 0° and filtered to give 13.4 g. of yellow solid, m.p. 224–226° dec. A sample repeatedly recrystallized from butyrolactone–water or from acetic acid gave m.p. 232–233° dec.

Anal. Calcd. for $C_{16}H_{12}O_4$: C, 71.63; H, 4.51. Found: C, 71.60; H, 4.53.

2-Carboxyl-5-(1-naphthyl)-valeric Acid.—A solution of 16.3 g. of the above acid was slurried with 200 ml. of glacial acetic acid. One-half gram of 5% palladium–charcoal was added and the mixture was shaken under 2 atm. pressure of hydrogen until the theoretical absorption of gas occurred. Isolation of the product in the usual manner and recrystallization from ethyl acetate–petroleum ether (60–68°) gave 13.95 g. of colorless solid (2 crops), m.p. 153–155° dec.

Anal. Calcd. for $C_{16}H_{16}O_4$: C, 70.57; H, 5.92. Found: C, 70.51; H, 6.07.

5-(1-Naphthyl)-valeric Acid.—An 11.50-g. sample of the above dicarboxylic acid was heated at 190–200° (1 atm. pressure) until CO_2 evolution ceased. The cooled liquid crystallized upon trituration with petroleum ether and was recrystallized from ethyl–petroleum ether (60–68°) to give 8.50 g. of nearly colorless solid, m.p. 88–89°.

Anal. Calcd. for $C_{15}H_{16}O_2$: C, 78.91; H, 7.07. Found: C, 78.65; H, 7.12.

The amide of the above substituted valeric acid was prepared by treating 7.57 g. with 20 ml. of thionyl chloride at 45° for 30 minutes (until gas evolution ceased). Excess thionyl chloride was removed using a water aspirator and warming on a steam-cone. The residue was poured slowly, with stirring, into 60 ml. of cold concentrated ammonium hydroxide. The solid thus formed was recrystallized from aqueous methanol or an ethyl acetate–petroleum ether mixture, to give 6.52 g. of colorless amide, m.p. 127–128°.

Anal. Calcd. for $C_{15}H_{17}ON$: C, 79.26; H, 7.54. Found: C, 79.50; H, 7.36.

5-(1-Naphthyl)-pentylamine.—The amine was prepared by slowly adding a solution of 5.27 g. of the amide described above, dissolved in 100 ml. of dry ether, to a suspension of 2.28 g. of lithium aluminum hydride in 50 ml. of ether. The mixture was stirred for 20 hr. at room temperature and processed as before. Upon acidification three layers resulted, the amine salt being in the middle one. It was separated, made basic with dilute sodium hydroxide and extracted with ether. Distillation of the residue gave 3.40 g. of the amine as colorless liquid, b.p. 151–153° (1.0 mm.), $n^{25}D$ 1.5857.

Anal. Calcd. for $C_{15}H_{19}N$: N, 6.57. Found: N, 6.87.

2-Phenoxypropylamine.—This compound was prepared by reduction of the corresponding nitrile over Raney nickel catalyst and 50 lb./sq. in. hydrogen gas pressure, using the procedure previously described; b.p. 125–126° (22 mm.), $n^{20}D$ 1.5207.

Anal. Calcd. for $C_9H_{13}NO$: N, 9.27. Found: N, 9.29.

Attempted Condensation of 2-Hydroxy-1-naphthaldehyde with Ethyl Ethylidenemalonate.—Treatment of 20.0 g. of 2-hydroxyl-1-naphthaldehyde with 35.7 g. of ethyl ethylidenemalonate and 27.8 g. of 85% potassium hydroxide for a 20-hour period at 30° followed by the processing technique described above for 2-carboxyl-5-(1-naphthyl)-2,4-pentadienoic acid gave 16.3 g. (81%) of recovered starting material.

(21) The intermediates to form the various nitriles have previously been reported by P. L. Pickard and C. W. Young, THIS JOURNAL, 73, 42 (1951).

(22) Reported values, b.p. 163.5°, $n^{18}D$ 1.4646; O. Wallach, *Ann.*, 353, 297 (1907).

(23) Reported values, b.p. 85° (25 mm.), $n^{20}D$ 1.4656; B. L. Zenitz, E. B. Macks and M. L. Moore, THIS JOURNAL, 69, 1117 (1947).

2-Carboxyl-5-(2-thenyl)-penta-2,4-dienoic Acid.—This substance was prepared by the procedure described above in which 19.5 g. of 2-thiophenaldehyde, 48.5 g. of the ester, 37.8 g. of potassium hydroxide and 200 ml. of methanol was used. Acidification gave the product as a yellow solid which, after recrystallization from acetic acid, melted at 211–212° dec. and weighed 11.1 g.

Anal. Calcd. for $C_{10}H_8O_4S$: C, 53.56; H, 3.60. Found: C, 53.91; H, 3.60.

Reduction of this substance to the corresponding saturated derivative could not be effected under 2 atmospheres of hydrogen pressure using platinum as a catalyst.

2-Carboxyl-5-(2-furyl)-penta-2,4-dienoic Acid.—Application of the above-described reaction conditions to a mixture of 43.0 g. of potassium hydroxide, 250 ml. of methanol, 19.2 g. of furfural, and 55.8 g. of the ester gave 9.53 g. of red-brown solid, m.p. 197–198° dec. Further purification afforded a tan sample having the same melting point. This substance absorbed four mole-equivalents of hydrogen (platinum, ethanol) at 30° and 2 atmospheres pressure.

Anal. Calcd. for $C_{10}H_8O_5$: C, 57.69; H, 3.87. Found: C, 58.29; H, 4.00.

Subsequent reactions with this material proceeded anomalously in several respects and will be described in a later report.

6-(Substituted)-aminopurines.—The appropriate amines were condensed by the same general procedure whereby one part of 6-methylthiopurine was mixed with 2 to 5 parts of the corresponding amine, and the reaction mixture was sealed in a micro Carius tube and heated at 130 to 140° for 15 to 18 hours. At the conclusion of the heating period, the cooled bomb was opened carefully with an oxygen torch. The liberated methylmercaptan was immediately evident as a foul smelling by-product. In several instances a precipitate was present at this stage which could be washed with cold alcohol, dried, and analyzed directly. In other experiments the solvent had first to be removed under reduced pressure to yield a mass of crystals which, after treating with charcoal, and cooling, yielded the desired product. The yields varied considerably among the different amines; however, this may have been due more to solubility factors than to extent of the reaction, since the more soluble products were difficult to isolate in the small scale experiments that were conducted. Specific reaction conditions are itemized in Table I for each of the amines studied. The extent of purity of the reaction product could be ascertained readily by determining its ultraviolet absorption spectrum. 6-Methylthiopurine has a characteristic double peak at about 283 and 290 mμ (10 γ/ml. in 95% ethanol), which is absent in the 6-(substituted)-aminopurines. The 6-(substituted)-aminopurine spectra were almost identical in possessing a λ_{max} from about 267–271 mμ when examined at concentrations of 10 γ/ml. in 95% ethyl alcohol.

[Contribution from the Chemical Laboratory of Iowa State College and the Chemistry Department and the Oceanographic Institute of The Florida State University]

Recoverability of Phenylthiohydantoins from Amino Acids[1]

By Sidney W. Fox,[2] William Serat,[3] Thomas L. Hurst, Onnolee Underwood Trapp and Donna Lutjens

Received December 8, 1956

Factors in the reaction of phenyl isothiocyanate with amino acids and amino acid residues in the analysis of peptides have been studied. Some of the same phenomena which interfere with quantitation of the extractive procedure contribute to the validity of the subtractive procedure. Use of an excess of phenyl isothiocyanate enhances the decomposition of amino acids to other substances.

In the development of methods of peptide analysis the need for convenient determinations of residue sequence and of characterization has been apparent for well over a decade.[4] The characteristics of an ideal N-terminal reagent for sequence assignment were prescribed in 1945.[4] Many of the attributes of such a reagent were found in fluorodinitrobenzene (FDNB) which has been successfully used by Sanger,[5] du Vigneaud,[6] Craig[7] and others.

In the development of more highly quantitative methods, of stepwise methods, and of procedures for characterization, a reagent of choice,[8] however, appears to be phenyl isothiocyanate[9] (PTC). Direct identification of the extracted phenylthiohydantoin (PTH) formed by fission of the reaction product of phenyl isothiocyanate with protein or peptide nevertheless poses procedural difficulties. Recoveries are usually low[10] (typically 20–40%), although higher recoveries have been attained.[11]

Probably the greatest error in the direct extraction procedure is introduced by destruction of the phenylthiohydantoin by the same mineral acid used for its formation. Such an effect was evident in the earliest experiments with phenyl isothiocyanate in this Laboratory.[12] This picture of simultaneous formation and destruction of PTH has been mentioned,[8] confirmed in detail[10,11] and is in accord with the known behavior of hydantoins.[13] The probability that destruction of PTH was occurring in the presence of mineral acid first led, indeed, to use of a subtractive method. The subtractive method consists of amino acid assays of an hydrolyzate followed by subsequent hydrolyses and assays after the terminal residues are successively removed. If the PTH formed decom-

poses substantially to substances other than the original amino acid, the subtractive method would nevertheless yield the desired quantitative result. Experiments with synthetic peptides therefore emphasized finding conditions which would completely destroy N-terminal residues. The results indicated especially a need for a relatively high PTC/peptide ratio for quantitative loss of the N-terminal residue.[12]

These considerations emphasized the desirability of obtaining an evaluation of the extent of utilization of the PTHs following typical hydrolytic treatment and of the survival of the amino acids after the full analytical treatment with excess PTC.[12] Data on recovery from peptides have been provided for some of the amino acid residues.[12] In the absence of a roster of peptides representing all types of N-termini, free amino acids were carried through the treatment (Table IV).

Experimental and Results

The utilization of the PTHs from each of thirteen amino acids is reported in Table I. The PTHs were prepared as described by Edman.[9] In order to bring these into solution it was necessary to dissolve the compounds in ethanol and in some cases to autoclave promptly the resultant 5% ethanolic solution containing PTH and basal medium. The control and assay solutions contained the same proportion of ethanol.

TABLE I

UTILIZATION OF THIRTEEN PHENYLTHIOHYDANTOINS FROM AMINO ACIDS IN MICROBIAL ASSAY OF THE CORRESPONDING AMINO ACID

Amino acid as PTH	Assay organism	Assay titration values in ml. 0.05 *N* NaOH: Blank	PTH	Amino acid
Alanine	*L. citrovorum*	4.64	4.63	5.76
Arginine	*S. faecalis*	1.92	1.97	5.28
Aspartic acid	*L. mesenteroides*	1.56	1.59	3.16
Glutamic acid	*L. arabinosus*	5.42	5.52	6.51
Glycine	*L. brevis*	4.97	4.28	7.71
Isoleucine	*L. arabinosus*	1.02	3.00	5.56
Leucine	*L. arabinosus*	3.73	4.80	8.15
Lysine	*L. mesenteroides*	0.70	0.72	2.36
Methionine	*S. faecalis*	0.12	0.04	4.25
Phenylalanine	*L. brevis*	2.38	2.23	7.98
Proline	*L. brevis*	0.70	0.65	5.28
Tyrosine	*L. brevis*	1.13	1.17	6.40
Valine	*S. faecalis*	0.94	1.00	2.80

For the tests, 2.50 ml. of basal medium[14] lacking only the amino acid under study and including 0.25 ml. of the corresponding PTH in ethanol and 2.25 ml. of distilled water were combined in a culture tube. The amount of PTH chosen was that equivalent to 10 μg. of the amino acid in the final solution. In one set of control tubes, no PTH was included. In another set of tubes, 10 μg. of the amino acid was present. All tubes were prepared in triplicate; the figures given in Tables II–IV are averages. Except for glycine assays, individual values seldom exceeded ±5% variation from the average of triplicates. The tubes were covered with a towel, autoclaved for 15 minutes under 15 lb. of steam pressure, inoculated after cooling and incubated at 37° for 72 hr. The organisms used are given in Table I. It may be seen that the assay values in the use of PTH were almost the same as in the absence of the PTH except for three cases. These were glycine, isoleucine and leucine. Glycine–PTH appeared to be inhibitory. Although the individual assay values for glycine were the most variable, repetition of the experiment confirmed the finding that the derivative was truly inhibitory. The PTHs utilized were those of isoleucine and leucine.

[a] VI in B. F. Steele, H. E. Sauberlich, M. S. Reynolds and C. A. Baumann, *J. Biol. Chem.*, 177, 533 (1949). Letter combinations of organism and medium are given in S. W. Fox, T. L. Hurst and C. Warner, THIS JOURNAL, 76, 1154 (1954). Multiple symbols correspond to each determination; a single pair of symbols indicates the combination was used in all tests.

Accordingly, the PTHs were tested in a range of concentrations against standard curves for isoleucine and leucine. The results are presented in Table II.

In order to test the effect of the hydrolytic treatment on the PTH, samples of the leucine-PTH and isoleucine-PTH equivalent to 100 μg. of the L-amino acid per ml. of ethanol were each added to an equal volume of 12 *N* hydrochloric acid and autoclaved at 15 lb. steam pressure for 16 hr. These solutions were concentrated to dryness and dissolved in ethanol and prepared for assay as before. Results are given in Table III.

The recoveries of amino acids following full treatment of the type employed in analyses on peptides and proteins are given in Table IV. The procedure employed in these tests was to pipet 2.0 ml. of solution containing 2.00 mg. of standard L-amino acid into a 50-ml. beaker, to add 2.5 ml. of pyridine and 0.025 ml. of phenyl isothiocyanate and to add a small amount of brom thymol blue powder. To this was added sufficient 0.2 *N* sodium hydroxide to give an emerald green color. The beaker was covered and set in a 37° incubator for 6 hr., with maintenance of the original alkalinity by frequent additions of sodium hydroxide. The beakers were evaporated to dryness in evacuated desiccators containing sulfuric acid. When dry, 5.0 ml. of 3 *N* hydro-

claved at 15 lb. pressure for 16 hr. The hydrochloric acid was driven off over steam, and the beaker was set in a desiccator containing also a beaker of ammonium hydroxide to neutralize any free acid. The contents were then diluted to volume for assay.

The results in Table V were obtained in the same way as for Table IV, except for the quantities used. To 50 mg. of each amino acid were added 1.0 ml. of water, 2.0 ml. of pyridine and the designated volume of PTC.

TABLE V

RECOVERY FROM 50 MG. OF LEUCINE OR LYSINE AFTER TREATMENT WITH VARIOUS AMOUNTS OF PHENYL ISOTHIOCYANATE (PTC)

Amino acid	Amount of PTC 0.1 ml., %	0.5 ml., %	1.0 ml., %	Lysozyme standard assay L-amino acid
DL-Leucine	6.6 ± 0.4	3.5 ± 0.3	2.1 ± 0.2	6.5 ± 0.3
	6.3 ± .1	3.2 ± .2	2.0 ± .2	6.3 ± .3
L-Lysine	1.9 ± .1		1.0 ± .1	5.9 ± .1
	1.6 ± .1		1.2 ± .1	5.8 ± .2
	2.0 ± .1		1.3 ± .1	5.9 ± .2

Discussion

The results of Table I show that direct utilization does not occur for most amino acid PTHs. A more extensive study with benzoylamino acids[15] revealed a similarly highly selective pattern for an acylamino acid series. These results are of interest for comparison in that *L. arabinosus* was able to use benzoylleucine but no other benzoylamino acid in substantial proportion, with the partial exception of cystine. The study with benzoylamino acids showed also that *S. faecalis* could not make use of benzoylleucine. In any analytical situation in which it might be significant, utilizability of leucine-PTH or isoleucine-PTH might thus be circumvented by employing another assay microbe. As will be seen, this need probably does not exist in the present type of application (Table IV).

The results of Table II reveal a commonly observed phenomenon, that of decreasing utilization with increasing concentration of a limiting nutrient. Tables II and III taken together demonstrate that in those few cases in which a derivative is utilizable most of this is lost by hydrolytic treatment. These results also help to explain low recoveries recorded in the literature for the extractive Edman procedure.

In evaluating effects in the steps of the subtractive procedure, it should be emphasized that this differs particularly in employing a large excess of PTC. The fact that higher ratios of PTC to glycylvaline result in more complete subtraction of N-terminal glycine[12] demonstrates that these considerations apply to peptides as well as to unsubstituted amino acids (Table IV). In addition such results support the conclusion that excess PTC contributes to destruction of terminal residue.

The ideal type of experiment in which to estimate the quantitative non-recoverability of an N-terminal amino acid residue would involve reaction with PTC of a variety of peptides for each of the residues in the N-terminal position. Some such experiments have been performed,[11,12] but the comprehensive completion of such a study is at present infeasible. Accordingly, each of the amino acids has been carried through such a process, as has been done for the companion C-terminal method,[16] to gain further insight into the reliability of the method. In addition, extended studies comparing concordance of C-terminal exposures and N-terminal exposures during proteolysis provide an independent type of check.[17] When the values of Table II are compared with the low recovery of valine following treatment with *excess* PTC and then hydrolysis as in Table V, it becomes evident that the treatment itself can lead to degradation of the N-terminal residue. Although the mechanism is not understood, this difference in behavior can explain how recoveries of extracted PTH can be incomplete whereas the subtractive method can yield quantitative results within the limits of error of assay.

With the partial exception of proline all of the recoveries in Table IV are essentially negligible within the limits of error of microbial assay. The loss of amino acid is more nearly complete in the N-terminal method than in the companion C-terminal procedure.[16] (In addition, the large difficulties encountered with glutamic acid, aspartic acid and proline at the C-terminus are not observed with the PTC procedure.) The destruction of N-proline in a peptide is more complete than in the amino acid.[12] The greater destructibility in a peptide, when superposed on incomplete utilizability of whatever PTH is formed (Table I) imparts to the subtractive method maximum validity.

The effect of varying ratio of PTC/amino acid also has been studied for lysine and leucine. The results of Table V show a trend similar to that observed with peptides.[12] The results in this table were controlled by simultaneous assay of lysozyme. The ± figures are standard deviations calculated from quadruplicate determinations at each of five levels of assay.

Among principal advantages of the subtractive PTC method are (1) that it functions by virtue of some factors which incidentally interfere with the quantitation of the extractive method and (2) the applicability to studying unfractionated mixtures of peptides[17] in a stepwise manner.[18] The stepwise nature of the method permitted distinguishing unfractionated and unfragmented cereal proteins containing a dominant lysine–arginine sequence[19] from lysozyme containing a lysylvalyl sequence.[8] This quality is particularly needed in a method employed for characterization of unfractionated proteins. A number of such applications have been reported[17–21] as have other advantages and limitations of the method.[17,22]

Studies of the Reversible Epimerization Occurring in the Tetracycline Family. The Preparation, Properties and Proof of Structure of Some 4-*epi*-Tetracyclines

BY J. R. D. MCCORMICK, SIDNEY M. FOX, LELAND L. SMITH, BARBARA A. BITLER, JULES REICHENTHAL, VICTOR E. ORIGONI, WALTER H. MULLER, ROBERT WINTERBOTTOM AND ALBERT P. DOERSCHUK

RECEIVED SEPTEMBER 19, 1956

The four known members of the tetracycline family of broad-spectrum antibiotics (tetracycline, 7-chlorotetracycline, 7-bromotetracycline and 5-hydroxytetracycline) can undergo a reversible epimerization at carbon four to form a new series of compounds, the 4-*epi*-tetracyclines. For each of the four epimeric pairs, the equilibrium mixture in a variety of solvents is composed of approximately equal amounts of the tetracycline and the 4-*epi*-tetracycline. The 4-*epi*-tetracyclines have been isolated from the equilibrium mixtures, crystallized, and characterized. The epimerization occurs in the *p*H range of approximately two to six and is aided by the presence of buffers; it becomes unmeasurably slow under more strongly acidic conditions or more strongly basic conditions. The proof that the new materials are carbon four epimers of the tetracyclines depends on consideration of (1) the conditions permitting and preventing epimerization, (2) the reversible nature of the epimerization, (3) the nature of the ultraviolet spectral differences between epimeric pair members and (4) the nature of the chemical transformations required to convert both members of an epimeric parent pair to a single substance.

The tetracycline family (I) consists of a small group of closely related hydronaphthacenes that are of interest because of their broad-spectrum antibiotic activity. The known members of this family are tetracycline,[1] 7-chlorotetracycline,[1] 7-bromotetracycline and 5-hydroxytetracycline.[2] The reactions of these compounds under strongly acidic conditions and under strongly alkaline conditions have been studied extensively in connection with the determinations of their structures.[3-5] It recently has been found that these substances, and certain of their derivatives, undergo a reversible isomerization under *p*H conditions in the range of two to six.[6] This reversible isomerization has been shown to be an epimerization occurring at carbon four, giving rise to a new series of compounds, the 4-*epi*-tetracyclines (II).[7,8] These new substances have been called the quatrimycins.[6] This paper describes conditions permitting and preventing the epimerization, methods of preparation and characteristics of some 4-*epi*-tetracyclines and evidence for the conclusion that the reaction leading to the new compounds is a reversible epimerization at carbon four.

The epimerization occurs in a variety of solvent systems within the *p*H range of approximately two to six; its rate is increased by the presence of certain anions, such as phosphate, citrate or acetate. Saturated solutions of tetracyclines or 4-*epi*-tetracyclines in glacial acetic acid (25°) or in 2:1 dimethylformamide–1 *M* aqueous phosphate (*p*H 3.5, 25°) are equilibrated within 24 hours. The mole fraction of 4-*epi*-tetracycline in a given equilibrium mixture varies from 0.4 to 0.6. Tables I and II present examples of conditions allowing epimerization. Epimerization rates are unmeasurably small in solutions more acidic than *p*H 2. For tetracycline in 0.03 *N* HCl, the epimerization rate is unmeasurably small and acid-catalyzed dehydration to anhydrotetracycline (III)[9,10] does not occur; tetracycline in such solutions is chemically stable over long periods of time. Further increases in acid strength bring about dehydration and aromatization to anhydrotetracycline; in 1.0 *N* HCl, 4-*epi*-tetracycline yields, without measurable isomerization, anhydro-4-*epi*-tetracycline (IV) (Table III, Fig. 1). Anhydro-4-*epi*-tetracycline is isomeric with, distinguishable from and reversibly convertible to anhydrotetracycline under conditions epimerizing the tetracyclines. Epimerization rates of the tetracyclines and their epimers are unmeasurably small in solutions more basic than

	R	R′
Tetracycline	H	H
7-Chlorotetracycline	Cl	H
7-Bromotetracycline	Br	H
5-Hydroxytetracycline	H	OH

*p*H 9. In 0.1 *N* NaOH, 7-chloro-4-*epi*-tetracycline yields, without measurable epimerization, iso-7-chloro-4-*epi*-tetracycline (VI) (Table III, Fig. 2). Iso-7-chloro-4-*epi*-tetracycline is isomeric with, distinguishable from and reversibly convertible to iso-7-chlorotetracycline (V)[10,11] (Fig. 3) under conditions epimerizing the tetracyclines.

Separation of the 4-*epi*-tetracyclines from the equilibrium mixtures has been accomplished by partition chromatographic methods and also by differential crystallization methods convenient for the preparation of large quantities of materials. A tabulation of the properties of the 4-*epi*-tetracyclines and the corresponding tetracyclines is presented in Tables III and IV and Fig. 2. In general, the 4-*epi*-tetracycline member of each pair has the lesser ultraviolet absorbency in the 250–300 mμ region, the greater alkali stability, the greater acid stability, the more negative optical rotatory power, the greater water solubility, the greater tendency to be associated with the aqueous phase of partition separation systems and the lower *in vitro* antibacterial activity against *Staphylococcus aureus*. All these differences in properties have been used for analyzing mixtures of epimeric pair members. However, the most useful properties were the antibacterial activity against *S. aureus* and the shapes of the ultraviolet curves, expressed as ratios of the absorbencies at different wave lengths. Of the several absorbancy ratios possible, the most useful for analytical purposes was the ratio between the absorbencies at 254 and at 267 mμ; this method is called the Absorbency Ratio (AR) Assay. Where 220–300 mμ ultraviolet interference was present, use was made of the ratio of *S. aureus* antibacterial activity to ultraviolet absorbency at the long wave length ultraviolet absorption maximum (~360 mμ); this method is called the Biological-Spectrophotometric Ratio (BSR) Assay. Ultraviolet interference in the 220–300 mμ region was more commonly encountered than was interference in the 360 mμ region, and the BSR assay was the more generally applicable of the two. Table V presents values of these properties for the pure compounds of the two series.

The constant nature throughout all pairs of the differences in properties between pair members, the fact that a single set of conditions can accomplish the epimerization of all members of the two series, and the fact that the limitations on the conditions allowing the epimerization are, insofar as they have been studied, similar for all members of the two series, indicate that the structural relationships between members of the pairs are the same for all pairs and that only a single process, common to all the cases, is involved in the conversions. Some confirmation of this comes from the fact that catalytic hydrogenation (palladium-on-carbon, 1.1 atmosphere) of 7-chloro-4-*epi*-tetracycline yields 4-*epi*-tetracycline.

EFFECT OF BUFFER CONCENTRATION ON THE EPIMERIZATION RATE OF A 20% TETRACYCLINE HYDROCHLORIDE SOLUTION IN 2:1 METHANOL/AQUEOUS BUFFER AT *p*H 4 AND 25°

Buffer concn.	Extent of epimerization, %				
	1 hr.	2 hr.	4 hr.	6 hr.	24 hr.
0.1 *M* NaH_2PO_4	4	12	35	40	49
1.0 *M* NaH_2PO_4	13	26	44	47	52

That the members of the pairs are not related as keto–enol tautomers is indicated by the facts that strong acid or strong base acts to prevent interconversion, rather than having a catalytic effect. The isomerization rate–*p*H value relationships and the effect of buffer anions suggest a mechanism of interaction of both acid and base with the isoelectric form; an analogy may be drawn to the mutarotation of glucose.[12] It follows from the equilibrium mixture composition that the free energy change accompanying epimerization is small; therefore the structures of pair members are probably not greatly different. From the essential ultraviolet absorption similarity between pair members it follows that epimerization does not involve any extensive change in the chromophores. It is, however, significant that, in all cases, the pair members differ only slightly in ultraviolet absorption characteristics in the 340–380 mμ region

5-Hydroxy-4-*epi*-tetracycline	21.8 hr. in 0.1 *N* NaOH (aq.) at 23°	6.0	50[a]
5-Hydroxytetracycline	10.9 hr. in 0.1 *N* NaOH (aq.) at 23°	6.3	50[a]

[a] For these cases, the product of the acid-catalyzed reaction is of the apoterramycin type[13] rather than of the anhydrotetracycline type.

tetracycline structure as a whole acts as two essentially independent chromophores.[10] The ring A chromophore contributes only to the 250–300 mμ absorption, while the rings B-C-D chromophore contributes to both the 250–300 mμ absorption and the 340–380 mμ absorption. The fact that epimerization changes principally the 250–300 mμ absorption indicates that a change in the ring A chromophore is involved. A partial confirmation of this is found in the fact that the anhydro compounds arising from the acid-catalyzed dehydration of tetracycline and of 4-*epi*-tetracycline retain the isomeric, distinguishable and reversibly interconvertible characteristics of the parent pair. Formation of these anhydro compounds involves aromatization of ring C, eliminating, as possible sites for the reversible change, all asymmetric carbon atoms except those of ring A. Inversion of configuration at C.4a or C.12a was ruled out because of the very mild nature of the conditions allowing the change and the lack of side reactions.

TABLE V

ULTRAVIOLET ABSORBENCY RATIOS AND BIOLOGICAL TO SPECTROPHOTOMETRIC ACTIVITY RATIOS USED FOR ASSAY OF EPIMERIC PAIR MIXTURES

Compound	Ratio of absorbency[a] at 254 mμ to absorbency at 267 mμ (AR)	Biological[b] to spectrophotometric activity[a] ratio (BSR) Value	Wave length used, mμ

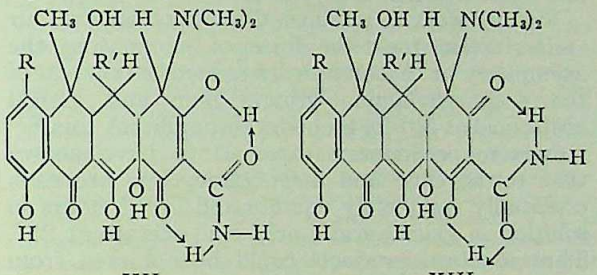
5-Hydroxy-4-*epi*-tetracycline	1.13	0.032	352

[a] In 0.1 *N* H_2SO_4. [b] Turbidimetric assay against *S. aureus*.

The foregoing makes it most likely that the epimerization involves only a change in the configuration of C.4. The other possibility suggested by the published structures of the tetracyclines involves changes in the orientation of the 2-carboxamide group, whose free rotation might be prevented by strong hydrogen bonding with the two adjacent oxygen functions. The two interconvertible, isomeric possibilities resulting are represented by XII and XIII.



XII

XIII

This relationship has been suggested earlier to explain the existence of the two isomeric, distinguishable and interconvertible apoterramycins.[13] However, the interconversion of the apoterramycins is catalyzed by either acid or base. An attempt to exclude the carboxamide orientation possibility took the form of dehydrating the non-symmetric carboxamide group to the linear nitrile group. Treatment of tetracycline and 4-*epi*-tetracycline with benzenesulfonyl chloride in pyridine[13] resulted in carboxamide dehydration accompanied by esterification to form benzenesulfonylnitriles.[7,14] The benzenesulfonyltetracyclinonitrile and the benzenesulfonyl-4-*epi*-tetracyclinonitrile were isomeric and distinguishable (Table III), but neither could be reversibly interconverted under conditions equilibrating the tetracyclines in four minutes nor under a variety of other conditions, including a series of *p*H values suggested by the gain in acid strength occurring on nitrile formation. To exclude the possibility that benzenesulfonyl substitution was preventing epimerization and the possibility that the two benzenesulfonylnitriles were distinguishable because of differences in position of benzenesulfonyl substitution, 7-chlorotetracycline and 7-chloro-4-*epi*-tetracycline were treated with methanesulfonyl chloride in pyridine to form the unsubstituted nitriles VII and VIII (Table III, Fig. 2).[10,15] The two unsubstituted nitriles were likewise isomeric and distinguishable, but could not be reversibly interconverted under the conditions described for the substituted nitriles. The experiment demonstrates that the intact carboxamide group, although it may be involved in the ready interconversion of the parent compounds, is not essential to the existence of isomeric pairs. Interconversion of the nitrile pair members under conditions equilibrating the tetracyclines, had it been possible as it was with other derivatives,

(14) The product of the corresponding reaction of 5-hydroxytetracycline has been described as being the 10-benzenesulfonylnitrile.[13]

(15) The method is that of R. Wilkinson, Research Division, American Cyanamid Company, who had previously prepared the nitrile of 7-chlorotetracycline by this method (unpublished).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

would have provided a simple, certain proof that the nitriles were indeed related as were the parent compounds and therefore that the sulfonyl chloride reagents had acted in completely parallel ways on all four compounds. The lack of this proof, taken with the lack of any other independent proof of the relationship between the nitrile pair members, such as independent synthesis, weakens the argument that distinguishable sulfonyl chloride reaction products have eliminated the carboxamide orientation possibility and have proved the carbon four epimerization alternative.[16]

Further work to establish the fact of carbon four epimerization took the form of eliminating the asymmetry at carbon four by reductive removal of the 4-dimethylamino group. Zinc and glacial acetic acid at 30° for six hours accomplishes this.[10,13] However, preliminary experiments have shown that tetracycline and 4-*epi*-tetracycline are each essentially completely equilibrated in 2.5 hours in solution in glacial acetic acid–zinc acetate at 25°. Thus identical products could be obtained from both members of an epimeric pair by reduction under these conditions either through the elimination of the asymmetry at carbon four or through the epimerization to a common product during the reaction. The problem of distinguishing between these two alternatives was resolved by the finding that the methiodides could be reduced under non-epimerizing conditions. Tetracycline methiodide (IX) and 4-*epi*-tetracycline methiodide (X) (Table III, Fig. 2) were prepared[17] and found to be isomeric, distinguishable and reversibly interconvertible. Neither methiodide was measurably epimerized after remaining four hours in a simulated reduction solvent consisting of 1:1 acetic acid–water with four equivalents of zinc acetate. In 1:1 acetic acid–water, reduction with zinc for 30 minutes was sufficient for reductive cleavage of the trimethylammonium group from both methiodides. The two resulting desdimethylamino compounds were identical (XI, Table III). Criteria of identity included elemental analysis, optical rotation, mixed melting point, ultraviolet spectra, infrared spectra, counter-current distribution and solubility. This represents sufficient proof that the quatrimycins are the 4-*epi*-tetracyclines.

Acknowledgment.—The authors wish to acknowledge, with appreciation, the work of Neva-Tay Smith on the catalytic hydrogenation of 7-chloro-4-*epi*-tetracycline to 4-*epi*-tetracycline and the work of A. G. Mistretta on the counter-current distribution of desdimethylaminotetracycline. The antibacterial activity determinations and many of the instrumental assays, the elemental analyses and the optical rotation determinations were done under the direction of H. S. Kelsey, L. Brancone and W. Fulmor, respectively.

Experimental

4-*epi*-Tetracycline Ammonium Salt Monohydrate.—A solution of 200 g. of tetracycline hydrochloride in 1 liter of 2:1 methanol–1 *M* aqueous NaH_2PO_4 was allowed to remain 20 hr. at 25°; epimerization occurred to the extent of 58%, as judged by the AR assay. Acetone (1500 ml.) was added and the mixture allowed to remain for 2 hr. at 4°. The resulting precipitate (primarily inorganic salts) was filtered out and the filtrate concentrated *in vacuo* to 400 ml. Saturation of the solution with gaseous ammonia resulted in the formation of a crystaline product which was filtered out and washed twice with 100-ml. portions of concentrated ammonia water and twice with 200-ml. portions of acetone. After drying *in vacuo* the product weighed 166 g. and represented a recovery of 93% of the 4-*epi*-tetracycline formed by the epimerization, as judged by the AR assay. One kilogram of material prepared in this way (~70% 4-*epi*-tetracycline) was dissolved in 3 liters of water by adjusting the *p*H to 8 with 400 ml. of concentrated hydrochloric acid. After being clarified by filtration, the solution was adjusted to *p*H 8.8 with 100 ml. of concentrated ammonia water. Scratching induced the formation of a crystalline product which was filtered out, slurry-washed with one liter of an 80:15:5 mixture of acetone, water and concentrated ammonia water, and washed on the filter with two liters of acetone and then with one liter of acetone. After drying *in vacuo*, the product, a crystalline ammonium salt, weighed 373 g. and assayed 96% total tetracyclines and 95% 4-*epi*-tetracycline by the AR assay.[18] Reprocessing the product through the procedure described above yielded 213 g. of crystalline 4-*epi*-tetracycline ammonium salt monohydrate which assayed 100% 4-*epi*-tetracycline ammonium salt monohydrate by both the AR and BSR assays. The antibacterial activity (turbidimetric) against *S. aureus* was 6.4% that of tetracycline hydrochloride; $[\alpha]^{25}D$ −321° (0.5% in 0.03 *N* HCl), m.p. 170° dec. The ultraviolet absorption spectrum in 0.1 *N* H_2SO_4 (aq.) showed λ_{max} in mμ (ε): 216 (14,100), 255 (16,700), 270 (15,600, shoulder), 355 (14,800).

Anal. Calcd. for $C_{22}H_{27}N_3O_8 \cdot H_2O$: C, 55.11; H, 6.11; N, 8.76; H_2O, 3.76. Found: C, 55.68; H, 6.08; N, 8.82; H_2O, 4.14.

4-*epi*-Tetracycline Monohydrate.—To a filtered solution of 390 g. of 4-*epi*-tetracycline ammonium salt in 2.5 liters of water and 60 ml. of concentrated hydrochloric acid (solution *p*H, 5.3) was added concentrated ammonia water to a final *p*H of 6.8. Scratching induced the formation of crystals which, after being washed twice with 1-liter portions of water and dried *in vacuo*, weighed 200 g. An analytical sample was prepared by dissolving 2 g. of this material in 25 ml. of water adjusted to *p*H 1.2 with concentrated hydrochloric acid, filtering, and adjusting the filtrate *p*H to 5.8 with concentrated ammonia water. The resulting crystalline product, after being washed with 10 ml. of water and 25 ml. of acetone and dried *in vacuo*, weighed 1.3 g. and assayed 100% 4-*epi*-tetracycline monohydrate by the AR and BSR assays. The antibacterial activity (turbidimetric) against *S. aureus* was 6.4% that of tetracycline hydrochloride; $[\alpha]^{25}D$ −335° (0.5% in 0.03 *N* HCl), m.p. 178° dec. The ultraviolet absorption spectrum in 0.01 *N* H_2SO_4 (aq.) showed λ_{max} in mμ (ε): 216 (13,900), 255 (16,400), 270 (15,200, shoulder), 355 (14,700).

Anal. Calcd. for $C_{22}H_{24}N_2O_8 \cdot H_2O$: C, 57.12; H, 5.68; N, 6.06; H_2O, 3.89. Found: C, 57.41; H, 5.62; N, 6.00; H_2O, 3.90.

(16) A related experiment has shown that N-mono-*t*-butylanhydrotetracycline (J. E. Lynch and C. R. Stephens, "Antibiotics Annual," Medical Encyclopedia, Inc., 1955–1956, p. 466), when allowed to remain in solution in 2:1 dimethylformamide/1 *M* aqueous NaH_2PO_4, undergoes a change in ultraviolet absorption spectrum comparable in rate, direction and magnitude to that undergone by anhydrotetracycline under the same conditions. Although the experiment does not clarify the nature of the epimerization, it does provide an example of a change in the carboxamide group that does not interfere with easy epimerization. The N-mono-*t*-butylanhydrotetracycline was prepared by J. Boothe, Research Division, American Cyanamid Co.

(17) The methods of methiodide preparation and reduction and an authentic sample of tetracycline methiodide for comparison purposes were obtained from J. Boothe, Research Division, American Cyanamid Co.

(18) Diluting the mother liquor with an equal volume of acetone and adjusting the *p*H to 9.0 with concentrated ammonia water yielded a second crop of crystals which, after washing and drying as before, weighed 444 g. and assayed 96% total tetracyclines and 70% 4-*epi*-tetracycline by the AR assay. The operations of this preparative process bring about little change in tetracycline or 4-*epi*-tetracycline except epimerization, so that recycle of second crystal crops, solvent-free mother liquors, etc., through re-equilibration and re-isolation is a feasible method of increasing the over-all yield.

June 5, 1957

Tetracycline from 4-*epi*-Tetracycline.—A solution of 5 g. of 4-*epi*-tetracycline ammonium salt monohydrate in 100 ml. of glacial acetic acid was allowed to remain 24 hr. at 25° and was then mixed with 400 ml. of water and seeded with a small quantity of tetracycline neutral. The crystals which formed on aging were collected, washed, dried and dissolved in 5 volumes of 4:1 Ethyl Cellosolve–*n*-butyl alcohol. The *p*H of the solution was adjusted to 1.5 with concentrated hydrochloric acid. The crystals which formed on aging were collected, washed, dried and identified as tetracycline hydrochloride (with possible trace amounts of 4-*epi*-tetracycline hydrochloride) by ultraviolet and infrared spectra, antibacterial activity (turbidimetric) against *S. aureus* and paper chromatography.

7-Chloro-4-*epi*-tetracycline Ammonium Salt Monohydrate.—A solution of 100 g. of 7-chlorotetracycline in 500 ml. of 2:1 dimethylformamide–1 *M* aqueous NaH_2PO_4 was allowed to remain 20 hr. at 25°; epimerization occurred to the extent of 45%, as judged by the AR assay. Acetone (1 liter) was added and the resulting precipitate (primarily inorganic salts) filtered out. Adjustment of the filtrate to *p*H 8 with concentrated ammonia water yielded a crystalline product which, after being washed once with 25 ml. of a 2:1 acetone–dimethylformamide mixture and twice with 100-ml. portions of acetone and dried *in vacuo*, weighed 53.1 g. and represented a recovery of 78% of the 7-chloro-4-*epi*-tetracycline formed by the epimerization. To a filtered solution of 10 g. of this material in 25 ml. of water was added sufficient concentrated ammonia water to give a *p*H of 9.5. Aging for one hour yielded a crystalline product which, after being washed once with 10 ml. of 4:1 acetone–water and once with 20 ml. of acetone and dried *in vacuo*, weighed 4.2 g. and assayed 96% 7-chloro-4-*epi*-tetracycline ammonium salt by BSR assay. An analytical sample was prepared by dissolving 1.0 g. of this material in 10 ml. of water, filtering, adding 10 ml. of acetone to the filtrate, and adjusting the *p*H to 9.0 with concentrated ammonia water. The resulting crystalline product, after being washed with 3 ml. of 4:1 acetone–water and 10 ml. of acetone and dried *in vacuo*, weighed 0.64 g. and assayed 100% 7-chloro-4-*epi*-tetracycline ammonium salt monohydrate as judged by the AR and BSR assays. The antibacterial activity (turbidimetric) against *S. aureus* was 4.2% that of 7-chlorotetracycline hydrochloride; $[\alpha]^{25}D$ −321° (0.5% in 0.03 *N* HCl), m.p. 163–164° dec. The ultraviolet absorption spectrum in 0.1 *N* H_2SO_4 (aq.) showed λ_{max} in mμ (ε): 230 (18,300), 255 (17,700), 368 (9,400).

Anal. Calcd. for $C_{22}H_{26}N_3ClO_8 \cdot H_2O$: C, 51.40; H, 5.49; N, 8.18; Cl, 6.90; H_2O, 3.50. Found: C, 51.88; H, 5.63; N, 8.58; Cl, 7.02; H_2O, 2.88.

7-Chloro-4-*epi*-tetracycline.—To a filtered solution of 49.7 g. of 7-chloro-4-*epi*-tetracycline ammonium salt monohydrate in 400 ml. of water was added 9.2 ml. of concentrated hydrochloric acid. The resulting crystalline product, after being washed with water and with acetone and dried *in vacuo*, weighed 22.7 g. An analytical sample was prepared by dissolving 1 g. of this material in 30 ml. of methanol and filtering. On standing, crystals appeared which, after being washed with water and with methanol and dried *in vacuo*, weighed 0.64 g. and assayed 100% 7-chloro-4-*epi*-tetracycline by AR and BSR assay. The antibacterial activity (turbidimetric) against *S. aureus* was 4.0% that of 7-chlorotetracycline hydrochloride; $[\alpha]^{25}D$ −350° (0.5% in 0.03 *N* HCl), m.p. 209–213° dec. The ultraviolet absorption spectrum in 0.1 *N* H_2SO_4 (aq.) showed λ_{max} in mμ (ε): 230 (18,400), 255 (17,700), 368 (9,300).

Anal. Calcd. for $C_{22}H_{23}N_2ClO_8$: C, 55.18; H, 4.84; N, 5.84; Cl, 7.41. Found: C, 55.03; H, 4.90; N, 5.83; Cl, 7.56.

7-Chloro-4-*epi*-tetracycline Hydrochloride.—A solution of 40 g. of 7-chloro-4-*epi*-tetracycline ammonium salt monohydrate in 400 ml. of water was adjusted to *p*H 1 with 20 ml. of concentrated hydrochloric acid and aged for 30 min. The resulting crystalline product, after being washed with 25 ml. of cold water and dried *in vacuo*, weighed 19.3 g. and assayed 100% 7-chloro-4-*epi*-tetracycline hydrochloride by the AR and BSR assays. An analytical sample was prepared by dissolving 2.0 g. of this material in 75 ml. of 2-propanol and filtering, and aging. The resulting crystalline product, after being washed with 5 ml. of 2-propanol and dried *in vacuo*, weighed 1.7 g. and assayed 100% 7-chloro-4-*epi*-tetracycline hydrochloride by AR and BSR assay. The antibacterial activity (turbidimetric) against *S. aureus* was 4.7% that of 7-chlorotetracycline hydrochloride; $[\alpha]^{25}D$ −312° (0.5% in 0.03 *N* HCl), m.p. 211–214° dec. The ultraviolet absorption spectrum in 0.1 *N* H_2SO_4 (aq.) showed λ_{max} in mμ (ε): 230 (17,900), 255 (17,400), 368 (9,300).

Anal. Calcd. for $C_{22}H_{24}N_2Cl_2O_8$: C, 51.30; H, 4.69; N, 5.44; Cl, 13.77. Found: C, 51.80; H, 4.90; N, 5.26; Cl, 13.45.

5-Hydroxy-4-*epi*-tetracycline.—A solution of 100 g. of 5-hydroxytetracycline in 500 ml. of glacial acetic acid was allowed to remain 21 hr. at 25°; epimerization occurred to the extent of 29% as judged by the AR assay. Vacuum distillation to a volume of 200 ml., followed by the addition of 1500 ml. of water and vacuum distillation to 250 ml., resulted in the precipitation of unepimerized 5-hydroxytetracycline which, after being removed by filtration and dried *in vacuo*, weighed 61.7 g. and assayed 95% 5-hydroxytetracycline by microbiological assay (*S. aureus*) and 0% 5-hydroxy-4-*epi*-tetracycline by AR and BSR assay. The filtrate was adjusted to *p*H 7.7 with 70 ml. of concentrated ammonia water. The resulting crystalline product, after being washed twice with 50-ml. portions of water and dried *in vacuo*, weighed 14.9 g. and assayed 96% 5-hydroxy-4-*epi*-tetracycline by BSR assay. A filtered solution of 16.0 g. of material prepared in this way in 300 ml. of methanol and 1.5 ml. of concentrated hydrochloric acid was adjusted with concentrated ammonia water to *p*H 7 and aged for 2 hr. The resulting crystalline product was washed twice with 250-ml. portions of methanol, three times with 60-ml. portions of water, and twice with 50-ml. portions of acetone. After drying *in vacuo*, the product weighed 7.2 g. and assayed 100% 5-hydroxy-4-*epi*-tetracycline by AR assay and 98% by BSR assay. The antibacterial activity (turbidimetric) against *S. aureus* was 4.5% that of 5-hydroxytetracycline; $[\alpha]^{25}D$ −253° (0.5% in 0.03 *N* HCl), m.p. 163–164° dec. The ultraviolet absorption spectrum in 0.1 *N* H_2SO_4 (aq.) showed λ_{max} in mμ (ε): 215 (12,200), 253 (14,200), 275 (12,000), 355 (12,100).

Anal. Calcd. for $C_{22}H_{24}N_2O_9$: C, 57.34; H, 5.30; N, 6.08. Found: C, 57.68; H, 5.34; N, 6.42.

Anhydro-4-*epi*-tetracycline Hydrochloride.—A solution of 10 g. of 4-*epi*-tetracycline in a mixture of 75 ml. of butanol, 19 ml. of water and 31 ml. of concentrated hydrochloric acid was heated to 70° for one hour, cooled and diluted with 40 ml. of water. The *p*H was adjusted to 5.5 with 5 *N* sodium hydroxide and the resulting precipitate washed with water and dried (6.5 g.). One gram of this precipitate was slurried in 30 ml. of methanol containing 1 ml. of concentrated hydrochloric acid and the mixture filtered. One ml. of concentrated hydrochloric acid was added to the filtrate. The crystalline product that resulted after two hours aging was washed with cold methanol and cold water and dried (0.45 g.); $[\alpha]^{25}D$ −265° (0.5% in 0.03 *N* HCl), m.p. 210–212 dec. The ultraviolet absorption spectrum in 0.1 *N* NaOH (aq.) showed λ_{max} in mμ (ε): 225 (22,200), 268 (29,600), 320–340 (4,200, shoulder), 425 (9,300).

Anal. Calcd. for $C_{22}H_{23}N_2ClO_7$: C, 57.08; H, 5.01; N, 6.05; Cl, 7.66. Found: C, 56.84; H, 5.34; N, 5.86; Cl, 7.59.

Reversible Epimerization of Anhydrotetracycline Hydrochloride and Anhydro-4-*epi*-tetracycline Hydrochloride.—A solution of 0.032 g. of anhydrotetracycline hydrochloride[9,10] in 10 ml. of 2:1 methanol/1 *M* aqueous NaH_2PO_4 was allowed to remain at 25° for 20 hr. The same operation was carried out starting with anhydro-4-*epi*-tetracycline hydrochloride. The ultraviolet absorption spectra in 0.1 *N* sodium hydroxide were determined for both solutions before and after equilibration. At the end of 20 hr. the two solutions had identical ultraviolet absorption spectra which did not change further on additional standing. The ultraviolet absorption spectra of the equilibrium solutions corresponded to an equilibrium composition of 63% anhydrotetracycline and 37% anhydro-*epi*-tetracycline. The experiment demonstrates the approach to the same equilibrium composition starting from each of the two pure components.

Iso-7-chloro-4-*epi*-tetracycline Monohydrate.—A solution of 20 g. of 7-chloro-4-*epi*-tetracycline ammonium salt in 180 ml. of 0.5 *N* aqueous sodium hydroxide (*p*H of solution was

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

9.4) was allowed to remain 24 hr. at 25°. The ultraviolet absorption spectrum of the solution indicated that the rearrangement to iso-7-chloro-4-*epi*-tetracycline had occurred without epimerization and in 86% yield. Adjustment of the *p*H of the solution to 7.0 yielded a gelatinous precipitate which, after being slurry-washed with water and dried over phosphorus pentoxide *in vacuo*, weighed 12.4 g. (64% yield). The ultraviolet absorption spectrum of this crude iso-7-chloro-4-*epi*-tetracycline indicated that epimerization had occurred during work-up to the extent of about 30%. The contaminating iso-7-chlorotetracycline was removed by successive extractions with hot methanol to yield crystalline iso-7-chloro-4-*epi*-tetracycline monohydrate, $[\alpha]^{25}D$ −160° (0.5% in 0.03 *N* HCl), m.p. 235–237° dec. The ultraviolet absorption spectrum in 0.1 *N* sodium hydroxide (aq.) showed λ_{max} in mμ (ε): 255 (15,400), 285 (12,300), 345 (7,100). The infrared spectrum indicated diketone bands in the 6–7 μ region and a phthalide band at 5.75–5.80 μ. A single pK_a of 8.3 was found in 1:1 water–methanol. The material migrated as a single component (R_f 0.80) in a 3% sodium arsenite paper chromatographic system[19] and also in a 1:1 water–methanol system (R_f 0.60).

Anal. Calcd. for $C_{22}H_{23}N_2ClO_8 \cdot H_2O$: C, 53.17; H, 5.07; N, 5.64; Cl, 7.14; H_2O, 3.63. Found: C, 52.98; H, 5.00; N, 5.33; Cl, 7.41; H_2O, 4.19.

Iso-7-chlorotetracycline.—7-Chlorotetracycline hydrochloride was dissolved in 0.1 *N* aqueous sodium hydroxide and processed as was the 7-chloro-4-*epi*-tetracycline above, to yield iso-7-chlorotetracycline monohydrate in 68% yield, $[\alpha]^{25}D$ −97° (0.5% in 0.03 *N* HCl), m.p. 213–224° dec. A single pK_a of 7.80 was found in 1:1 water–methanol.

Anal. Calcd. for $C_{22}H_{23}N_2ClO_8 \cdot H_2O$: C, 53.17; H, 5.07; N, 5.64; Cl, 7.14; water, 3.63. Found: C, 52.70; H, 5.20; N, 5.32; Cl, 7.14; water, 2.43.

Addition of concentrated hydrochloric acid to an acetone solution of the monohydrate yielded iso-7-chlorotetracycline hydrochloride,[11] $[\alpha]^{25}D$ −94.5° (0.5% in 0.03 *N* HCl), m.p. 255–258° dec. A single pK_a of 7.80 was found in 1:1 water–methanol. The ultraviolet absorption spectrum in 0.1 *N* sodium hydroxide (aq.) (Fig. 2) showed λ_{max} in mμ (ε): 255 (14,800), 285 (14,700), 345 (7,300). The ultraviolet and infrared spectra were identical with those of an authentic preparation.[11] The substance migrated as a single component (R_f 0.80) in a 3% sodium arsenite paper chromatographic system[19] and also in a 1:1 water–methanol system (R_f 0.60).

Reversible Epimerization of Iso-7-chlorotetracycline and of Iso-7-chloro-4-*epi*-tetracycline.—Repeated determinations of the ultraviolet absorption spectrum (in 0.1 *N* sodium hydroxide) of a 40 μg./ml. solution of iso-7-chlorotetracycline in 2:1 dimethyl formamide–1 *M* aqueous NaH_2PO_4 at 25° showed systematic changes occurring during the first 180 min. after preparation of the solution, with no additional changes occurring with further time. The ultraviolet absorption spectrum at equilibrium corresponded to a mixture of 32% iso-7-chlorotetracycline and 68% iso-7-chloro-4-*epi*-tetracycline.

The same sequence with iso-7-chloro-4-*epi*-tetracycline as the starting material yielded, after 120 min., a stable ultraviolet absorption spectrum corresponding to a mixture of 32% iso-7-chlorotetracycline and 68% iso-7-chloro-4-*epi*-tetracycline.

Figure 3 illustrates this approach to a common equilibrium mixture from both pure components.

4-*epi*-Tetracycline from 7-Chloro-4-*epi*-tetracycline.—A solution of 5 g. of 7-chloro-4-*epi*-tetracycline ammonium salt in 45 ml. of water containing 1.4 g. of 5% palladium-on-carbon was contacted with hydrogen on a Parr shaker. A rapid uptake of hydrogen ensued until, after 25 minutes, one equivalent of hydrogen was absorbed, at which time the rate decreased sharply. After filtration, the solution was diluted with 100 ml. of acetone, and the *p*H was adjusted to 9.0 with 1.0 ml. of concentrated ammonia water. Seeding induced the formation of crystalline ammonium salt which, after washing with acetone and drying *in vacuo* at 25°, weighed 2.60 g. The product had the ultraviolet absorption spectrum and microbiological assay of the ammonium salt of 4-*epi*-tetracycline.

(19) T. Berti and L. Cima, *Boll. Ist. Sieroterap. Milan.*, **33**, 643 (1954).

Benzenesulfonyl-4-*epi*-tetracyclinonitrile Monohydrate.—Twelve milliliters of benzenesulfonyl chloride was added dropwise with stirring to a mixture of 10 g. of 4-*epi*-tetracycline and 20 ml. of pyridine at 10° (ice-bath); the rate of addition was controlled so that the temperature did not exceed 40°. When the temperature began to fall, the reaction was continued for 30 min. without the ice-bath. One hundred ml. of ether was added with stirring, followed by settling and decantation of the supernatant. The thick, gummy residue was stirred with 500 ml. of water to yield an amorphous solid which was air-dried and slurried with 250 ml. of acetone to yield a yellow, crystalline, product which was filtered off, washed with acetone, and dried *in vacuo*. The product was dissolved in 15 ml. of dimethylformamide and 50 ml. of acetone was added. The resulting yellow, crystalline product, after drying *in vacuo*, weighed 5.2 g., $[\alpha]^{25}D$ −336° (0.5% in dimethylformamide), dec. at 200°. The ultraviolet absorption spectrum in 0.1 *N* H_2SO_4 (aq.) containing 1% by volume of dimethylformamide showed λ_{max} in mμ (ε): 270 (14,200), 347 (9,900) and λ_{min} in mμ (ε): 310 (7,650). The infrared spectrum showed a nitrile band at 4.56 μ.

Anal. Calcd. for $C_{28}H_{29}N_2SO_{10}$: C, 57.40; H, 4.96; N, 4.78; S, 5.47. Found: C, 57.51; H, 5.29; N, 4.74; S, 4.97.

Benzenesulfonyltetracyclinonitrile Dimethylformamide Solvate.—Twenty-four milliliters of benzenesulfonyl chloride was added dropwise with stirring to a mixture of 20 g. of tetracycline and 40 ml. of pyridine at 10° (ice-bath); the rate of addition was controlled so that the temperature did not exceed 50°. When the temperature began to fall, the reaction was continued for 30 min. without the ice-bath; 75 ml. of ether was added with stirring, followed by settling and decantation of the supernatant. To the thick, gummy residue was added 500 ml. of water; on stirring, the mixture was partly converted to a crystalline solid. The residue remaining after filtration was dried *in vacuo* and dissolved in 10 ml. of Ethyl Cellosolve containing 4.4 ml. of triethylamine (*p*H 9.5). After filtration, the solution was adjusted to *p*H 2.5 with concentrated HCl and allowed to remain on the rotary shaker overnight. The resulting crystalline product, after being washed with 10 ml. of Ethyl Cellosolve containing 1 ml. of 2 *N* HCl and being dried *in vacuo*, weighed 6.3 g. The product was recrystallized from 1:4 dimethylformamide–acetone, $[\alpha]^{25}D$ −416° (0.5% in dimethylformamide), dec. at 210°. The ultraviolet absorption spectrum in 0.1 *N* H_2SO_4 (aq.) containing 1% by volume of dimethylformamide showed λ_{max} in mμ (ε): 275 (15,250), 348 (11,350) and λ_{min} in mμ (ε): 319 (9,650). The infrared spectrum showed a nitrile band at 4.55 μ.

Anal. Calcd. for $C_{31}H_{34}N_3SO_{10}$: C, 58.20; H, 5.31; N, 6.56; S, 5.00. Found: C, 58.25; H, 5.24; N, 5.93; S, 4.93.

7-Chloro-4-*epi*-tetracyclinonitrile Monohydrate.—Four milliliters of methanesulfonyl chloride was added dropwise with stirring to a mixture of 5.0 g. of 7-chloro-4-*epi*-tetracycline and 20 ml. of pyridine at −5° (ice-bath); the addition rate was controlled so that the temperature did not exceed 5°. The mixture was stirred 1 hr., and 150 ml. of ether was then added, followed by stirring, settling, and decantation of the supernatant. The solids were leached with 75 ml. of water at *p*H 1. The wet residue remaining after filtration was dissolved in 10 ml. of dimethylformamide, after which was added 30 ml. of chloroform. Crystalline nitrile precipitated which, after being washed with acetone, washed with ether, and dried *in vacuo*, weighed 1.5 g., $[\alpha]^{25}D$ −300° (0.5% in dimethylformamide), dec. at 200°. The ultraviolet absorption spectrum in 0.1 *N* H_2SO_4 (aq.) containing 1% by volume of dimethylformamide showed λ_{max} in mμ (ε): 272 (14,100), 366 (8,750) and λ_{min} in mμ (ε): 320 (6,750). The infrared spectrum showed a nitrile band at 4.57 μ.

Anal. Calcd. for $C_{22}H_{23}N_2O_8Cl$: C, 55.10; H, 4.80; N, 5.85; Cl, 7.40. Found: C, 54.91; H, 4.76; N, 5.72; Cl, 7.89.

7-Chlorotetracyclonitrile.—Four milliliters of methanesulfonyl chloride was added dropwise with stirring to a mixture of 5.0 g. of 7-chlorotetracycline and 20 ml. of pyridine at −5° (ice-bath); the addition rate was controlled so that the temperature did not exceed 5°. The mixture was stirred 45 minutes and 100 ml. of water was then added with stirring. The yellow residue remaining after filtration was dissolved in dimethylformamide. Five volumes of acetone

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

were added; the resulting crystalline product, after being washed with acetone and dried *in vacuo*, weighed 2.6 g., $[\alpha]^{25}D$ −338° (0.5% in dimethylformamide), dec. at 220°. The ultraviolet absorption spectrum in 0.1 *N* H_2SO_4 (aq.) containing 1% by volume of dimethylformamide showed λ_{min} in mμ (ε): 276 (14,100), 365 (9,350) and λ_{max} in mμ (ε): 325 (7,250). The infrared spectrum showed a nitrile band at 4.54 μ

Anal. Calcd. for $C_{22}H_{21}N_2O_7Cl$: C, 57.30; H, 4.56; N, 6.07; Cl, 7.69. Found: C, 56.99; H, 5.01; N, 6.37; Cl, 7.37.

Attempted Epimerization of the Nitriles. A. Benzenesulfonyl-4-*epi*-tetracyclinonitrile.—To a series of solutions of benzenesulfonyl-4-*epi*-tetracyclinonitrile in 4:1 dimethylformamide–water was added enough 85% orthophosphoric acid to give the following *p*H values: 0.3, 2.2, 2.6, 3.1, 3.5. In no case did aging for 114 hr. at 25° bring about any epimerization detectable by ultraviolet absorption spectrum changes. Both 4-*epi*-tetracycline and 7-chloro-4-*epi*-tetracycline were completely equilibrated in 24 hr. under the conditions of the *p*H 3.5 experiment above.

B. 7-Chloro-4-*epi*-tetracyclinonitrile.—A solution of 7-chloro-4-*epi*-tetracyclinonitrile (1 mg./ml.) in 4:1 dimethylformamide–water, brought to a *p*H of 1 with 85% orthophosphoric acid, was allowed to remain at 25° for 2 hr. and also at 40° for 44 hr. A solution of 7-chloro-4-*epi*-tetracyclinonitrile (1 mg./ml.) in 1:4 dimethylformamide–*p*H 7.0 phosphate buffer was allowed to remain at 25° for 22 hr. In no case could any epimerization be detected by ultraviolet absorption spectrum changes.

C. 7-Chlorotetracyclinonitrile.—To a series of solutions (1 mg./ml.) of 7-chlorotetracyclinonitrile in 4:1 dimethylformamide–water was added enough 85% orthophosphoric acid to give the following *p*H values: 0.3, 2.2, 2.6, 3.3. All solutions were aged at 25° for 22 hr. The *p*H 0.3 solution was heated to 40° for 22 hr. The *p*H 3.3 solution was heated to 85° for 3 hr. A solution of 7-chlorotetracyclinonitrile (1 mg./ml.) in 1:4 dimethylformamide—*p*H 7.0 phosphate buffer was allowed to remain at 25° for 22 hr. In no case could any epimerization be detected by ultraviolet absorption spectrum changes. Both 4-*epi*-tetracycline and 7-chloro-4-*epi*-tetracycline were completely equilibrated in 24 hr. under the conditions of the *p*H 3.5, 25° experiment above.

In the cases of all attempted nitrile equilibrations, the limits on the severity of the conditions tried were set by the appearance of other types of chemical changes.

4-*epi*-Tetracycline Methiodide.—A solution of 10 g. of 4-*epi*-tetracycline and 35 ml. of methyl iodide in 100 ml. of tetrahydrofuran was stirred for 24 hr. at room temperature. The resulting crystalline product was washed with 20 ml. of tetrahydrofuran and dried *in vacuo* at 40° to give a yield of 10.1 g. This was dissolved in 250 ml. of ethanol at 50°. Aging the solution with stirring at room temperature for 2 hr. gave a crop of crystalline methiodide contaminated with substantial amounts of unreacted 4-*epi*-tetracycline. The mother liquor was warmed to 40° and mixed with an equal volume of petroleum ether. On cooling, additional crystalline product precipitated which, after being washed with petroleum ether and dried, weighed 4.42 g., $[\alpha]^{25}D$ −265° (0.5% in 0.03 *N* HCl), m.p. 161–162° dec. The ultraviolet absorption spectrum in 0.1 *N* H_2SO_4 (aq.) showed λ_{max} in mμ (ε): 223 (21,900), 250 (15,100), 270 (15,000, shoulder), 355 (13,500).

Anal. Calcd. for $C_{23}H_{27}N_2O_8I$: C, 47.11; H, 4.64; N, 4.71; I, 21.64. Found: C, 47.32; H, 4.74; N, 4.64; I, 21.29.

Tetracycline Methiodide.—A solution of 30 g. of tetracycline and 105 ml. of methyl iodide in 450 ml. of tetrahydrofuran was stirred for 24 hr. at room temperature. The resulting crystalline product was washed with 50 ml. of tetrahydrofuran and dried *in vacuo* at 40° to give a yield of 34.5 g. Recrystallization from 750 ml. of ethanol (50°), washing with cold ethanol, and drying *in vacuo* yielded 19.3 g. of product, $[\alpha]^{25}D$ −198° (0.5% in 0.03 *N* HCl), m.p. 178–180° dec. The ultraviolet absorption spectrum in 0.1 *N* H_2SO_4 (aq.) showed λ_{max} in mμ (ε): 223 (25,400), 274 (18,000), 355 (14,600).

Anal. Calcd. for $C_{23}H_{27}N_2O_8I$: C, 47.11; H, 4.64; N, 4.71; I, 21.64. Found: C, 47.38; H, 4.58; N, 4.91; I, 22.15.

Reversible Epimerization of Tetracycline Methiodide and 4-*epi*-Tetracycline Methiodide.—A solution of 40 mg. of 4-*epi*-tetracycline methiodide in 1 ml. of 2:1 dimethylformamide–1 *M* aqueous NaH_2PO_4 was allowed to remain 16.5 hr. at 25°. At the end of that time a crystalline solid had formed whose ultraviolet absorption spectrum showed it to be pure tetracycline methiodide. An AR assay of the mother liquor indicated a composition of 65% tetracycline methiodide and 35% 4-*epi*-tetracycline methiodide.

Rapid Reversible Epimerization of Tetracycline and 4-*epi*-Tetracycline in Glacial Acetic Acid with Four Equivalents of Zinc Acetate (Simulated Reduction Solvent).—A solution of 50 mg. of tetracycline and 50 mg. of zinc acetate dihydrate (4 equivalents) in 1 ml. of glacial acetic acid was allowed to remain at 25° while its ultraviolet absorption spectrum was determined repeatedly. After 20 min., the tetracycline was approximately 13% epimerized; after 140 min., approximately 35% epimerized. The same sequence starting with 4-*epi*-tetracycline showed 13% tetracycline after 20 min., 50% after 140 min.

Slow Reversible Epimerization of Tetracycline Methiodide and 4-*epi*-Tetracycline Methiodide in 1:1 Acetic Acid–Water with Four Equivalents of Zinc Acetate (Simulated Reduction Solvent).—A solution of 55 mg. of tetracycline methiodide and 38 mg. of zinc acetate dihydrate (4 equivalents) in 1.0 ml. of 1:1 acetic acid–water was allowed to remain at 25° while its ultraviolet absorption was repeatedly determined. After 260 min., essentially no change (~3% epimerization) had occurred. The same sequence starting with 4-*epi*-tetracycline methiodide yielded essentially no change after 120 min. and approximately 9% change in the direction of tetracycline methiodide after 260 min. Under these conditions the epimerization rates for the methiodides are measurably slower than those for the parent compounds (Table I).

Desdimethylaminotetracycline. A. From Tetracycline Methiodide.—A solution of 1.0 g. of tetracycline methiodide in 30 ml. of 1:1 acetic acid–water was purged with nitrogen; 1.5 g. of zinc dust was added and the mixture shaken under nitrogen for 30 min. and filtered. The filtrate was diluted with an equal volume of water and freeze-dried. The resulting solid was slurried 30 min. with 80 ml. of water containing 0.8 ml. of concentrated hydrochloric acid. The residue was washed with water, dried *in vacuo* (354 mg.), and dissolved in 3 ml. of methanol. Fifty milliliters of ether was added and the resulting precipitate removed by filtration. The filtrate was evaporated to about 1 ml. and triturated with 3 ml. of water. Crystals formed which after water washing and drying weighed 270 mg. Recrystallization from warm methanol yielded desdimethylaminotetracycline, $[\alpha]^{25}D$ −250° (0.5% in Methyl Cellosolve), m.p. 195° dec. The ultraviolet absorption spectrum in 0.1 *N* methanolic sulfuric acid showed λ_{max} in mμ (ε): 221 (23,100), 263 (24,700), 360 (21,400).

Anal. Calcd. for $C_{20}H_{19}NO_8$: C, 59.75; H, 4.77; N, 3.49. Found: C, 59.80; H, 4.72; N, 3.30.

B. From 4-*epi*-Tetracycline Methiodide.—Three grams of 4-*epi*-tetracycline methiodide was reduced, freeze-dried, leached with hydrochloric acid and dried *in vacuo*, using the conditions described above for tetracycline methiodide, to yield 2.4 g. of product. Two grams of this material was extracted with 100 ml. of hot ethyl acetate, leaving 0.76 g. of unextractables consisting largely of unreacted methiodide. Dilution of the extract with four volumes of petroleum ether yielded a precipitate which on drying weighed 0.9 g. A solution of this precipitate in 5 ml. of warm methanol gave, after one hour aging at room temperature, a crystalline product which, after being washed with methanol and dried, weighed 0.23 g., $[\alpha]^{25}D$ −251° (0.5% in Methyl Cellosolve), m.p. 195° dec. Mixed melting point with the product from tetracycline methiodide showed no depression. The ultraviolet absorption spectrum in 0.1 *N* methanolic sulfuric acid showed λ_{max} in mμ (ε): 221 (22,200), 263 (24,300), 360 (21,300).

Anal. Calcd. for $C_{20}H_{19}NO_8$: C, 59.75; H, 4.77; N, 3.49. Found: C, 59.40; H, 4.88; N, 3.42.

Identity and Homogeneity of Desdimethylaminotetracycline from Tetracycline Methiodide and from 4-*epi*-Tetracycline Methiodide.—The samples of desdimethylaminotetracycline prepared from the two sources were judged identical on the basis of optical rotation, melting point, ultraviolet absorption spectrum and the elemental analysis data presented above. In addition, infrared spectra were identical.

Countercurrent distribution in a 50-tube Craig machine, using the system chloroform against 0.2 *M* aqueous phosphate buffer (*p*H 7.53), gave, for each sample, a single peak at tube 34. The shape of the peak for each sample corresponded with the theoretical curve for a single component peaking at tube 34. The ultraviolet absorption spectra of both peak tube contents were identical with each other and with those of the two starting materials.

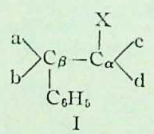
Studies in Stereochemistry. XXVI. Solvolytic Rearrangements in the 1,2-Diphenyl-2-methyl-1-butanol System[1]

BY DONALD J. CRAM AND JANET ALLINGER

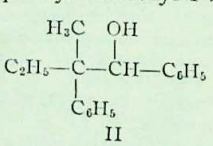
RECEIVED OCTOBER 1, 1956

The tosylates of the optically pure diastereomers of the 1,2-diphenyl-2-methyl-1-butanol system have been solvolyzed in dry acetic and formic acids, respectively. Phenyl migration from C$_\beta$ dominates the reaction course, at the most only a trace of alkyl migration being observed. In the more nucleophilic and poorer ionizing solvent (acetic acid), a larger amount of unrearranged product was observed, the simple substitution reaction being somewhat stereospecific in the *direction of inversion*. In the less nucleophilic and better ionizing solvent (formic acid), a smaller amount of unrearranged product was observed, the simple substitution reaction being somewhat stereospecific in the *direction of retention*. The results indicate that three stereochemically discrete processes compete with one another, all three leading to simple substitution product: (1) a simple solvolytic inversion mechanism; (2) a simple solvolytic mechanism whose specificity is sterically induced by the asymmetry at C$_\beta$; (3) a phenonium ion mechanism which can lead to simple substitution product with retention of configuration. That rearranged products arise from both bridged and rearranged open carboniun ions is indicated.

In previous investigations of this series, the solvolytic behavior of systems I have been studied in which a = c = alkyl and b = d = hydrogen[2]; a = b = c = d = alkyl[3]; a = alkyl, b = c = hydrogen and d = phenyl[4]; and a = phenyl, b = c = hydrogen and d = alkyl.[5] Others have studied systems I in which a = alkyl, b = c = d = hydrogen[6]; a = b = c = hydrogen and d = alkyl[7]; a = c = phenyl, b = d = hydrogen.[8] The tendency for phenyl to participate in ionization was found to vary markedly with the electrical nature of substituents at C$_\alpha$ and C$_\beta$, as well as the character of the solvent, and the steric situation within the molecule. The 1,2-diphenyl-2-methyl-1-butanol



I



II

system (II) belongs in a borderline category with respect to phenyl involvement in ionization, and this paper reports the results of an investigation of the acetolysis and formolysis of its diastereomeric tosylates.

Methods

The four stereoisomers of II were isolated in a pure state and their configurations assigned in a previous investigation.[9] The four tosylate derivatives were prepared from the corresponding potassium alcoholates and tosyl chloride, the derivatives possessing the *threo* configuration being particularly unstable. The products were isolated in the usual way, the olefin–ester mixtures being converted (LiAlH$_4$) to alcohol–olefin mixtures which were separated into olefin and alcohol components. In runs involving *erythro* materials and *threo* materials, 73 and 87%, respectively, of the starting materials were accountable.

Analysis of Alcohol Fractions.—Comparison of the infrared spectra of the alcohol components obtained from the solvolyses with those of *threo*- and *erythro*-II and of III (product of phenyl migration) suggested the bulk of the material to consist of these components. Accordingly, infrared analytical procedures were developed based on these three components utilizing the six most advantageous wave lengths in the infrared for analysis. Two independent sets of three simultaneous equations when solved provided estimates of percentage composition. Known mixtures of the three components indicated the deviations from Beer's law to be small. The analyses for the acetolysis runs (runs 1 and 2 of Table I) for the total secondary alcohol (diastereomers of II) and tertiary alcohol III have a probable error of about 2% since the optical densities differ by factors from 1 to 4. The analyses for the individual diastereomers of II are grossly inaccurate because the optical densities of these components are rather close together, the biggest factor being 1.6. To improve the accuracy of this analysis and to examine the optical character of the diastereomeric components (II), the alcohol mixtures were heated with strong

base under conditions that destroyed III and left II.[10] The isolation of diphenylmethane from the reaction provides qualitative evidence for III in the starting material. The diastereomeric mixtures of II thus obtained were submitted to a two-component infrared analysis utilizing four wave lengths in the infrared and appropriate known mixtures. A polarimetric analysis was also used (a plot of rotation *vs.* % composition is linear)[9] based on the assumption that the diastereomers were optically pure. The agreement between the two methods indicates this assumption to be valid. Independent evidence for their optical purity was found in the coincidence of rotations of IV obtained from known mixtures of optically pure diastereomers and from these mixtures obtained from the acetolyses. Table I records the results of these analyses, a sample of raw data being recorded in the Experimental.

$$\text{II} \xrightarrow[2,\ LiAlH_4]{1,\ CH_3C_6H_4SO_2Cl} C_6H_5{-}\underset{\displaystyle C_2H_5}{\overset{\displaystyle CH_3}{\overset{|}{\underset{|}{C}}}}{-}CH_2{-}C_6H_5 \qquad \text{IV}$$

The rotations of alcohols obtained from the acetolysis containing tertiary alcohol III were of course different from the corresponding alcohols after III had been removed. To see if III was active or inactive, synthetic mixtures of optically pure *threo*- and *erythro*-II and racemic III were prepared in the same proportions as the mixtures obtained from the solvolysis reactions. The rotations of these mixtures demonstrated that the rotational contributions of the three components were virtually additive. The differences in rotation between the synthetic mixtures and those obtained from the solvolyses suggest that the tertiary alcohol III in the solvolysis mixtures possesses a specific rotation of about 5° in the presence of *threo*- and *erythro*-II. The large number of analytical values utilized in the calculation makes this conclusion tentative. Since optically pure III was not prepared, the *degree* of optical purity of the III produced from the solvolyses cannot be estimated.

Similar analytical procedures were applied to the formolysis products (runs 3 and 4, Table I). Although the analysis at the first set of wave numbers gave internally consistent data (the sum of the components came to 100%), some of the values at the other set were not real. After being submitted to the treatment with base, the polarimetric and infrared analysis of the alcohol product pointed to the presence of only *threo*- and *erythro*-II in this final mixture. These facts suggest that small amounts of other components were present in the initial alcohol mixtures obtained from solvolysis, which were destroyed by the treatment with base. The ketone fragments obtained from the basic treatment were converted to their 2,4-dinitrophenylhydrazones. Although crystalline derivatives were obtained, pure compounds could not be isolated. The color of the solid material was characteristic of derivatives of ketones conjugated with benzene rings. The data taken as a whole suggest the contaminants to be products of either methyl or ethyl migration (V to VI) or both, which upon treatment with strong base would give acetophenone and propiophenone, respectively.[10] Unfortunately, the trace amounts involved did not permit definitive identification.

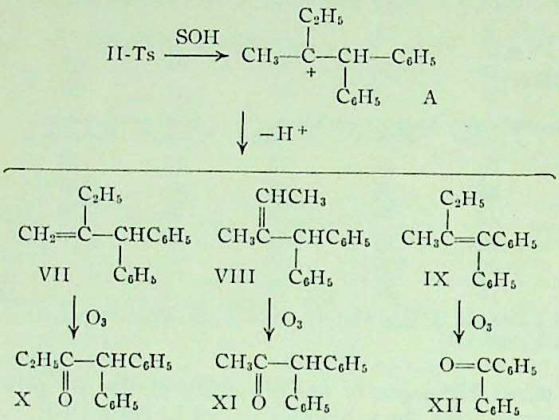
possible products of the reaction. Three olefins VII, VIII and IX could arise from the carbonium ion A produced by phenyl migration during the solvolysis of II-Ts. The analysis problem was simplified by converting the mixture of olefins obtained to their ketones (X, XI and XII) through ozonolysis, the ketonic mixtures being analyzed



through infrared techniques for these three components (see Experimental for details). The 2,4-dinitrophenylhydrazone of XI was isolated from the ketonic mixture obtained in run 2 and was compared with an authentic sample. These analyses provided only estimates of the amounts of the three components, since small amounts of unidentified components (~10%) interfered. Table II records these estimates as well as the yields of olefin and ketone obtained.

TABLE II

ESTIMATED % COMPOSITION OF KETONE DERIVED FROM OLEFINS ARISING IN SOLVOLYSIS OF II-Ts

[a] Run numbers same as in Table I. [b] Details of method are in Experimental. [c] Based on tosylate.

Control Experiments.—Control experiments demonstrated that the acetates of II and III once formed were stable. The formates of II and III could not be prepared. The stabilities of the diastereomeric 1,2-diphenyl-1-propyl formates in formic acid at 25° have been examined previously[4] and were found to have been formed decidedly faster than they were interconverted. The similarity between this system and II taken in conjunction with the balance between the diastereomeric formates obtained from formolysis of II-tosylate (see Table I) indicates that the formates are formed somewhat faster than they react. The olefinic products in both the formolysis and acetolysis were demonstrated not to change upon further submission to solvolysis conditions. Earlier results[11] suggest that the balance of olefins is kinetically controlled in the acetolysis reaction, but might be thermodynamically controlled in the formolysis. The effectiveness of the removal of III from mixtures of II and III by treatment with strong base was demonstrated with experiments utilizing synthetic mixtures.

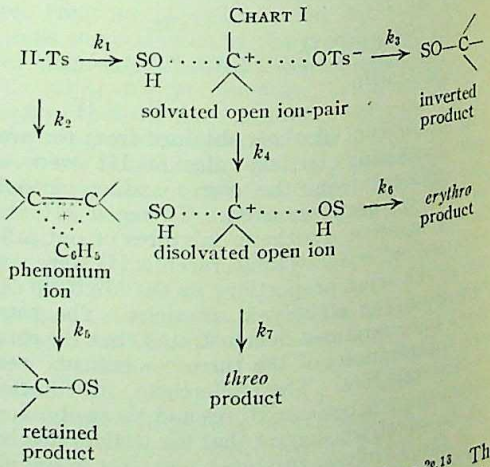
Discussion

The Products of Simple Substitution.—The results indicate that in the solvolysis of the 1,2-diphenyl-2-methyl-1-butyl system, a number of primary processes compete with one another, each of which leads to intermediates that partition between several different products. Phenyl and solvent participation in ionization are the likely primary processes, the first leading to phenonium ion,[2] the second to solvated open ion. Evidence for these two primary processes is found in the stereochemical course of substitution that occurs *without rearrangement*. In acetolysis the ratios of

Starting material	*erythro*-II-Ac / *threo*-II-Ac	*erythro*-II-Fm / *threo*-II-Fm
threo-II-Ts	2.3	0.85
erythro-II-Ts	1.3	3.0

erythro to *threo* acetates are different from the diastereomeric starting materials, predominating inversion occurring with *threo* and predominating retention with *erythro* material. These results can be most simply interpreted without assuming a phenonium ion intermediate. In Chart I, the starting material (II-Ts) can ionize with either phenyl or solvent participation, depending on the values of k_1 and k_2. If $k_1 >> k_2$, then the balance between product of retained and inverted configuration is controlled by the relative values of k_3 and k_4 on the one hand and k_6 and k_7 on the other. For the acetolysis of *threo*-II-Ts, k_3 being greater than k_4 explains the results. With *erythro*-II-Ts $k_4 > k_3$ and $k_6 > k_7$. Since the disolvated open ion is the same for each diastereomer,[12] k_6 and k_7 should be independent of starting configuration. This predisposition of the system to give *erythro* material is

CHART I



consistent with previous generalizations.[2c,13] The over-all process described by k_1-k_3 is similar in its

(12) Implicit in this statement is the assumption that the disolvated ion has a half-life longer than that of the rotations which lead to equilibration between the various conformations.

(13) D. J. Cram and F. A. Abd Elhafez, THIS JOURNAL, 74, 5851 (1952).

steric requirements to SN2 processes, which is visualized in Chart II as occurring with the displacing group (X^-) coming across the smallest group (S) attached to the adjacent asymmetric carbon atom. The transition state for isomer A which is a model for *threo*-II-Ts should be more stable than that for B which is a model for *erythro*-II-Ts. Thus $k_3 > k_4$ for *threo*-II-Ts and $k_4 > k_3$ for *erythro*-II-Ts. Of the three conformations of the disolvated open ion in Chart III, only C allows the incoming solvent to come in across the smallest

CHART II

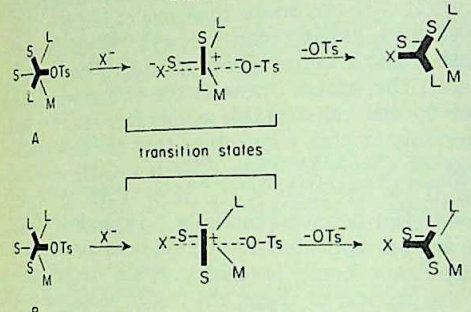

CHART III

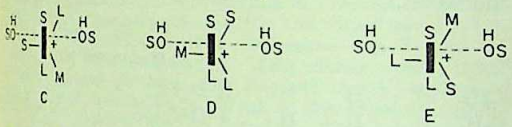
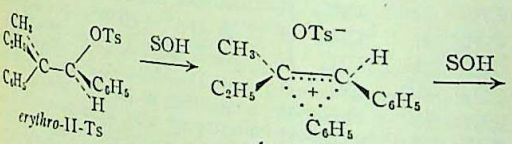
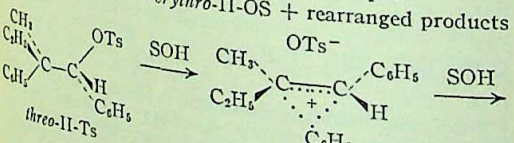


group (S) attached to the adjacent carbon, and at the same time allows the two large groups (L) to be as far away from each other as possible. Thus *erythro* product should dominate, and $k_6 > k_7$, as is indeed observed.



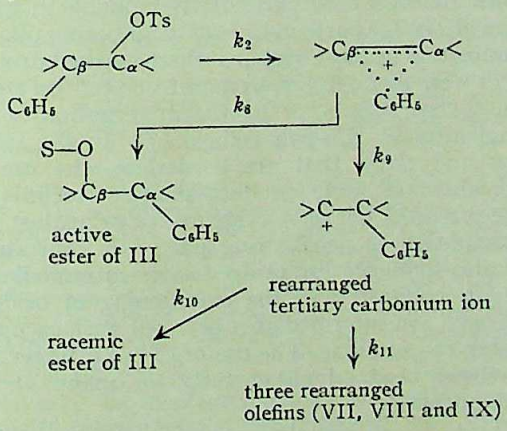


In the formolysis, on the other hand, with both starting materials the simple substitution reactions occurred with predominating retention of configuration. The stereospecificity was more marked with *erythro* isomer as the starting material. In this more ionizing and less nucleophilic solvent, the results cannot be explained only on the basis of the primary process described by k_1. In view of the facts that much of the product has undergone phenyl rearrangement and that in other systems a phenonium ion intermediate has been demonstrated,[2] it seems likely that the process described by k_2 leading to a phenonium ion is responsible for the dominating retention process. That the retention is more marked with *erythro* starting material is probably due to $k_4 > k_3$ in formic acid, and $k_6 > k_7$ (the relative values of these rates should be much more insensitive to solvent).

Although other processes such as the formation of phenonium ions from open ions or *vice versa* or ion-pair collapse might also play a role in the solvolyses, they are not demanded by the data.

The Products of Rearrangement.—Although the migration of methyl or ethyl groups probably occurred to a small extent particularly in the formolysis, the reaction products were largely those in which a phenyl migration had occurred. In the acetolysis the ratios of rearranged to unrearranged product were 4.6 and 4.0 for *erythro* and *threo* materials, respectively, while the corresponding values in the formolysis were 6.1 and 5.2. In each solvent, the amount of starting material accounted for was higher (85–88%) with *threo* than with *erythro* starting material (75–71%), and the absolute yields of both rearranged and simple substitution products were greater for the *threo* than for the *erythro* materials. It is clear that neither the slightly more important eclipsing effects expected from the phenonium bridge from *erythro* material nor the greater ease with which *threo* material enters into simple substitution play anything more than minor roles in directing the reaction courses.

The question of the optical purity of the tertiary alcohol III ultimately obtained in these experiments unfortunately was not settled. What few data are available suggest that it was at least partially active, which in turn points to the process de-



scribed by k_2–k_8. That most of the tertiary ester came from rearranged open ion (k_2–k_9) in the acetolysis is suggested by the fact that the ratios of yields of olefin (rearranged) to rearranged tertiary alcohol are about the same from both *threo* and *erythro* starting materials (15.2 and 14.1, respectively). The absolute yields of rearranged alcohol III were much higher (factor of 6) in the formolysis, and the ratios of yields of olefin to alcohol III were 1.71 and 1.61 from *threo* and *erythro* materials. In this solvent probably a lower proportion of III-ester came from rearranged open ion and a higher proportion directly from the phenonium bridge. That bridged ion-pairs go directly to ester product in the more dissociating formic acid solvent (as contrasted to acetic acid) has been demonstrated in other sys-

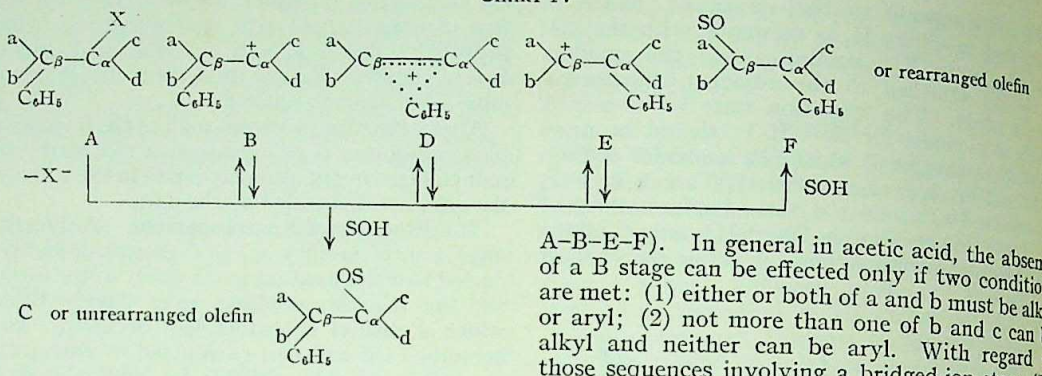
CHART IV



tems.[2c,e,14] That essentially all of the olefin came through the rearranged open ion (process k_9–k_{11}) in acetic acid is indicated by the fact that their ratios are independent of the starting configuration (see Table II). The same thing also probably is true in formic acid, although the analyses were so poor due to contaminants that this has not been demonstrated (Table II). It is interesting that in both solvents only small amounts of the most conjugated olefin (IX) were formed, presumably because of eclipsing effects.

The Variation in Mechanism of the Wagner–Meerwein Rearrangement (Phenyl the Migrating Group) as a Function of the Substituents at C_α and C_β.—Enough systems have now been studied in detail so that the dependency of the mechanism on the non-migrating substituents at C_α and C_β can be examined from a general standpoint. The kinetic tool has been particularly valuable in gaining evidence for participation of neighboring phenyl in ionization in those systems where marked driving forces were evident and were not masked by steric or inductive effects, or by the intervention of internal return[14] (ion-pair collapse).[2c] In the latter cases and those that are borderline, the use of stereochemical and product-analysis techniques have provided not only evidence for or against the participation of neighboring phenyl in ionization, but also evidence for bridged ionic intermediates, ion-pair collapse, and the partitioning of bridged and open ion intermediates between various paths leading to product. The use of C^{14} as a tracer has also been used advantageously for many of the same purposes.

Chart IV represents a general and simplified mechanistic scheme, reference to which permits the classification of systems according to what stereochemically differentiated gross mechanism for solvolysis applies. The capital letters refer to discrete species and the dashes to transition states separating these species. These data show that by appropriately substituting C_α and C_β and by utilizing the proper solvents, many combinations of intermediates can be detected. The following sequences have not been demonstrated: A–F, A–E–F (as distinct from a possible A–D–E–F), A–B–E–F (as distinct from a possible A–B–D–E–F) A–B–D–F (as distinct from a possible A–B–D–E–F), A–B–D–E–F (as distinct from a possible A–B–E–F). In general in acetic acid, the absence of a B stage can be effected only if two conditions are met: (1) either or both of a and b must be alkyl or aryl; (2) not more than one of b and c can be alkyl and neither can be aryl. With regard to those sequences involving a bridged-ion stage (D-stage), the bridge opens at the carbon which could lead to the most stable carbonium ion. It is interesting in this connection that the last two systems of Chart IV (a = CH_3, b = C_2H_5, c = C_6H_5, and d = H; a = CH_3, b = C_2H_5, c = CH_3, d = C_2H_5) behaved similarly. In the first of these, the bridge appeared to open in both directions, the quaternary being favored over the benzyl carbon. In the second of these, the bridge of course opened in both directions. In both systems open carbonium ions (B and E stages) appeared to be intermediates.

$[\alpha]^{25}D$ +1.86° (benzene, *c* 10.1)[9] and 1.5 g. of potassium metal were held at reflux under anhydrous conditions under nitrogen for 4 hours. The mixture was cooled to 0°, 7.16 g. of freshly crystallized tosyl chloride was added under nitrogen and the resulting mixture was stirred for 30 minutes. The mixture was filtered always keeping the cake wet with benzene (metallic potassium). The filtrates were washed with water, twice with dilute sodium carbonate solution, again with water and dried. The solvent was evaporated at 25°, and the residue was crystallized from pentane at 0° to give a 6.5-g. 1st crop and a 1.46-g. 2nd crop. Recrystallization of this material from an ether–pentane mixture at 0° afforded 6.4 g. (43% yield) of white needles, m.p. 52° dec., $[\alpha]^{26}D$ +60.2° (benzene, *c* 3.91).

Anal. Calcd. for $C_{24}H_{26}SO_3$: C, 73.06; H, 6.64. Found: C, 73.08; H, 6.60.

In a similar manner, 8.7 g. of (−)-*erythro*-II $[\alpha]^{25}D$ −1.91°, (benzene, *c* 10.5)[9] was converted to 9.8 g. (69% yield) of tosylate ester, m.p. 54° dec., $[\alpha]^{25}D$ −59.8° (benzene, *c* 3.70).

Anal. Calcd. for $C_{24}H_{26}SO_3$: C, 73.06; H, 6.64. Found: C, 73.23; H, 6.51.

Similarly, from (+)-*threo*-II $[\alpha]^{25}D$ +59.4° (benzene, *c* 10.4)[9] was obtained a 74% yield of tosylate (white needles), m.p. 54° dec. This ester was so unstable it decomposed before rotations and analysis could be obtained. From (−)-*threo*-II $[\alpha]^{2}D$ −59.3° (benzene, *c* 10.4)[9] was obtained a 53% yield of tosylate (white needles), m.p. 56° dec. The sample decomposed before rotation could be recorded.

Anal. Caled. for $C_{24}H_{26}SO_3$: C, 73.06; H, 6.64. Found: C, 73.19; H, 6.90.

Acetolysis of the Tosylates of the Isomeric 1,2-Diphenyl-2-methyl-1-butanols (II).—A solution of 1722 ml. of freshly distilled acetic acid, 64 ml. of acetic anhydride and 12.5 g. of C.P. anhydrous potassium carbonate was heated at reflux for 24 hours and cooled. This solution was 0.1002 *M* in potassium acetate. The tosylate of (+)-*erythro*-II (6.4 g., run 2) was added to 180 ml. of this solution. Solution of the ester required 20 minutes. This solution protected from moisture was allowed to stand at 25° for 83 hours, and then poured into 600 ml. of water containing 10 ml. of a saturated sodium chloride solution. The resulting mixture was extracted with pure pentane, the pentane solution was washed with water, sodium bicarbonate solution and again with water. The organic layer was dried, evaporated, and the residual oil was distilled at 2 mm. with a final bath temperature of 135° to give 4.21 g. of colorless oil. The small amount of residue (<0.05 g.) when triturated with water gave an acidic solution. The distillate was added to a stirred mixture of 0.4 g. of lithium aluminum hydride and 100 ml. of anhydrous ether and, after stirring for 50 minutes at 25°, the mixture was diluted first with wet ether and then with ice-cold water. The layers were separated, the organic layer was washed with water, dried and evaporated to an oil. This oil was dissolved in 5 ml. of pure pentane and chromatographed on a column of 120 g. of neutral Activity III alumina[15] made up in pentane. The olefin was washed from the column with pentane, 1.98 g. of distilled eluate being obtained, $n^{25}D$ 1.5690, $\alpha^{25}D$ +0.09° (1 dm., neat). The alcoholic fraction was eluted with 250 ml. of C.P. methanol to give 0.59 g. of viscous oil (distilled material), $n^{25}D$ 1.5689, $[\alpha]^{24}D$ +24.1° (benzene, *c* 10.0). These two fractions (olefin and alcohol) were used in the subsequent infrared and polarimetric analyses.

A similar acetolysis and isolation procedure (run 1) as applied to the tosylate of (+)-*threo*-II (6.10 g.) gave 3.5 g. of distilled alcohol–olefin product (residue 0.03 g.). Chromatographic separation of these fractions gave 2.33 g. of olefin, $n^{25}D$ 1.5711, $\alpha^{27}D$ +0.07° (1 dm., neat) and 0.79 g. of alcohol, $n^{25}D$ 1.5687, $[\alpha]^{25}D$+18.3° (benzene, *c* 10.2), which were submitted to infrared and polarimetric analysis.

Formolysis of the Tosylates of the Isomeric 1,2-Diphenyl-2-methyl-1-butanols (II).—A solution of 1.0 liter, 25% C.P. alcohol-free chloroform–75% anhydrous formic acid (% by volume) and 3.7 g. of anhydrous sodium formate was titrated[16] and found to be 0.0538 *M* in sodium formate. Kinetic measurements[16] indicated the rates of formolysis of a mixture of the diastereomeric tosylates to be too fast to measure, the reaction being over in less than 2 minutes at 25°. The tosylate ester of (−)-*erythro*-II (6.9 g., run 4) was dissolved in 360 ml. of the above solution (immediate solution was observed), allowed to stand at 25° for two minutes, and was poured onto one l. of crushed ice–water mixture containing 10 ml. of saturated sodium chloride solution. The isolation procedure was the same as in the acetolysis, 4.05 g. of distilled olefin–alcohol being obtained (no residue from the olefin–formate distillation was observed). The olefin fraction amounted to 1.60 g., $n^{25}D$ 1.5714, $\alpha^{25}D$ −0.26° (1 dm., neat), and the alcohol, 1.42 g., $n^{25}D$ 1.5686, $[\alpha]^{24}D$ −13.0° (benzene, *c* 10.2).

Similar treatment (run 3) of 7.0 g. of (−)-*threo*-II gave 4.22 g. of olefin–alcohol mixture (distilled). No residue was obtained from the olefin–formate distillation. The olefin fraction amounted to 1.91 g., $n^{25}D$ 1.5710, $\alpha^{25}D$ −1.71° (1 dm., neat), and the alcohol fraction was 1.59 g., $n^{25}D$ 1.5683, $[\alpha]^{24}D$ −17.7° (benzene, *c* 10.1).

The olefin fractions from both solvolyses appeared to be unstable to air and could not be allowed to stand.

Ozonolysis of Olefins Obtained from Solvolyses.—The procedure is illustrated as applied to olefin from run 2. To olefin (1.0 g.) dissolved in 40 ml. of C.P. methylene chloride at 0° was added (bubbled through) ozone for one hour. After this time a rubber tube fitted to the exit tube showed signs of decomposition. The mixture was then added dropwise to a refluxing mixture of 1.0 g. of zinc dust, a crystal of silver nitrate and 50 ml. of distilled water. The resulting mixture was refluxed for 15 minutes, cooled and extracted with pentane. The pentane layer was washed, dried, evaporated, and the residue was distilled at 2 mm. (bath temperature 135°) to give 0.92 g. of a ketonic mixture, $n^{25}D$ 1.5703, $\alpha^{25}D$ −0.11° (1 dm., neat). A small amount of this material when treated with 2,4-dinitrophenylhydrazine reagent afforded after two recrystallizations of the product yellow needles, m.p. 137.8–139.2°, undepressed by admixture with an authentic sample of the 2,4-dinitrophenylhydrazone of 1,1-diphenyl-2-propanone (m.p. 140°, see below for preparation).

The aqueous phase from the above ozonolysis decomposition reaction was filtered and was qualitatively tested for formaldehyde (Deniges method)[17a] and acetaldehyde, (Ley reagent).[17b] Both tests were positive, and appropriate controls established that the aldehydes did not come from solvent impurities.

Olefin (1.0 g.) from run 1 gave upon ozonolysis 1.0 g. of ketone, $n^{25}D$ 1.5760, $\alpha^{25}D$ −0.22° (1 dm., neat). Positive tests for acetaldehyde and formaldehyde were obtained.

Olefin (1.0 g.) from run 3 gave 0.88 g. of ketonic mixture, $n^{25}D$ 1.5722, $\alpha^{26}D$ −1.60° (1 dm., neat), whereas olefin (1.0 g.) from run 4 gave 0.95 g. of ketone, $n^{25}D$ 1.5730, $\alpha^{26}D$ −0.39° (1 dm., neat).

Reverse Condensation Reactions Run on Alcohol Fractions.—The procedure is illustrated as applied to a synthetic mixture of alcohols II and III. A mixture of potassium metal (0.111 g.) and 2 ml. of anhydrous N-methylaniline (distilled from potassium) was heated at 200° under nitrogen for two hours, cooled to 72°, and a solution of 0.214 g. of racemic 1,1-diphenyl-2-methyl-2-butanol (III, see below) and 0.451 g. of (+)-II (mixture of optically pure diastereomers, $[\alpha]^{25}D$ +20.33° (benzene, *c* 9.99) in 1 ml. of anhydrous N-methylaniline was added. The reaction mixture was stirred at 72° for 30 minutes, cooled to 0°, and the trace of unreacted potassium metal was decomposed with ethanolic N-methylaniline. The resulting mixture was shaken with 4 ml. of concentrated hydrochloric acid in 40 ml. of water, 20 g. of ice and pentane. The pentane extract was washed with acid, water, was dried and the solvent was evaporated. The resulting oil was chromatographed on 30 g. of Activity III neutral alumina[15] made up in pentane. Development of the column with pentane gave eluent which upon distillation gave 0.106 g. (71%) of hydrocarbon which possessed an infrared spectrum identical to that of diphenylmethane. The alcohol was washed from the column with 100 ml. of C.P. methanol. The solvent was evaporated, the residue was taken up in pentane, and this solution was washed with water, dried and evaporated. Distillation of the residue (2 mm. and 145° bath temperature) gave 0.35 g. (77% recovery) of the same mixture of diastereomers of II that was used as starting material, $[\alpha]^{24}D$ +20.1° (benzene,

c 9.32), $n^{25}D$ 1.5692. Utilizing a similar procedure, alcohol from run 1 (0.70 g.) gave 0.08 g. of hydrocarbon and 0.48 g. of II, $[\alpha]^{25}D$ +19.3° (benzene, *c* 10.1). Likewise alcohol from run 2 (0.76 g.) gave 0.11 g. of hydrocarbon and 0.55 g. of II, $[\alpha]^{25}D$ +27.1° (benzene, *c* 10.1). Alcohol from run 4 (1.42 g.) gave 0.59 g. of hydrocarbon and 0.21 g. of alcohol, $n^{25}D$ 1.5685, $[\alpha]^{27}D$ −16.8° (benzene, *c* 5.23). Alcohol from run 3 (1.59 g.) gave 0.74 g. of hydrocarbon and 0.28 g. of II, $n^{25}D$ 1.5685, $[\alpha]^{25}D$ −32.9° (benzene, *c* 9.2). In all four of these runs, the infrared spectra of the hydrocarbon fractions were virtually identical to that of diphenylmethane. The chromatographs in runs 3 and 4 were run slightly differently than in the same procedure. Hydrocarbon was eluted with pentane, a ketonic contaminant was eluted with 20% ether in pentane, and the alcohol was eluted with methanol. The ketonic fraction in each case formed a *red* 2,4-dinitrophenylhydrazone which after two recrystallizations from ethanol gave *ca.* 2 mg. of red crystals which melted over a range and lower than 100°.

Conversion of 1,2-Diphenyl-2-methyl-1-butanol (II) to 1,2-Diphenyl-2-methylbutane (IV).—The procedure is illustrated as applied to a mixture of optically pure diastereomers of II. Alcohol (1.0 g.), $[\alpha]^{25}D$ +20.3° (benzene, *c* 9.91) was dissolved in 10 ml. of C.P. anhydrous benzene, and treated with 0.168 g. of potassium metal and 0.79 g. of tosyl chloride as in the procedure recorded above for the preparation of the tosylates of II. The crude tosylate ester thus obtained was added to a slurry (stirred) of 1.32 g. of lithium aluminum hydride and 100 ml. of anhydrous ether. The resulting mixture was stirred for two hours and allowed to stand at room temperature for 12 hours. Wet ether now was added and then finally a cold solution of aqueous ammonium chloride. The organic layer was washed with water, dried and evaporated. The residue was chromatographed on 30 g. of Activity I neutral alumina[16] made up in pure pentane. The desired product was eluted with 100 ml. of pure pentane, the solvent was evaporated, and the residual oil was distilled at 3 mm. and a bath temperature of 125°, wt. 0.55 g. This impure material was dissolved in 5 ml. of glacial acetic acid, 0.6 g. of 2,4-dinitrobenzenesulfenyl chloride was added and the resulting solution was heated at 100° for one hour. The reaction mixture was cooled and placed directly on a chromatographic column of 40 g. of activity III neutral alumina[15] made up in pure pentane. The desired hydrocarbon was eluted with 100 ml. of pure pentane, the solvent was evaporated, and the residue was distilled to give 0.55 g. (59% yield) of (+)-1,2-diphenyl-2-methylbutane (IV), $n^{25}D$ 1.5550, $\alpha^{25}D$ +66.3° (1 dm., neat), d^{25}_4 0.9718, $[\alpha]^{25}D$ +67.4° (neat).

Anal. Calcd. for $C_{17}H_{20}$: C, 91.01; H, 8.99. Found: C, 90.95; H, 8.98.

Application of this procedure to 0.48 g. of the alcohol II obtained from run 1 gave 0.27 g. (60% yield) of optically pure hydrocarbon (IV), $n^{25}D$ 1.5542, $\alpha^{26}D$ +66.40 (1 dm., neat). From 0.55 g. of alcohol from run 2 was obtained 0.31 g. (60% yield) of optically pure IV, $n^{25}D$ 1.5547, $\alpha^{25}D$ +66.5° (1 dm., neat).

1,1-Diphenyl-2-propanone (XI).—This material was obtained in 55% yield[18] (two recrystallizations from pentane), m.p. 59–60.2° (reported[18] m.p. 60–61°). The 2,4-dinitrophenylhydrazone was prepared as yellow needles (absolute ethanol), m.p. 138–139.6° (reported[19] m.p. 140°).

Anal. Calcd. for $C_{21}H_{18}N_4O_4$: C, 64.61; H, 4.65. Found: C, 64.66; H, 4.81.

1,1-Diphenyl-2-butanone (X).—Application of a reported procedure[20] to the preparation of 1,1-diphenyl-1-hydroxy-2-butanol gave material, m.p. 114–115.1° (reported[20] m.p. 92°).

Anal. Calcd. for $C_{16}H_{18}O_2$: C, 79.31; H, 7.49. Found: C, 79.33; H, 7.60.

Conversion of 5 g. of this glycol to X[20] gave 4.3 g. (97% yield) of product, $n^{25}D$ 1.5678. This material was converted to its semicarbazone, five recrystallizations of which (benzene) gave soft needles (50% yield), m.p. 187.6–189.8°, reported m.p. 194–195°[21] and 185°.[22] Regeneration of the ketone X[23] (85% yield) gave X as a colorless liquid, $n^{25}D$ 1.5668. A 2,4-dinitrophenylhydrazone derivative was prepared, yellow needles (absolute ethanol), m.p. 118.2–119.8°.

Anal. Calcd. for $C_{22}H_{20}N_4O_4$: C, 65.33; H, 4.98. Found: C, 65.22; H, 5.06.

(+)-1,2-Diphenyl-1-butanone.—Since this compound was a potential product of the rearrangement, it was prepared in optically pure form. Resolution of 2-phenylbutanoic acid[24] gave material, b.p. 130–132° (4 mm.), $n^{25}D$ 1.5128, $[\alpha]^{25}D$ +90.3°(1 dm., neat), reported[24] $[\alpha]^{25}D$ +89.9° (1 dm., neat). The acid chloride was obtained from 9 g. of the acid and 16.5 ml. of thionyl chloride, and was allowed to react with diphenylcadmium prepared from 18.5 g. of bromobenzene, 2.83 g. of magnesium and 11.3 g. of anhydrous cadmium chloride in the usual manner.[25] The product was distilled through a 2.5-foot Podbielniak type of column to give 10.2 g. (83% yield) of ketone, b.p. 150–151° (5 mm.), m.p. 54.2–57.8°. Recrystallization of this material (three times) from ethanol–pentane gave 4.3 g. of ketone, m.p. 57–58°, $[\alpha]^{25}D$ +230.2° (benzene, *c* 4.99).

Anal. Calcd. for $C_{16}H_{16}O$: C, 85.67; H, 7.14; Found: C, 85.48; H, 7.17.

Racemic 1,1-Diphenyl-2-methyl-2-butanol (III).—Ethyllithium was prepared from 5.29 g. of lithium metal, 41.6 g. of ethyl bromide and 300 ml. of anhydrous ether. The reagent was filtered through a cotton plug, cooled under nitrogen to 0°, and mixed with 16 g. of 1,1-diphenyl-2-propanone in 50 ml. of dry ether. The solution (yellow) was stirred at 0° for one hour, and ammonium chloride solution was added. The organic layer was washed with water, dried and evaporated. The residual oil was treated with 27.8 g. of Girard T reagent[26] dissolved in 278 ml. of 10% (by volume) glacial acetic acid–absolute ethanol solution for 45 minutes. The mixture was then shaken with water and pure pentane, the pentane was washed with water, dried and evaporated. The residue was chromatographed on 320 g. of neutral ActivityIII alumina[15] made up in pure pentane. The column was washed with pentane, and developed with ether–pentane mixtures to give a number of fractions, each of which contained oil whose refractive indices and boiling points were virtually identical. This material was distilled (bath temperature 130–135° at 1 mm.) to give 12.4 g. of alcohol, $n^{25}D$ 1.5687. The infrared spectrum of this material contained a carbonyl band of weak intensity at 1705 cm.$^{-1}$.

When 5 g. of this material was treated with excess ethyllithium (6 mole ethyllithium to 1 mole "alcohol") at 25° for 4 hours there was obtained upon distillation of the crude reaction product 4.8 g. of the desired alcohol, $n^{25}D$ 1.5678. This material had no carbonyl absorption at 1705 cm.$^{-1}$.

Anal. Calcd. for $C_{17}H_{20}O$: C, 84.95; H, 8.39. Found: C, 84.74; H, 8.33.

The acetate of this tertiary alcohol III was prepared as follows: Alcohol III (2.9 g.) was treated at 135–140° for 68 hours with 12.3 g. of distilled acetic anhydride and 9.55 g. of pure pyridine. The black reaction mixture was shaken with pure pentane and dilute acid, the pentane layer was washed with acid solution, water, was dried and evaporated. The residue was chromatographed on 120 g. of Activity III neutral alumina[15] made up in pure pentane. From the eluent obtained with 5% ether–pentane was obtained 2.08 g. of a colorless oil, $n^{25}D$ 1.5473 (after distillation at 2 mm., 135° bath temperature). Crystallization of this material from methanol at −80° gave white tablets, m.p. 42.3–43.8°.

Anal. Calcd. for $C_{19}H_{22}O_2$: C, 80.80; H, 7.86. Found: C, 80.89; H, 7.87.

Both olefin and starting alcohol were isolated from the other chromatographic fractions.

(+)-*erythro*-1,2-Diphenyl-2-methyl-1-acetoxybutane.—From 2.25 g. of optically pure (+)-*erythro*-II, 9.48 g. of C.P. distilled acetic anhydride and 7.34 g. of pure pyridine (reaction at 135–140° for 10 hours) the product was obtained by the usual method. The crude acetate was dissolved in 10 ml. of pentane. After standing at −10°, the material crystallized as dense white tablets, m.p. 40–44°, 1.62 g. Recrystallization of the solid from pentane gave 1.5 g., m.p. 42.4–44°. Additional material (0.5 g.) was obtained by chromatography of the filtrates, m.p. 42.4–44°, total yield 75%, $[\alpha]^{25}D$ +8.93° (benzene, *c* 4.71).

Anal. Calcd. for $C_{19}H_{22}O_2$: C, 80.80; H, 7.86. Found: C, 80.98; H, 7.91.

(+)-*threo*-1,2-Diphenyl-2-methyl-1-acetoxybutane.—By a similar procedure except that a chromatographic purification was involved, 1.25 g. of (+)-*threo*-II gave 1.26 g. of its acetate as a colorless viscous oil, $n^{25}D$ 1.5476, $[\alpha]^{25}D$ +7.72° (benzene, *c* 4.72).

Anal. Calcd. for $C_{19}H_{22}O_2$: C, 80.80; H, 7.86. Found: C, 80.82; H, 7.75.

Other Materials for Infrared Analyses.—Benzophenone (commercial material) was recrystallized from ether–pentane to constant melting point, m.p. 52–54°. An analytical specimen of (−)-1,2-diphenyl-1-propanone was available from other studies,[27] m.p. 34–35°, $[\alpha]^{25}D$ −206° (chloroform, *c* 4.2).

Control Experiments.—The olefin mixture (0.6 g., $n^{25}D$ 1.5706) obtained from run 2 was resubmitted to the whole acetolysis and isolation procedure to give 0.51 g. of recovered material (85%), $n^{25}D$ 1.5708. Ozonolysis of this olefin gave 0.51 g. of ketonic mixture, $n^{25}D$ 1.5752, $\alpha^{25.5}D$ −0.05° (1 dm., neat). Similar ozonolysis of the original olefin gave ketone, $n^{25}D$ 1.5756, $\alpha^{25}D$ −0.05° (1 dm., neat). The infrared spectra of the two ketone mixtures were identical.

An olefin mixture was obtained by chromatography of (−)-*threo*-II-tosylate on alumina, $n^{25}D$ 1.5750, $\alpha^{25}D$ −0.06° (1 dm., neat). This material (0.35 g.) was also subjected to the acetolysis procedure and recovered, $n^{25}D$ 1.5750, $\alpha^{26}D$ −0.06° (1 dm., neat). Both the original olefin and that subjected to the acetolysis procedure were converted to their ketones. The infrared spectra, indices of refraction and rotations of these two samples were essentially identical ($n^{25}D$ 1.5709 and $\alpha^{25}D$ +0.40°, 1 dm., neat).

An olefin mixture obtained from the acetolysis of the tosylate of *rac-erythro*-II (0.50 g., $n^{25}D$ 1.5692) was submitted to the conditions of formolysis and recovered, wt. 0.45 g., $n^{25}D$ 1.5692.

A mixture of optically pure diastereomeric acetates of (+)-*threo*-II and (+)-*erythro*-II (1.0 g., $n^{25}D$ 1.5478, $[\alpha]^{25}D$ +8.31° (benzene *c* 7.33) was subjected to the acetolysis conditions, and 0.90 g. of acetate was recovered, $n^{25}D$ 1.5482, $[\alpha]^{25}D$ +8.35° (benzene, *c* 7.33). Reduction of this material with lithium aluminum hydride gave 0.70 g. of (+)-*threo* and (+)-*erythro*-II, $n^{25}D$ 1.5694, $[\alpha]^{25}D$ +35.4° (benzene, *c* 10.06). This rotation corresponds to a composition of 58% (+)-*threo*-II and 42% (+)-*erythro*-II which corresponds to the composition of the original acetate mixture.

The tertiary acetate of III (0.50 g., $n^{25}D$ 1.5475) was submitted to the acetolysis procedure to give 0.42 g. of recovered acetate, $n^{25}D$ 1.5476, whose infrared spectrum was identical to that of the starting material. Submission of this acetate to the lithium aluminum hydride reduction procedure gave 0.30 g. of tertiary alcohol III, $n^{25}D$ 1.5680 (as compared to $n^{25}D$ 1.5678 of an authentic sample). The infrared spectrum of this material was the same as that of III.

Attempts to prepare the formates of II and III failed, so analogous controls could not be applied to the formolyses.

Infrared Analyses of the Alcohol Fractions.—These analyses were performed with a Perkin–Elmer recording spectrophotometer, model 21. The samples were run in a 0.027-mm. cell (sodium chloride) as liquid films with a solid salt block of identical thickness to the cell windows as a blank. The instrument was balanced at 1355.5 cm.$^{-1}$ with response 1:1, gain 4.5, supression 5, speed 0 and resolution 940. Table III records the optical densities of *threo*- and *erythro*-II and III at those wave lengths most advantageous for analysis, a synthetic mixture of the three components, and the alcohol fractions from the acetolyses. A similar type of data was obtained for the alcohol fractions from the formolysis which contain these three components, as well as for the alcohol fractions from the formolyses and acetolyses from which tertiary alcohol III had been removed.

Infrared Analysis of the Ketone Fractions from Olefin.—The same instrument and cells were employed, except the instrument was balanced at 1423.5 cm.$^{-1}$. The total spectra of the ketonic mixtures from the acetolysis (runs 1 and 2) were nearly identical to one another, differing only slightly in the intensity of some peaks. The carbonyl region exhibited only two absorption maxima at 1705 and 1655 cm.$^{-1}$, which correspond to unconjugated carbonyl and doubly conjugated carbonyl absorptions, respectively.[28] There was no absorption maximum that corresponded to singly conjugated carbonyl absorption[28] at 1680 cm.$^{-1}$, and the sensitivity of the instrument to this type of compound was demonstrated with a synthetic mixture of ketones X, XI and XII to which only 8% of 1,2-diphenyl-1-propanone was added. This mixture exhibited significant optical density (0.75) at this wave length. Two absorption maxima at 1580 (conjugated phenyl absorption)[28] and 1355 cm.$^{-1}$ (acetyl group absorption)[28] further identified the components of the unknown mixtures as probably containing 1,1-diphenyl-2-propanone (XI) and benzophenone (XII). The amounts of X, XI and XII in these mixtures were estimated utilizing the "base line density" method[29] and synthetic mixtures and the optical densities at the following most advantageous wave numbers, X at 1105 cm.$^{-1}$, XI at 1355 cm.$^{-1}$ and XII at 809 and 920 cm.$^{-1}$.

TABLE III

DATA FOR INFRARED ANALYSIS OF ALCOHOL FRACTIONS OBTAINED FROM ACETOLYSIS (RUNS 1 AND 2)[a]

	Optical densities at cm.$^{-1}$

Studies in Stereochemistry. XXVII. Conformational Control of the Migrating Group in the Deamination of 3-Phenyl-2-butylamine[1]

BY DONALD J. CRAM AND JOHN E. MCCARTY

RECEIVED OCTOBER 1, 1956

The optically pure stereoisomers of 3-phenyl-2-butylamine have been deaminated in acetic acid and the products examined. With the *threo* isomer, methyl migration from Cβ dominated over phenyl migration by a factor of 1.5 to 1, whereas with the *erythro* isomer, phenyl migration from Cβ exceeded methyl migration by a factor of about 8 to 1. Methyl migration could not be detected when the stereoisomeric 3-phenyl-2-butyl tosylates were acetolyzed. These results coupled with those of others support the following hypothesis. Neither solvent nor neighboring group participation play much role in the breaking of the C–N_2^+ bond, and the fate of the *high energy open carbonium ion* thus created is determined by the relative proximity of the various neighboring groups and of solvent molecules. The relative positions of these species are therefore determined by the conformational populations of the starting diazotized amine. The products of methyl migration were partially optically active at the migration origin, this benzyl carbon atom having been partially inverted during the methyl migration. This result provides some evidence for the intervention of a *bridged methyl carbonium ion* intermediate in the rearrangement.

The propensity of the deamination reaction of aliphatic amines for initiating molecular rearrangements has been established by a large number of investigations. A number of recent mechanistic studies and observations have a direct bearing on the present research. Bernstein and Whitmore[2] demonstrated that the highly stereospecific rearrangement of (−)-1,1-diphenyl-2-amino-1-propanol to (+)-1,2-diphenyl-1-propanone observed much earlier by McKenzie, *et al.*,[3] occurred with inversion at the migration terminus. Roberts and co-workers[4c] found both methyl and hydrogen migration in the deamination of *n*-propylamine, but in this and other systems could find no evidence for the intervention of either hydrogen-[4a] or methyl-bridged carbonium ions.[4c,d] In the deamination of various *p*-substituted β-phenylethylamines, these authors[4b] observed a much smaller difference between the migratory aptitudes of *p*-nitrophenyl, phenyl and *p*-methoxyphenyl than had been observed in studies involving leaving groups other than N_2^+. Burr and Ciereszko[5] found in parallel studies of β-aryl-β-phenylethyl systems that with OH as a leaving group much greater differences in migratory aptitudes of phenyl and substituted phenyl were observed than when the leaving group was N_2^+. Curtin and co-workers[6] in an elegant study of the semipinacolic deamination reaction of various diastereomeric 2-phenyl-2-aryl-1-phenyl (or methyl)-1-ethylamines demonstrated that that aromatic nucleous migrated which gave a transition state where the bulky (non-migrating) groups attached to the two asymmetric carbon atoms were distributed *trans* to one another.

The present study describes the deaminative acetolysis of the optically pure diastereomers of 3-phenyl-2-butylamine (I). This system possesses certain peculiar advantages for mechanistic studies. (1) The acetolysis of 3-phenyl-2-butyl tosylate has been thoroughly studied,[7] and the effects of differences between tosylate and N_2 as leaving group can be assessed. (2) The intervention of "ethylene-phenonium ions" as intermediates in the migration of phenyl from Cβ to Cα can be detected making use of the symmetry properties of this system. (3) The three groups on Cβ, phenyl, methyl and hydrogen, all compete with one another in undergoing Wagner–Meerwein rearrangements, and in this system a correlation between the amounts of each group which migrate and the known configurations of the starting material is possible. (4) The system allows the stereochemistry of methyl migration to be examined at the migration origin (Cβ).

Three of the four optically pure stereomers of the 3-phenyl-2-butylamine system were prepared and their configurations determined in a previous study.[8] All four of the optically pure benzamide derivatives were reported.[8] In the current investigation the fourth isomeric amine possessing the D(−)-*erythro* configuration was prepared by the simple inversion in dioxane of the tosylate of optically pure D(−)-*threo*-3-phenyl-2-butanol. The rotation of this amine (α^{25}D −9.20°, *l* 1 dm., neat) compares favorably with that of its enantiomer prepared by direct resolution (α^{25}D +9.01°, *l* 1 dm., neat).

The methods of analysis and separation of the products of the deamination of the active isomers of 3-phenyl-2-butylamine are recorded in the Experimental, along with a number of control experiments on the solvolyses, the separations and the analyses.

Discussion

Table I records the yields of the various alcohol components obtained from the deaminative acetolysis of the stereomers of 3-phenyl-2-butylamine, as well as those obtained in previous studies[7] of the acetolyses under similar conditions of the tosylates

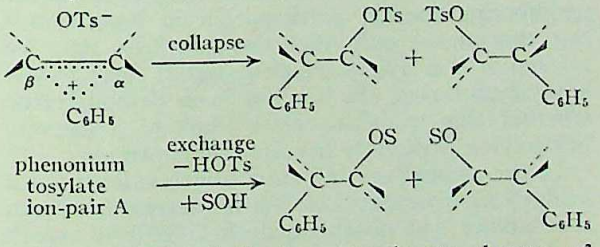
[a] The deaminative and tosylate acetolysis (ref. 7c) were both run at room temperature. However, a complete analysis of the secondary alcohol components of tosylate acetolysis was made only on product obtained from runs at 75° (ref. 11b). Enough data were obtained at both temperatures to indicate the patterns of results to be almost identical. The ratios of the various secondary alcohols to one another were taken from the runs at 75°. [b] Total alcohol fraction = 100%. [c] Starting amine or tosylate = 100%. [d] These are maximum values. Actual values are probably lower (see Experimental).

of the stereomers of 3-phenyl-2-butanol (III). In the deamination reaction each diastereomer gave appreciable but different amounts of products resulting from simple solvolysis (no rearrangement), from phenyl migration, from hydrogen and from *methyl migration*. In the tosylate solvolysis, the products of phenyl migration (3-phenyl-2-butanol) clearly dominated in both diastereomeric series, with small amounts of hydrogen migration, very small amounts of simple solvolysis product, and *no detectable product* from *methyl migration*.

Phenonium Ions as Intermediates in the Deamination Reaction.—In the tosylate solvolyses, both the high stereospecificity[7] and the enhancement of the rate of ionization[9] point to predominant phenyl participation in ionization. A complete analysis of the data for the *threo*-3-phenyl-2-butyl tosylate acetolysis[7c] provided the ratio 66/1 for phenyl over solvent participation in ionization and the ratio of 8/1 for hydrogen over solvent participation. Although a detailed calculation could not be carried out for the *erythro* isomer, it is clear that similar factors apply.[7b] In this and in similarly constituted systems,[10] phenonium tosylate ion-pairs (A) have been demonstrated to result from phenyl participation in ionization. These intermediates can collapse in either direction to give tosylate or can undergo anion exchange to give solvolyzed product. In acetic acid for the *threo*-3-phenyl-2-butyl system, collapse occurs four times as frequently as exchange.[7b]

A very different pattern of products arises in the deaminative acetolysis. That phenyl migrates from C_α to C_β is clear from the fact that in the *threo* series 24% of the alcoholic product is racemic 3-phenyl-2-butanol (III), 19% *threo* and 5% *erythro*. That simple substitution occurs to almost the same extent is indicated by the 20% of active 3-phenyl-2-butanol (6% *threo* and 14% *erythro*) obtained. With the *erythro* isomer, the high yield of product (68%) of configuration identical to that of starting material (substitution with retention) indicates that here as well phenyl migration occurred, although the symmetry properties of the system prevent its direct detection. The 6% of *threo* product indicates a somewhat lower degree of simple solvolysis in this as compared to the *threo* series.



These results indicate a moderate degree of stereospecificity for the process involving phenyl migration but of a much lower order than was observed in tosylate solvolysis. Of the 25% of *threo* product from *threo* starting material, 19% was racemic, pointing to the intervention of the internally compensated phenonium ion (B) as an

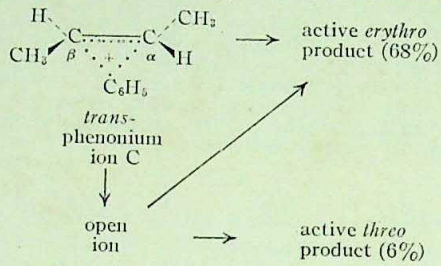
intermediate. This intermediate appears to have been disposed of both by direct ring opening to give *threo* product and by giving racemic open ion which in turn could go to either racemic *threo* or *erythro* material. This phenonium ion is then different in some respect from that produced from tosylate solvolysis, which only underwent direct ring opening to give racemic *threo* product. This point will be discussed later. In the *erythro* series, the phenonium ion produced is asymmetric, and direct ring



opening at either Cα or Cβ would give active material of the same configuration as the starting material. If this bridged ion gave open ion, this intermediate would be optically active and would give a mixture of active *threo* and *erythro* product. The results suggest that *direct ring opening* predominated in both series, but some rearranged, racemic, open ion is needed to explain the production of 5% racemic *erythro* product obtained from active *threo* starting material.

The Question of Bridged Methylcarbonium Ions as Intermediates in the Wagner–Meerwein Rearrangement.—Although bridged methylcarbonium ions frequently have been discussed[11] and deliberately sought for, not a shred of evidence for their intervention as reaction intermediates has been forthcoming. Some evidence has been obtained from rate comparisons in the solvolysis of neopentyl and more ramified tertiary systems for neighboring methyl participation in ionization,[12] but this means only that the *transition state for ionization is a hybrid* which *possesses some methyl bridged character*. It has not been demonstrated whether this transition state leads to a discrete bridged ion or directly to rearranged open ion.

In the present investigation some evidence for a bridged methylcarbonium ion is presented. From *threo*-amine was obtained alcohol, 32% of which was the product of methyl migration (1-phenyl-2-methyl-1-propanol or II) and from *erythro*-amine 6% was similarly rearranged. Of this rearranged material, 16% was optically active in the *threo* and 3% in the *erythro* runs. The stereochemistry of this rearrangement can be determined only if the relative configurations of reactant and product are known. The configurations of the starting materials have been established relative to D-glyceraldehyde,[8] but the configuration of 1-phenyl-2-methyl-1-propanol (II) has never been determined by chemical interconversions. However, the configuration of this compound can be assigned with a high probability of correctness relative to that of D-glyceraldehyde through the use of Freudenberg's displacement rule.[13,14] Levene, Mikeska and Marker[15] gathered the rotational data set forth in Table II, which when coupled with the known[16] configuration of 1-phenyl-1-ethanol allows the configurations of the other alcohols of Table II to be assigned the structures there set forth. The stereochemistry of the methyl migration thus becomes known and is formulated in Chart I.[17]

[a] $M^{25}D$ (l 1 dm., neat). [b] Acid phthalate. [c] $M^{25}D$ (l 1 dm., c 0.01 M, ethanol). [d] From the present investigation.

Any mechanism used to explain this methyl migration must satisfy three main facts. (1) Both racemic and active product were obtained from both diastereomers. (2) The ratios of racemic to active product differ widely for the two diastereomers (*threo*, 5/1; *erythro*, 30/1). (3) In the production of optically active II, the migration origin was inverted. A completely concerted mechanism[18] by which all of the product was produced is thus eliminated, although the very remote possibility remains that the active portion of product arose by a completely concerted process, and the racemic material by a multistage course involving carbonium ions devoid of asymmetry. A mechanism in which *all of the product* arose from such a carbonium ion is also eliminated.

The data support the mechanistic scheme set forth in Chart I.[19] Here the *threo*-amine goes to a methyl bridged asymmetric carbonium ion with inversion of the migration terminus, the phenyl and methyl groups being *trans* to one another. Similarly the *erythro*-amine goes to a methyl bridge, also asymmetric, in which the methyl and

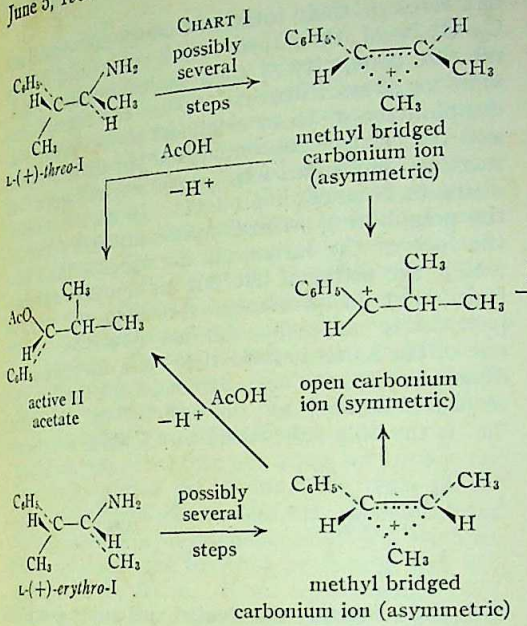
CHART I

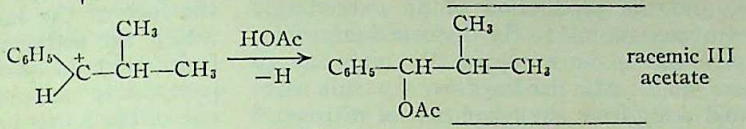


phenyl groups are *cis* to one another. Each of these bridged ions partition between two processes, one involving ring opening at the benzyl carbon to give directly (one transition state) optically active rearranged acetate with the migration origin inverted, the other involving ring opening to give the symmetrical phenyl isopropylcarbonium ion which goes to racemic rearranged acetate. Since the two bridges are diastereomerically related, they would partition differently between these two processes. The *trans* bridge from *threo* material might be expected to be the more stable of the two, and therefore to be the species more favorably disposed to undergo ring opening by solvent to give active product, as is indeed observed.

A second mechanistic scheme should also be considered (Chart II), in which the methyl bridges are transition states, not discrete intermediates. Thus *threo* material passing through a *trans* bridged transition state might give a rearranged disolvated open ion (D) which differs from that from *erythro* material (E) in rotational conformation. Should k_c be the same order of magnitude as k_e, optically active acetate with the migration origin inverted could arise. That D or E collapse *directly* from both sides with equal probability to give racemic material is unlikely, since the steric situation distinctly favors entrance from the top. The ratio of k_c/k_e should differ for D and E, and the greater stability of D should favor a higher value for this ratio, leading to a higher degree of optical activity for rearranged acetate, as was observed.

Of these two explanations, that involving the methyl bridge as a discrete intermediate is preferred on both the basis of simplicity and analogy. Since the leaving group in this deamination reaction is a nitrogen molecule, mechanisms involving rearranged ion-pairs or open carbonium ions solvated by nitrogen on one side and solvent on the other are highly unlikely.

The Hydrogen Migration in the Deamination Reaction.—In the acetolysis of the active diastereomers of 3-phenyl-2-butyl tosylate, evidence[7c] was obtained that hydrogen participated in the ionization stage to give both stereospecifically produced olefin as well as the rearranged methylethylphenylcarbonium ion, which reacted with solvent to give racemic tertiary acetate. In the present study, both diastereomers gave this same acetate in considerably higher yields. Unfortunately the methods of analysis prevented the optical character



of this tertiary acetate from being examined (see Experimental). A second difference between the tosylate acetolysis and the deaminative acetolysis is that nearly all of the *conjugated* olefin produced was destroyed by the nitrous acid, and therefore the stereospecificity of this elimination could not be studied. A peculiar consequence of this destruction of *conjugated* olefin was that the olefin isolated was largely 3-phenyl-1-butene. The total olefin fraction from *threo*-amine (11% yield) was reduced to 2-phenylbutane whose rotation indicated the olefin to be free of conjugated material and to have arisen by a completely stereospecific process. This fact prohibits the intervention of phenonium ions in the production of this unconjugated olefin, a point also demonstrated for the tosylate solvolyses. The olefin from *erythro*-amine (4%) reduced to 2-phenylbutene whose activity was only about 80% of what was to be expected from the completely unconjugated olefin which had arisen by a completely stereospecific path. Apparently a small amount of conjugated olefin survived the nitrous acid in this particular run.

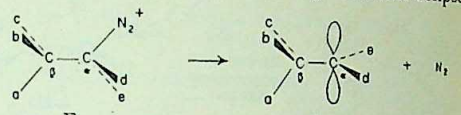
The Differences in Mechanism Between N_2 and OTs^- as Leaving Groups in Solvolyses.—The above results clearly demonstrate rather gross differences in the mechanisms for the deaminative and tosylate solvolyses. In the deaminative reaction the first stage is very probably the formation of a diazonium ion, which dissociates to a nitrogen molecule and a carbonium ion of some kind. The diazonium ion for aliphatic systems is unstable, and the production of an exceedingly stable nitrogen molecule in the dissociation process should give rise to an exceptionally high energy carbonium ion.[20] The driving force for this reaction should come from the formation of nitrogen[20] and not from neighboring group or solvent participation. Thus neighboring group or solvent probably become involved to an appreciable extent only at a later stage, that is, only after the production of a little-solvated, high energy, very short lived, *open* carbonium ion. The stereochemical consequences of this latter possibility will be examined as applied to the system at hand.

Chart III formulates the three conformations for each of the diastereomeric diazonium ions. Utilizing the principles developed earlier,[21] it seems probable that IV > V > VI and VII > VIII > IX in relative thermodynamic stability, and that in the diazonium ions the populations are distributed accordingly. The process of dissociation probably does not involve rotating any of these substituents through an eclipsed geometry, and the three open ions produced from each of the diastereomers fall into the same stability order as do the conformations of the starting diazonium ion. Since the geometry for the transition states for dissociation lies somewhere between that of the diazonium ion and the open ion,[22] the activation energies for dissociation of the three conformers should be very similar. Therefore, the relative populations of the three open ions from each diastereomer would be similar to those of the starting diazonium ions. If these open, flat carbonium ions are of such high energy that their half-lives are much less than the half-lives of their rotation through 60° about the C_β–C_α bond, then their fate is determined by the relative proximity of their nearest neighbors (solvent or β-substituents). Thus the relative nucleophilicity of these neighbors plays a minor role and the relative conformational populations of the starting diazonium ion become controlling in the ultimate balance of products. In such a scheme, the neighboring β-substituents must still approach the face of the carbonium ion opposite from that which the nitrogen left but for a reason different from that in which the β-substituents actually participate in carbonium ion formation. If F, one of the three conformations of a diazonium ion, dissociates to give open carbonium ion G, then "a" on C_β is flanked by "d" and "e" on C_α. Thus "a" is the only substituent on C_β which is eclipsed



F G

with the relatively unsolvated and empty p-orbital of the short lived "hot" carbonium ion. Other groups (b and c) could become involved only if rotation about C_β–C_α occurred to the extent of either 60 or 120°.

This hypothesis suggests that in the deamination of *threo*-3-phenyl-2-butylamine, methyl migration should exceed phenyl which should exceed hydrogen migration. The data (Table I) show that methyl accounted for 32%, phenyl for 24% and hydrogen migration for a maximum of 24% of the acetate produced.[23] For the *erythro* series, the hypothesis would predict that phenyl would predominate over hydrogen, which would exceed methyl migration. Of the acetate produced by this diastereomer (Table I), up to 68% could have involved phenyl[24] migration, a maximum of 20% hydrogen and only 6% methyl migration.

Two features make it unlikely that eclipsing effects in the formation of bridged transition states control the migrating group in these diastereomeric series. (1) These eclipsing effects played little or no role in either selecting the migrating group or effecting the rates of ionization for the acetolysis of the diastereomers of 3-phenyl-2-butyl tosylate. If eclipsing effects were important in this system, they certainly would be more likely to assert themselves in tosylate solvolysis where driving forces due to neighboring group participation are present. (2) The groups that are being eclipsed are rather small (*e.g.*, two methyl groups during phenyl migration in the *threo* series). In other reactions in other systems, the "*cis* effect" becomes important only when a medium and large or two large groups become involved.[25]

Tosylate and halide solvolyses differ in a second important respect from deaminative solvolyses.

(21) (a) F. A. Abd Elhafez and D. J. Cram, THIS JOURNAL, **74**, 5846 (1952); (b) **74**, 5851 (1952).

(22) Hammond's postulate [*ibid.*, **77**, 334 (1955)] would suggest that for this very exothermic reaction, the transition state would resemble the starting material in geometry.

(23) These values could be slightly in error as measures of the extent of each substituent migration since rearranged open carbonium ions could also give small amounts of conjugated olefin which was then destroyed by nitrous acid.

(24) A small part of this 68% undoubtedly arose by simple solvolysis with retention of configuration.

Although ion-pair intermediates have been demonstrated[7b,26] in a number of halide and tosylate solvolyses, no such species can intervene in the deamination reaction with N_2 as the leaving group. Such a molecule would not even be expected to solvate the carbonium ion it was leaving, as is probable with the conjugate acid of an ester, ether or alcohol dissociates. Unlike the phenonium tosylate produced in tosylate solvolysis of the 3-phenyl-2-butyl system,[7b] a phenonium ion produced from a high energy, open ion would be relatively naked and reactive. Unlike the phenonium tosylate ion-pair, this bridged ion might not only capture solvent, but also give rearranged open ion which in turn could capture solvent. Such a process might explain the production of the 5% of racemic *erythro*-acetate produced from active *threo*-amine.

This amount of acetate produced by *simple solvolysis* is greater in the deaminative than in the tosylate solvolysis. In the former, *threo* material gave 6% acetate with retention and 14% with inversion as compared to 0.6% retention and 4% inversion in the latter. From *erythro*-amine, 6% acetate resulted from simple acetolysis with inversion, whereas with tosylate, 4% acetate. The amount of acetate resulting from simple acetolysis with retention could not be measured. The relatively higher amount of simple solvolysis in the deamination reaction probably reflects the ability of solvent to compete better with neighboring groups for a less hindered open carbonium ion than for either the back side of a saturated carbon atom or either side of an ion-pair. Again it would appear that in passing from tosylate solvolysis to the deamination reaction selectivity based on steric effects becomes more important at the expense of electronic effects.

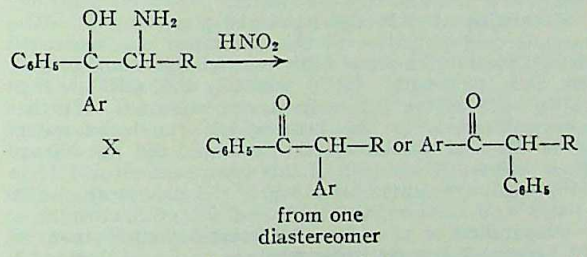
Other Solvolytic Deamination Reactions.—The general interpretation of the course of the deamination reaction in the present study is consistent with the results obtained in a wide variety of systems. Bartlett and Knox[27] observed that although the deamination of 1-apocamphylamine to give 1-apocamphanol or 1-chloroapocamphane occurred readily, attempts at substitution at this bridge-head carbon utilizing other leaving groups (H_2O^+ or Cl) failed even under brutal conditions. Thus participation by solvent or neighboring groups does not seem to be a necessary condition for dissociation in this deaminative substitution.

The demonstration by Bernstein and Whitmore[2] that the migration terminus is inverted in the deaminative rearrangement of 1,1-diphenyl-2-amino-1-propanol does not necessarily mean that phenyl participated in the dissociation of the diazonium ion. The most stable rotational conformation of the diazonium ion places one phenyl oriented 180° from the N_2 leaving group and a short lived, high energy, open carbonium ion produced by dissociation is sterically oriented to best attack this phenyl group, thus giving the observed stereochemical result.

The numerous observations[4b,5,6f] that the difference in migratory aptitude of various *p*-substituted phenyls became diminishingly small in the deamination reaction as compared to other carbonium ion-forming reactions are consistent with the concept of dissociation of the diazonium ion without neighboring group participation in the deamination reaction.

The high energy carbonium ion produced in the deamination reaction does not show any more tendency to rearrange than does the carbonium ion formed by simple ionization of an alkyl bromide or tosylate, at least in the α-phenylneopentyl system. Here the fate of the α-phenylneopentyl carbonium ion produced from a variety of leaving groups is similar.[11b,28]

Curtin, *et al.*, outlined two possible reasons why in the deamination of a series of diastereomeric amino alcohols X the migrating aryl group should be different for each diastereomer.[6a] In the first explanation, the relative stability of the various conformations of the starting molecule was considered as the controlling feature. However, it was pointed out[6g] that if the rate of conformational



equilibration is fast compared to rearrangement, the activation energy for one group migrating compared to a second in a given diastereomer is independent of the relative populations of the conformations of the initial molecule. The second and preferred[6g] explanation deals with the difference in energy of the transition states for rearrangement of two competing migrating groups in the same molecule, that transition state being the more stable in which the non-migrating groups are distributed *trans* to one another.[6a,6g] Implicit in both of these explanations is the assumption that the transition state for migration and for dissociation are one and the same; in other words, that the neighboring group participates in the dissociation. If on the other hand one assumes that a discrete intermediate, an open carbonium ion, intervenes between the dissociation and rearrangement processes, the analysis of this semipinacolic deamination reaction becomes similar to that applied to the deaminative Wagner–Meerwein rearrangement in this paper. Thus the first of Curtin's original hypotheses[6a] that the migrating group is controlled by the relative populations of conformations of the starting material might still apply to these pinacolic deamination reactions.

In the deamination of substituted cyclohexylamines, conformation control of the migrating

group seems to be enforced.[29] In simple solvolysis, however, both equatorially and axially oriented cyclohexylamines give mainly equatorially oriented alcohols.[30] This fact is consistent with a high energy, relatively unsolvated carbonium ion intermediate whose stereochemical fate is controlled not by solvent participation in ionization, but by the relative proximity of solvent molecules to the equatorial or axial faces of the carbonium ion once the nitrogen molecule has left. Apparently the same carbonium ion is created from *cis* to *trans* diastereomers and solvent molecules can get closer to the equatorial than the axial face of the ion, thus giving equatorially oriented alcoholic product.

Experimental

Preparation of Optically Pure D(−)-*erythro*-3-Phenyl-2-butylamine.—The procedure employed is identical to that used previously[8] to make the benzamide of this amine,[8] except that a large enough amount of material was used to allow isolation of the amine itself. From 4.92 g. of D(−)-*threo*-3-phenyl-2-butyl tosylate[7a,b] (m.p. 64.8–65.1°, prepared from optically pure alcohol) was obtained 0.432 g. of D(−)-*erythro*-3-phenyl-2-butylamine as a colorless oil, $n^{25}D$ 1.5157, $\alpha^{26}D$ −9.21° (*l* 1 dm., neat).

Anal. Calcd. for $C_{10}H_{15}N$: C, 80.46; H, 10.15. Found: C, 80.39; H, 10.37.

The enantiomer of this amine prepared by direct resolution gave $\alpha^{25}D$ +9.01° (*l* 1 dm., neat).[8]

Resolution of 2-Methyl-1-phenyl-1-propanol (II).—The racemic acid phthalate of this substance was resolved[15] in 24% yield (racemate = 100%) to give active acid phthalate, m.p. 93.6–94.1°, $[\alpha]^{23}D$ +45.1 (*c* 3.5, $CHCl_3$), lit.[15] $[\alpha]^{20}D$ +21.08° (*c* 9.2, solvent not reported). Further recrystallizations of the brucine salt (methanol–water) or of the acid phthalate (ether–pentane) did not change these values. Hydrolysis of this ester gave alcohol II in 94% yield, $n^{25}D$ 1.5113, $\alpha^{23}D$ +20.6° (*l* 1 dm., neat), $[\alpha]^{23}D$ +48.3° (*c* 6.7, ether), lit.[15] $[\alpha]^{20}D$ +47.7° (*c* 6.8, ether).

Preparation of L(−)-*threo*-2-Acetoxy-3-phenylbutane, D-(+)-*erythro*-2-Acetoxy-3-phenylbutane, (+)-1-Acetoxy-2-methyl-1-phenylpropane and 2-Acetoxy-2-phenylbutane.—L(−)-*threo*-2-Acetoxy-3-phenylbutane and D(+)-*erythro*-2-acetoxy-3-phenylbutane were prepared from L(+)-*threo*-3-phenyl-2-butanol ($n^{25}D$ 1.5160, $\alpha^{26}D$ +27.25°, *l* 1 dm., neat) and D(−)-*erythro*-3-phenyl-2-butanol ($n^{25}D$ 1.5168, $\alpha^{25}D$ −0.62°, *l* 1 dm., neat) by methods already reported[7b] in 93 and 96% yields, respectively, $n^{25}D$ 1.4877, $\alpha^{26}D$ −7.80° (*l* 1 dm., neat) and $n^{25}D$ 1.4877, $\alpha^{26}D$ +32.38° (*l* 1 dm., neat). The literature[7b] reports $n^{25}D$ 1.4877, $\alpha^{23}D$ −8.08° (*l* 1 dm., neat) and $n^{25}D$ 1.4877, $\alpha^{25}D$ +32.55 (*l* 1 dm., neat) for these compounds. (+)-1-Acetoxy-2-methyl-1-phenylpropane was prepared in an entirely analogous fashion from optically pure (+)-2-methyl-1-phenyl-1-propanol, $n^{25}D$ 1.5113, $\alpha^{26}D$ +21.57 (*l* 1 dm., neat), in a 96% yield, $n^{26}D$ 1.4853, $\alpha^{26}D$ +104.68° (*l* 1 dm., neat).

Anal. Calcd. for $C_{12}H_{16}O_2$: C, 74.96; H, 8.38. Found: C, 75.06; H, 8.20.

Racemic 2-acetoxy-2-phenylbutane was prepared as before[7c] in 35% yield, $n^{25}D$ 1.4946 (lit.[7c] 1.4944).

Deamination Reactions of 3-Phenyl-2-butylamine.—Four reactions were carried out, one with optically pure L(+)-*erythro*-isomer, one with the optically pure D(−)-*threo*-isomer, one with partially optically pure D(−)-*erythro*-isomer and one with partially optically pure L(+)-*threo*-isomer. The reactions were all carried out in the same way, but in the two runs involving optically pure materials, different methods of isolation and analysis were employed from in the two runs involving partially optically pure amines. The procedure for the reaction itself is illustrated utilizing L(+)-*erythro*-3-phenyl-2-butylamine (run 1). To 4.63 g. of amine[8] ($\alpha^{23}D$ +8.91°, *l* 1 dm., neat; $n^{25}D$ 1.5159) dissolved in 300 ml. of dry glacial acetic acid was added over a period of 30 minutes, 31.4 g. of potassium nitrite. During this addition the temperature was held at 25–27° through external cooling. The resulting solution was stirred vigorously for one hour and shaken with 1.5 l. of water and 200 ml. of pure pentane. The aqueous layer was again washed with pentane, the pentane extracts were thoroughly washed with water, with dilute base, dried, and the solvent was evaporated through a short column. The residual oils were treated differently depending on which run was involved (see next section).

Isolation of Products from the Deamination Reaction; Method I.—This procedure is illustrated with the work up of the oil obtained from the deamination reaction in run 1 (see above). The residual oil was dissolved in 100 g. of anhydrous glacial acetic acid and maintained at 75° for 26 hours. This procedure has been demonstrated previously[7c] to completely convert 2-acetoxy-2-phenylbutane to olefin. Removal of this acetate in runs 1 and 2 simplified the analysis of the remaining components. The mixture was cooled, diluted with 1 l. of water and extracted twice with pure pentane. The pentane solution was washed with dilute sodium carbonate solution, water, dried, and the solvent was evaporated through a short column. The residual oil was a mixture of olefin, ketone and three acetates. The ketone was removed as follows: This oil was dissolved in 150 ml. of methanol containing 15 ml. of water, 15 g. of trimethylacethydrazine ammonium chloride (Girard reagent "T"), 4.1 g. of sodium acetate and 3.0 g. of glacial acetic acid. The resulting solution was heated at reflux for 90 minutes, cooled, diluted with 1 l. of water and extracted with pure pentane. The pentane extract was washed with dilute sodium bicarbonate solution, water, dried, and the solvent was evaporated through a short column. The residual oil was dissolved in dry ether and added to a slurry of 1.3 g. of lithium aluminum hydride in dry ether. In this fashion the acetates were converted to the parent alcohols. The excess hydride was decomposed with dilute hydrochloric acid, and the aqueous phase was extracted with pure pentane. The combined ether and pentane solutions were washed with dilute sodium bicarbonate solution, dried, and the solvent was evaporated through a short column. The residual oil was subjected to chromatography on 150 g. of activity I alumina[31] under pure pentane. The olefin fraction was washed from the column with pure pentane and was twice distilled at 18 mm. to give 0.43 g. (10% yield) of this product. The alcohol fraction was washed from the column with ethanol, the resulting solution being evaporated. The residual oil was distilled at 1 mm. through a short-path still to give 1.86 g. or 40% yield of a mixture of diastereomeric 3-phenyl-2-butanols and 2-methyl-1-phenyl-1-propanol, $\alpha^{23}D$ +3.18° (*l* 1 dm., neat), $n^{25}D$ 1.5167. This material was subjected to quantitative infrared analysis to determine the amount of each of the above three alcohols in the mixture (see later section). A sample (0.74 g.) of this alcohol fraction was converted by the pyridine–acetic anhydride method to acetate in 95% yield, $\alpha^{24}D$ −27.55° (*l* 1 dm., neat), $n^{25}D$ 1.4874. To 0.90 g. of the alcohol fraction was added 25 ml. of glacial acetic acid containing 2.5 g. of acetic anhydride and 0.25 g. of *p*-toluenesulfonic acid monohydrate, and the resulting solution was maintained at 75° for 18 hours. This treatment was demonstrated in control experiments (see later section) to completely racemize and partially convert to olefin the 2-methyl-1-phenyl-1-propanol component and to leave the diastereomeric 3-phenyl-2-butanols intact. The solution was cooled, diluted with 400 ml. of water, extracted with pure pentane, and the pentane extracts were washed with dilute base, dried and evaporated through a short column. The residual oil was dissolved in dry ether and added to a slurry of 0.3 g. of lithium aluminum hydride. This procedure converted any acetates formed back to alcohols. The olefin–alcohol mixture was isolated in the usual way and chromatographed on 50 g. of activity I alumina[31] as before. The fraction eluted with methanol was distilled at 15 mm. to give 0.72 g. of colorless oil, $\alpha^{23}D$ +3.21° (*l* 1 dm., neat). A sample (0.43 g.) of this alcohol was converted by the acetic anhydride–pyridine method to the acetate in 95% yield, $\alpha^{26}D$ −26.96° (*l* 1 dm., neat), $n^{25}D$ 1.4879. The rotational data on the alcohol and acetate before and after racemization of the 2-methyl-1-phenyl-1-propanol coupled

Digitized by Arya Samaj Foundation Chennai and eGangotri

with the rotations of synthetic mixtures allowed the optical character of the three components to be determined (see later section).

In run 2, 4.70 g. of optically pure D(−)-*threo*-3-phenyl-2-butylamine[3] was employed, $\alpha^{23}D$ −42.33° (*l* 1 dm., neat), $n^{25}D$ 1.5143. From this was obtained 0.53 g. or 13% yield of olefin and 1.80 g. or 38% yield of the three isomeric alcohols, $\alpha^{23}D$ −5.78° (*l* 1 dm., neat), $n^{25}D$ 1.5143. This alcohol fraction was submitted directly to infrared analysis. A sample of this alcohol was converted to its acetate in 96% yield, $\alpha^{23}D$ +0.05° (*l* 1 dm., neat), $n^{25}D$ 1.4869. A portion of this alcohol (0.86 g.) was submitted to the action of *p*-toluenesulfonic acid in acetic acid as above to give a mixture of the two active diastereomers and racemic 2-methyl-1-phenyl-1-propanol, wt. 0.61 g., $\alpha^{23}D$ −4.21° (*l* 1 dm., neat). A sample of this alcohol was converted to its acetate by the acetic anhydride–pyridine method in 94% yield, $\alpha^{25}D$ +8.41° (*l* 1 dm. neat), $n^{25}D$ 1.4872.

Isolation of Products from the Deamination Reaction; Method II.—This procedure differs from method I in the following respects: (1) The original mixture obtained from the solvolysis (ketone, olefin and four acetates) was not heated to 75° to remove 2-phenyl-2-acetoxybutane but was treated directly with Girard reagent to remove ketone. (2) The olefin was examined by its reduction to 2-phenylbutane and measurement of this substance's optical purity. In this procedure olefin came only from deamination reaction itself. (3) The infrared analysis was performed on the final mixture of three alcohols, the two diastereomers of 3-phenyl-2-butanol and racemized 2-methyl-1-phenyl-1-propanol. The procedure is illustrated with run 4.

From the acetolysis of 9.83 g. of L(+)-*threo*-3-phenyl-2-butylamine[3] ($\alpha^{24}D$ +6.42°, *l* 1 dm., neat; $n^{25}D$ 1.5142) was obtained an oil which was 15.2% optically pure. This material was treated with Girard reagent "T" as in method I, and the product was reduced with lithium aluminum hydride as in method I. The product was chromatographed as in method I, the olefin fraction after distillation amounting to 1.03 g. (12% yield) and the alcohol fraction to 4.90 g. (50% yield).

This olefin fraction was reduced to 2-phenylbutane as follows. To a suspension of platinum black (from 50 mg. of PtO_2) in 25 ml. of methanol was added 0.51 g. of the olefinic fraction, and the mixture was shaken under 752 mm. of hydrogen. After hydrogen uptake had stopped (76 ml.), the mixture was filtered, and the filtrate was shaken with 350 ml. of water and pure pentane. The pentane extract was washed with water, dried and the solvent was evaporated through a short column. The residual oil was distilled through a short-path still to give 0.45 g. of crude 2-phenylbutane. Careful fractional distillation of this material (0.30 g.) gave 0.23 g. of L(+)-2-phenylbutane, $\alpha^{23}D$ +3.82° (*l* 1 dm., neat), $n^{25}D$ 1.4878. Optically pure 2-phenylbutane has a rotation $\alpha^{23}D$ +24.2° (*l* 1 dm., neat), $n^{25}D$ 1.4878.[32] This material is therefore 15.8% optically pure as compared to the 15.2% optical purity of the starting amine. Thus only optically pure 3-phenyl-1-butene survived the deaminative solvolysis.

The alcohol fraction (2.00 g.) was submitted to the action of an acetic acid, acetic anhydride and *p*-toluenesulfonic acid mixture to racemize 2-methyl-1-phenyl-1-propanol and destroy 2-phenyl-2-butanol, the procedure being the same as in method I. The product was reduced with lithium aluminum hydride as before and chromatographed on alumina. The olefin obtained (mixture of 2-phenylbutenes from dehydration of 2-phenyl-2-butanol) was distilled to give 0.38 g. (11% yield) of material, $n^{25}D$ 1.5190. Distillation of the alcohol fraction gave 1.09 g. (27% yield) of material, $\alpha^{23}D$ +0.63° (*l* 1 dm., neat), $n^{25}D$ 1.5147. This material was submitted to infrared analysis. A sample (0.76 g.) of this alcohol was converted by the acetic anhydride–pyridine method to acetate in 96% yield, $\alpha^{24}D$ −1.18° (*l* 1 dm., neat), $n^{25}D$ 1.4873.

In run 3, 10.0 g. of D(−)-*erythro*-amine[3] was employed, $\alpha^{25}D$ −4.91° (*l* 1 dm., neat), $n^{25}D$ 1.5160, 45% optically pure. From this material was obtained 0.463 g. of olefin (5% yield) and 5.05 g. of alcohol (50% yield). The total olefin fraction was reduced as before to give 0.396 g. of distilled 2-phenylbutane. Careful fractionation of 0.300 g. of this material gave 0.232 g. of 2-phenylbutane, $n^{25}D$ 1.4578, $\alpha^{24}D$ −8.70° (*l* 1 dm., neat), 36% optically pure.

(32) D. J. Cram, THIS JOURNAL, **74**, 2149 (1952).

A portion of the alcohol fraction (2.00 g.) was treated with *p*-toluenesulfonic acid as in the other runs to give, after lithium aluminum hydride reduction and chromatography, an olefin and alcohol fraction. The olefin fraction (distilled), wt. 0.215 g. (6% yield), came from the decomposition of 2-phenyl-2-butanol. The alcohol fraction (distilled) amounted to 1.22 g. (30% yield), $n^{25}D$ 1.5166, $\alpha^{24}D$ −1.42° (*l* 1 dm., neat) and was submitted to infrared analysis. This alcohol was converted to its acetate by the acetic anhydride–pyridine method in 94% yield, $\alpha^{24}D$ +12.53° (*l* 1 dm., neat).

Demonstration of the Presence of 2-Methyl-1-phenyl-1-propanol Among the Products of Deaminative Acetolysis of D(−)-*threo*-3-Phenyl-2-butylamine.—Because the product of methyl migration was unexpected in this deamination, qualitative proof of its presence was sought. A deamination reaction was run utilizing the conditions and isolation procedure of run 2 except that 35% optically pure (−)-*threo*-amine was employed. A portion (0.78 g.) of the alcoholic product (this material had not been treated with *p*-toluenesulfonic acid at 75°) was converted to its acid phthalate. The resulting oil was subjected to partition chromatography on 164 g. of a mixture of one part of silicic acid to two parts of Celite made up in 1% ethanol in chloroform. Elution of the material with 1% ethanol in chloroform resulted in a partial fractionation of the acid phthalates. Four fractions, each containing about 0.35 g. of solute, were collected. These materials were crystallized and recrystallized from chloroform–pentane to a constant melting point. The material from the first fraction (9 mg., m.p. 131.8–132.2°) gave a m.m.p. of 133–133.8° with authentic acid phthalate of racemic 2-methyl-1-phenyl-1-propanol[15] (m.p. 133.7–134°). The other fractions, although obtained in somewhat larger amounts, gave melting points and mixed melting points which indicated them to be mixtures of acid phthalates.

Preparation of the Acetates of Various Alcohols; Pyridine–Acetic Anhydride Method.—This preparation will be illustrated with the conversion of (+)-2-methyl-1-phenyl-1-propanol to (+)-1-acetoxy-2-methyl-1-phenylpropane. To 7.0 g. of (+)-2-methyl-1-phenyl-1-propanol[15] ($\alpha^{26}D$ +21.57°, *l* 1 dm., neat; $n^{25}D$ 1.5113) was added 30.0 g. of acetic anhydride and 75 g. of anhydrous pyridine. The resulting solution was heated on a steam-bath for 3 hours. At the end of this time, 250 ml. of water and 100 g. of ice were added, and the resulting mixture was extracted twice with pure pentane. The pentane extracts were combined, washed with water, dilute hydrochloric acid, dilute sodium bicarbonate and dried. The pentane was evaporated through a short column. The residual oil was subjected to chromatography on a 4 × 35 cm. column (140 g.) of alumina made up in pure pentane. The column was washed with pure pentane (the pentane washes were discarded) and was eluted with a solution of 10% ether in pentane. The ether–pentane was evaporated through a short column and the residual oil was distilled through a short-path still at 15 mm. to give 8.5 g. of (+)-1-acetoxy-2-methyl-1-phenylpropane,[15] $\alpha^{26}D$ 104.68° (*l* 1 dm., neat), $n^{25}D$ 1.4853.

Control Experiments.—The following experiment demonstrates: (1) that the solvolysis products once formed are stable, (2) that the ketone could be quantitatively removed, (3) that 2-acetoxy-2-phenylbutane is completely converted to olefin at 75° in glacial acetic acid and (4) the three secondary acetates are not fractionated during the isolation procedure. A mixture of 0.89 g. of L(−)-*threo*-3-acetoxy-2-phenylbutane ($\alpha^{24}D$ −7.80°, *l* 1 dm., neat; $n^{25}D$ 1.4877), 0.90 g. of (+)-acetoxy-2-methyl-1-phenylpropane ($\alpha^{26}D$ +104.68°, *l* 1 dm., neat; $n^{25}D$ 1.4853) gave $\alpha^{25}D$ +41.72° (*l* 1 dm., neat) and $n^{25}D$ 1.4870. To this mixture was added 0.60 g. of 2-acetoxy-2-phenylbutane ($n^{25}D$ 1.4946), 0.20 g. of acetophenone ($n^{25}D$ 1.5343) and 0.09 g. of 3-phenyl-2-butanone ($n^{25}D$ 1.5104). This mixture was subjected to the exact conditions of the deamination reaction, and the isolation procedure of method I (the final acid treatment of the alcohols was omitted). The product was 0.38 g. of olefin ($n^{25}D$ 1.5214) and 1.00 g. of alcohol, a sample (0.60 g.) of which was converted to its acetate, wt. 0.65 g., $n^{25}D$ 1.4871, $\alpha^{24}D$ +41.84° (*l* 1 dm., neat). The initial mixture of acetates had $\alpha^{25}D$ +41.72° (*l* 1 dm., neat) and $n^{25}D$ 1.4870.

That treatment of the 2-acetoxy-3-phenylbutanes and 2-acetoxy-2-phenylbutane with lithium aluminum hydride yields the corresponding alcohols in an essentially quantita-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

following experiment shows that 1-acetoxy-2-methyl-1-phenylpropane may be converted to 2-methyl-1-phenyl-1-propanol in a similar fashion and in a similarly high yield. A sample of 1.03 g. of (+)-1-acetoxy-2-methyl-1-phenylpropane, $\alpha^{26}D$ +104.7° (*l* 1 dm., neat), was prepared from the corresponding alcohol, $\alpha^{26}D$ +21.57° (*l* 1 dm., neat) $n^{25}D$ 1.5113. Reduction of this material with lithium hydride by the ordinary procedure gave 0.83 g. of (+)-2-methyl-1-phenyl-1-propanol, $n^{25}D$ 1.5112, $\alpha^{26}D$ +21.59° (*l* 1 dm., neat).

To demonstrate that (+)-acetoxy-2-methyl-1-phenylpropane was stable to the treatment at 75° in glacial acetic acid (no *p*-toluenesulfonic acid) used to decompose 2-acetoxy-2-phenylbutane, the following experiment was run. To 20 ml. of glacial acetic acid was added 0.8 ml. of acetic anhydride and 1.00 g. of (+)-1-acetoxy-2-methyl-1-phenylpropane, $\alpha^{26}D$ +104.7° (*l* 1 dm., neat), $n^{25}D$ 1.4853, and the resulting solution was heated at 75° for 26 hours. Isolation of the material in the usual way gave 0.96 g. of starting material, $\alpha^{26}D$ +104.3° (*l* 1 dm., neat), $n^{25}D$ 1.4853.

The following experiment demonstrates the facts: (1) conjugated olefin is destroyed under the conditions of the deaminative solvolysis, (2) unconjugated olefin survives without racemization and (3) active unconjugated olefin can be catalytically reduced to 2-phenylbutane essentially without racemization. To 0.28 g. of D(−)-3-phenyl-1-butene, $\alpha^{23}D$ −5.62° (*l* 1 dm., neat), $n^{25}D$ 1.5054,[33a] was added 0.13 g. of *cis*-2-phenyl-2-butene ($n^{26}D$ 1.5402)[33b] and 0.08 g. of *trans*-2-phenyl-2-butene ($n^{25}D$ 1.5193). This mixture was dissolved in 100 g. of glacial acetic acid, and 10.3 g. of solid potassium nitrite was added in eight portions with vigorous stirring over a period of 30 minutes. The resulting mixture was stirred for 45 minutes, and the product was subjected to the isolation procedure outlined in method II for the isolation and reduction of olefin except that the treatment with Girard reagent was omitted. For the catalytic reduction of olefin, 25 ml. of methanol and 25 mg. of platinum oxide were used, 37 ml. of hydrogen being absorbed (750 mm. and 22°). The D(−)-2-phenylbutane obtained amounted to 0.15 g., $n^{25}D$ 1.4878, $\alpha^{24}D$ −23.62° (*l* 1 dm., neat). The literature reports for optically pure L(+)-2-phenylbutane, $\alpha^{23}D$ +24.2° (*l* 1 dm., neat), $n^{25}D$ 1.4878.[32]

The following experiment demonstrates that: (1) (+)-2-methyl-1-phenyl-1-propanol racemized at 75° in glacial acetic acid in the presence of *p*-toluenesulfonic acid; (2) 2-acetoxy-2-phenylbutane is converted to olefin by this treatment. To 25 g. of glacial acetic acid containing 2.5 g. of acetic anhydride and 0.25 g. of *p*-toluenesulfonic acid monohydrate was added 1.00 g. of 2-phenyl-2-butanol ($n^{25}D$ 1.5167) and 0.90 g. of (+)-2-methyl-1-phenyl-1-propanol ($\alpha^{24}D$ +21.34°, *l* 1 dm., neat; $n^{25}D$ 1.5113), and the resulting solution was heated at 75° for 18 hours. The product was isolated, subjected to a lithium aluminum hydride treatment and chromatographed as in methods I and II. The olefin fraction amounted to 0.89 g., $n^{25}D$ 1.5192. The recovered (+)-2-methyl-1-phenyl-1-propanol (0.61 g.) gave $n^{25}D$ 1.5113, $\alpha^{24}D$ +0.13° (*l* 1 dm., neat) which corresponds to 99.4% racemization. The relatively poor recovery of this alcohol (68%) and the good recovery of olefin (101% based only on 2-acetoxy-2-phenylbutane) indicates that some of the secondary alcohol dehydrated to olefin.

The optical and structural stability of the diastereomeric 3-phenyl-2-butanols to the action of glacial acetic acid and *p*-toluenesulfonic acid at 75° was demonstrated as follows: A mixture of 0.90 g. of L(+)-*threo*-3-phenyl-2-butanol ($\alpha^{22}D$ +31.61°, *l* 1 dm.; $n^{25}D$ 1.5166), 25 g. of glacial acetic acid, 2.5 g. of acetic anhydride and 0.25 g. of *p*-toluenesulfonic acid monohydrate was maintained at 75° for 18 hours. The product was subjected to the lithium aluminum hydride and chromatographic procedures of methods I and II. No olefin could be isolated. Only L(+)-*threo*-3-phenyl-2-butanol was isolated (0.72 g., 80% recovery), $\alpha^{24}D$ +31.51° (*l* 1 dm., neat; $n^{25}D$ 1.5164). Since this *threo* isomer is the one that racemizes on ionization,[7a,b] the stability of this isomer demonstrates the stability of the *erythro* isomer as well.

The following experiments were run to measure the over-all accuracy of the isolation and analytical procedure used in the latter part of method I. Two synthetic mixtures of the three secondary alcohols were made up, mixture 1 simulating the composition of alcohols obtained in run 1 and mixture 2 simulating that of run 2. The composition of mixture 1 was as follows: 0.010 g. of (+)-2-methyl-1-phenyl-1-propanol ($\alpha^{23}D$ +21.21°, *l* 1 dm., neat; $n^{25}D$ 1.5113), 0.082 g. of racemic 2-methyl-1-phenyl-1-propanol ($n^{25}D$ 1.5113), 0.103 g. of L(+)-*threo*-3-phenyl-2-butanol ($\alpha^{25}D$ +31.61°, *l* 1 dm., neat; $n^{25}D$ 1.5167) and 0.917 g. of L(+)-*erythro*-3-phenyl-2-butanol ($\alpha^{26}D$ +0.76°, *l* 1 dm., neat; $n^{25}D$ 1.5163). This mixture had $\alpha^{24}D$ +4.59° (*l* 1 dm., neat), $n^{25}D$ 1.5167. A portion was converted to acetate by the usual method in 93% yield, $\alpha^{24}D$ −25.9° (*l* 1 dm., neat). The composition of alcohol was therefore: the benzyl alcohol, 8% (11% optically pure); *threo*-alcohol, 9% (100% optically pure); *erythro*-alcohol, 82% (100% optically pure). The composition of mixture 2 was as follows: 0.068 g. of (+)-2-methyl-1-pheuyl-1-propanol ($\alpha^{23}D$ +21.21°, *l* 1 dm., neat; $n^{25}D$ 1.5113), 0.356 g. of racemic 2-methyl-1-phenyl-1-propanol ($n^{25}D$ 1.5113), 0.108 g. of L(+)-*threo*-3-phenyl-2-butanol ($\alpha^{24}D$ +31.67°, *l* 1 dm., neat; $n^{25}D$ 1.5167), 0.215 g. of racemic *threo*-3-phenyl-2-butanol ($n^{25}D$ 1.5167), 0.199 g. of L(+)-*erythro*-3-phenyl-2-butanol ($\alpha^{26}D$ +0.76; *l* 1 dm., neat; $n^{25}D$ 1.5163), and 0.063 g. of racemic *erythro*-3-phenyl-2-butanol ($n^{25}D$ 1.5163). This mixture had $\alpha^{24}D$ +5.82° (*l* 1 dm., neat), $n^{25}D$ 1.5142. A portion of this alcohol was converted to its acetate in 92% yield, $\alpha^{24}D$ −0.50° (*l* 1 dm., neat). The composition of mixture 2 was therefore: the benzyl alcohol, 42% (16% optically pure); *threo*-alcohol, 32% (33% optically pure); *erythro*-alcohol, 26% (76% optically pure).

Mixtures 1 and 2 (0.50 g. each) were submitted to the action of acetic acid and *p*-toluenesulfonic acid at 75° for 18 hours, the product being put through the lithium aluminum hydride and chromatographic procedures employed in runs 1 and 2. The alcohol obtained from mixture 1 (0.36 g.) gave $\alpha^{24}D$ +4.59 (*l* 1 dm., neat), and its acetate (92% yield) gave $\alpha^{26}D$ −28.49° (*l* 1 dm., neat). The alcohol from mixture 2 (0.30 g.) gave $\alpha^{24}D$ +4.75° (*l* 1 dm., neat), and its acetate gave $\alpha^{26}D$ −8.72° (*l* 1 dm., neat). Infrared analysis (see later section) of the final alcohol obtained by acid treatment of mixture 1 was as follows: the benzyl alcohol, 6%; *threo*-alcohol, 9%; *erythro*-alcohol, 84%. Analysis of final alcohol from mixture 2 was: the benzyl alcohol, 37%; *threo*-alcohol, 35%; *erythro*-alcohol, 28%.

This experiment demonstrates that no selective loss of *threo*- or *erythro*-alcohol occurs during this acid treatment, but that a small selective loss of 2-methyl-1-phenyl-1-propanol occurs. Racemization and partial loss of this alcohol in mixture 1 made practically no difference in the rotations of alcohols or acetates as was the case in run 1. Racemization and partial loss of the benzyl alcohol in mixture 2 changed the rotation from +5.82 to +4.75° as compared to a change in rotation of run 2 from −5.78 to −4.20°. The changes in rotation of the acetates are far more significant: mixture 2, from −0.50 to −8.72°; run 2, from +0.05 to +8.41°.

To demonstrate that (+)-2-methyl-1-phenyl-1-propanol is stable under the conditions used for the saponification of its acid phthalate, the following experiment was run. To 250 ml. of 0.32 *N* sodium hydroxide was added 0.529 g. of (+)-2-methyl-1-phenyl-1-propanol ($\alpha^{22}D$ +20.41°, *l* 1 dm., neat). The resulting mixture was brought to reflux and allowed to steam distil. The alcohol was isolated in the usual way to give 0.465 g. of material, $\alpha^{23}D$ +20.00° (*l* 1 dm., neat).

Infrared Analysis of Alcohol Mixtures.—These analyses were made on a Perkin–Elmer infrared spectrophotometer, model 21, NaCl prism and cells, utilizing liquid films 0.030 mm. thick. The optical densities of 2-methyl-1-phenyl-1-propanol (II) and *threo*- and *erythro*-3-phenyl-2-butanol (III) were determined at those wave lengths most advantageous for analysis. The optical densities of these knowns were then determined. The amounts of these components were calculated by solving simultaneous equations assuming that Beer's law applied. Synthetic mixtures of the three components were then made which approximated the unknowns (to within 3% for each component based on the final values for each unknown), and these were then analyzed similarly. The unknown mixtures were now corrected to the known for deviations in Beer's law. Table III records samples of raw intensity data. Table IV records the percentage compositions of alcohol obtained in the

(33) Literature (ref. 11c) reports for these olefins: (a) $\alpha^{22}D$ −6.39°, 1 dm., neat; $n^{25}D$ 1.5055; (b) $n^{25}D$ 1.5402; (c) $n^{25}D$ 1.5193.

four solvolytic runs corrected to the known synthetic mixtures. The facts that these percentages add up to almost 100% and that calculations based on different wave lengths give similar values indicate the absence of other components in the mixtures. The infrared analyses of the alcohols obtained in the control experiments were done the same way.

TABLE III

OPTICAL DENSITIES AT THE WAVE LENGTHS USED FOR INFRARED ANALYSES OF ALCOHOL MIXTURES

Composition, %			Optical density at λ in μ (slit width in mm.)				
threo III[a]	*erythro*-III[b]	II[c]	8.00 (0.142)	8.33 (0.148)	8.85 (0.163)	10.06 (0.222)	12.41 (0.322)
100	0	0	0.498	0.210	0.920	0.080	0.080
0	100	0	.324	.163	.626	.080	.081
0	0	100	.398	.418	.208	.275	.205
Unknown from run 1			.346	.180	.638	.091	.088
8	87	5	.348	.181	.639	.091	.095
Unknown from run 2			.426	.272	.590	.152	.129
36	33	31	.430	.262	.621	.142	.125

[a] *threo*-3-Phenyl-2-butanol, $n^{25}D$ 1.5167. [b] *erythro*-3-Phenyl-2-butanol, $n^{25}D$ 1.5163. [c] 2-Methyl-1-phenyl-1-propanol, $n^{25}D$ 1.5113.

The differences in results in Table IV between runs 1 and 3 and between 2 and 4 result from the fact that in runs 1 and 2 the analyses were made *before* the 2-methyl-1-phenyl-1-propanol was racemized and partially destroyed by treatment at 75° with an acetic acid–*p*-toluenesulfonic acid mixture. In runs 3 and 4 the analyses were made *after* this treatment. When runs 3 and 4 are corrected for loss of this component (as measured in the foregoing control experiments), the analyses for runs 1 and 3 and for 2 and 4 correspond to one another with a 1% maximum deviation.

The yields of 2-phenyl-2-butanol reported in Table I are based on the differences in total alcohol obtained in runs 1 and 3 and in 2 and 4. In runs 1 and 2 the acetate of 2-phenyl-2-butanol was destroyed before the alcohol was isolated. In runs 3 and 4 this acetate was preserved and carried into the alcohol initially isolated. Since almost twice as much amine was used as starting material in runs 3 and 4 as in 1 and 2, the mechanical losses in runs 1 and 2 were proportionately higher. Therefore the yields of 2-phenyl-2-butanol in Table I represent maximum values.

Calculations of the Optical Activities of Components in Alcohol Mixtures.—The infrared analyses give the percentages of the three secondary alcohol components both before and after the racemization of the 2-methyl-1-phenyl-1-propanol component. The optical activities of the *threo*- and *erythro*-alcohols were calculated as follows. After the benzyl alcohol was racemized, only the *threo*- and *erythro*-alcohols contributed to the rotation of the mixture. As noted earlier,[7b] the rotation of active *threo*-alcohol is about 30° and that of active *erythro*-alcohol is only about 1°, whereas the rotation of active *threo*-acetate is only 8° and that of *erythro*-acetate is about 32°. The optical purities of these two components were calculated first by solving two simultaneous equations in two unknowns, assuming the rotational contributions of the active alcohols and the active acetates were additive and that the racemized 2-methyl-1-phenyl-1-propanol component or its acetate had no effect on these rotations. Synthetic mixtures of these estimated compositions were then made, and the rotations of their alcohols and acetates used to calculate composition. The unknowns were then corrected to the knowns for the small deviations in additivity of the components. This gave the optical compositions of the *threo*- and *erythro*-alcohols both before and after the racemization of the 2-methyl-1-phenyl-1-propanol. The optical composition of this benzyl alcohol was then calculated making use of rotations of the alcohols and their acetates before the racemization reaction, the infrared data and the rotations of optically pure 2-methyl-1-propanol and its acetate. Fortunately the rotation of the acetate of 2-methyl-1-phenyl-1-propanol (105°) is an order of magnitude higher than those of the other acetates. Again additivity of the rotations of each component was assumed, synthetic mixtures of similar compositions were made and analyzed, and the unknowns were corrected to the knowns for small deviations in additivity of the components. Although these last calculations depend on a large number of separate experimentally determined values and are therefore not very accurate, there is no doubt about the following points. (1) The product of methyl migration from *threo*-amine is somewhere between 12 and 20% optically pure and of an identifiable configuration. (2) The product of methyl migration from *erythro*-amine is somewhere between 0 and 8% optically pure and of an identifiable configuration.

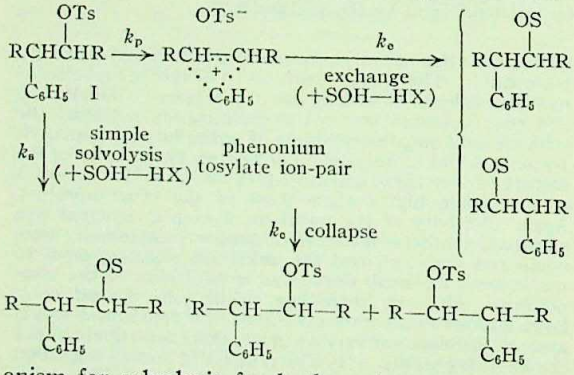
Studies in Stereochemistry. XXVIII. Reactivity Differences between Diastereomers in the Wagner–Meerwein Rearrangement[1]

BY DONALD J. CRAM, H. LEROY NYQUIST AND FATHY AHMED ABD ELHAFEZ

RECEIVED DECEMBER 7, 1956

The rates of formolysis and acetolysis of the diastereomers of 3-phenyl-2-butyl tosylate, 4-phenyl-3-hexyl tosylate and of 2,5-dimethyl-4-phenyl-3-hexyl brosylate have been measured. The $k_{erythro}/k_{threo}$(titrimetric) values for acetolysis are 1.2, 1.8 and 6.4, respectively, and 1.2, 2.6 and 8.2 for formolysis, respectively. That these ratios do not change much in the two solvents suggests that in each system, the division of phenonium tosylate (or brosylate) ion-pairs between collapse and exchange reactions with solvent is quantitatively similar for the *threo* and *erythro* diastereomers. The values of the ratios, k_α/k_t (polarimetric and titrimetric rate constants), decrease in value for the *threo* isomers in passing from the less to the more sterically hindered systems. As the bulk of the eclipsed groups increases, the ratio of exchange (with solvent) to collapse of these symmetrical *cis*-phenonium tosylate (or brosylate) ion-pairs increases. The products of solvolysis of 2,5-dimethyl-4-phenyl-3-hexyl brosylate have been examined in detail. Olefin or the products of hydrogen migration (mostly from the 2-position) dominate over those resulting from phenyl migration. Only traces of products of simple solvolysis were found. The yields of these various products indicate that the diastereomeric rate factor of 8.2 for the formolysis in this system is due not to differences in rate for the part of the reaction leading to phenonium ion, but to differences in rate for the part leading to olefin, and the products of hydrogen migration. These results suggest that in this system the differences in rate for solvolysis for the *threo* and *erythro* isomers reflect more the differences in energy of the diastereomeric starting states rather than differences in eclipsing effects for the diastereomeric transition states.

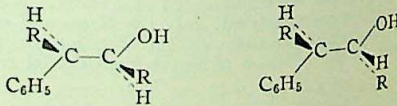
Previous studies of the Wagner–Meerwein rearrangement in systems represented by I have uncovered marked differences in behavior of I with R = CH_3[2] and R = C_2H_5.[3] Although the mechanism for solvolysis for both systems can be encompassed by the formulation, the ratios k_p/k_s and k_c/k_e vary enough to affect the balance of products. The rates of solvolysis (k_t is the titrimetric rate constant) and of change of optical activity (k_α is the polarimetric rate constant) have been reported for *threo*-I with R = CH_3 in both formic and acetic acids,[4] and k_t was reported for *erythro*-I with R = CH_3 in acetic acid.[4a] The rates k_t and k_α also were obtained in acetic acid for *threo*-I with R = C_2H_5, and k_α (but not k_t) was also determined in formic acid.



This paper is concerned with reactivity differences between diastereomers of I with R = CH_3, C_2H_5 and $CH(CH_3)_2$. The new kinetic data on particularly the *erythro* isomers of the first two systems coupled with product and kinetic data on the third system allow an evaluation of conformational and eclipsing effects in a series of homologous compounds of increasing steric constraints. All three of these systems possess symmetry properties which allow a maximum amount of information to be extracted concerning the role that phenonium ions play in the Wagner–Meerwein rearrangement.

Kinetics of Solvolyses

The kinetics of acetolysis and formolysis were followed utilizing methods previously described,[4b,3c] and in all cases were found to be cleanly first order. All four stereomers of 3-phenyl-2-butanol (II),[2] 4-phenyl-3-hexanol (III)[5] and 2,5-dimethyl-4-phenyl-3-hexanol (IV)[6] have been previously prepared in an optically pure state, and the absolute configurations of II and III have been completely assigned. As a result of the present work, all of the *relative* configurations of all four isomers of IV can be definitely assigned. None of the *absolute* configurations of the isomers of IV are known, and therefore a *completely arbitrary* assignment is made for convenience (see formulation).



L-*threo*	L-*erythro*
(+)-II, R = CH_3	(+)-II, R = CH_3
(+)-III, R = C_2H_5	(+)-III, R = C_2H_5
(+)-IV, R = $(CH_3)_2CH$	(+)-IV, R = $(CH_3)_2CH$

Table I reports the rate constants needed for comparison of the three systems and of the two diastereomers within each system. The rates were not all run under completely identical conditions. For instance, runs 1–6 were conducted in the absence of a salt for neutralization of the acid liberated, whereas runs 7–21 were made in the presence of such a salt. Enough data were obtained on system II[4a,4b] to indicate that the rate ratios reported in this paper were only slightly sensitive to the presence of salt. In the formolysis of systems III and IV, about 20% by volume of chloroform had

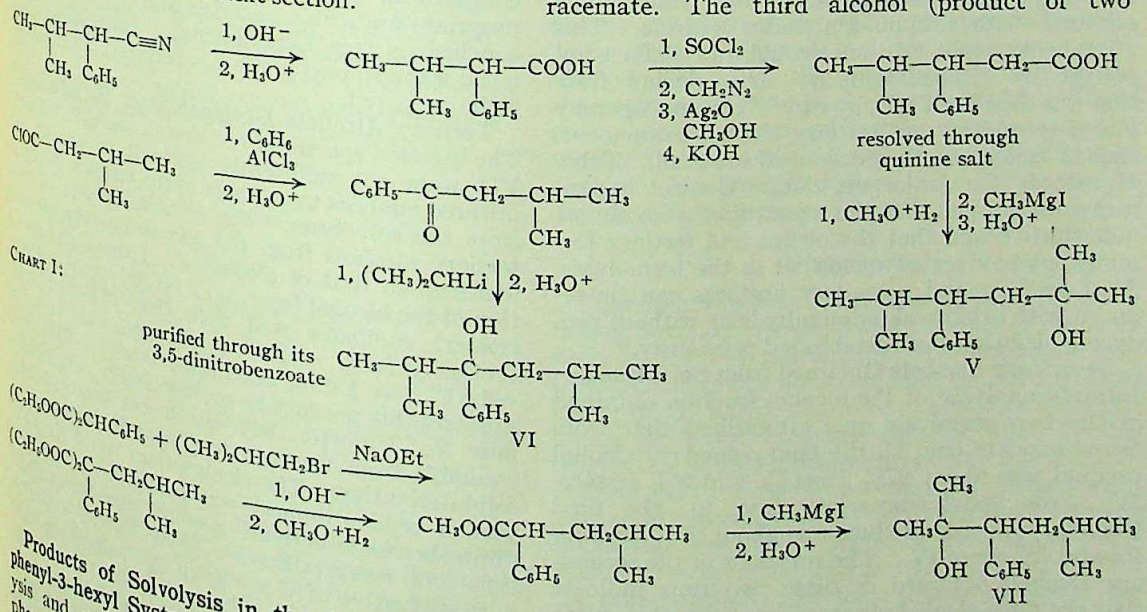
to be added to make the system homogeneous. The solvent was always the same for any two rates appearing as a ratio in this paper.

The polarimetric and titrimetric rates for *erythro*-II tosylate formolysis are almost the same (runs 7 and 8) and serve as a check on the method. Unfortunately the polarimetric rate of acetolysis could not be determined because some of the optically active products resulting initially underwent reaction at a rate comparable to that at which the solvolytic reaction occurred (see Discussion). An analysis of the meaning of these kinetic data depends upon a knowledge of the reaction products, a subject taken up in the next section.

CHART I:



Products of Solvolysis in the 2,5-Dimethyl-4-phenyl-3-hexyl System.—The products of formolysis and acetolysis of the tosylates of the 3-phenyl-2-butyl and 4-phenyl-3-hexyl systems have been previously reported.[2,3] The pattern of products obtained by the solvolyses of 2,5-dimethyl-4-phenyl-3-hexyl brosylate[7] (IV-Bs) is somewhat different from that found for the two simpler homologs. These products (alcohols V and VII) as well as the potential product VI were all prepared by conventional means since their detection in the alcohol mixtures from the hydrolysis of the solvolysis mixtures demanded a knowledge of their individual physical properties. Alcohol V was prepared in an essentially optically pure form since the analytical scheme necessitated a knowledge of its rotation. Alcohol VI was only prepared as its racemate. The third alcohol (product of two 1,2-H shifts) was also synthesized (see formulas) as a racemate.

(7) The tosylates of this system, although less reactive kinetically, are much harder to obtain in a pure state than the brosylates.

The brosylates of all four of the optically pure isomers of IV[6] were prepared. The sulfonate esters of the (+)-*threo*- and (+)-*erythro*-alcohols (these isomers differ only in configuration at the carbon carrying the oxygen) were acetolyzed at 50° for 8 titrimetric half-lives. The brosylates of the (−)-*threo*- and (−)-*erythro*-alcohols were formolyzed at 25° for 5 titrimetric half-lives. The olefin–ester products were converted to olefin–alcohol mixtures with lithium aluminum hydride. This mixture was split into an alcohol and olefin component by chromatography. The alcohol fraction was then itself split by careful chromatography into a secondary and tertiary alcohol component, each of which was then examined in detail. Table II records the important data. Control experiments established that the separations were almost quantitative and that the olefins and tertiary formates interconverted somewhat in the formolyses. That tertiary and secondary acetates can be reduced with lithium aluminum hydride without producing olefin has been established previously.[2c]

Secondary Alcohols Obtained from Solvolyses.—Infrared analysis[6] of the alcohol fraction obtained in the two acetolysis runs established that from *threo*-brosylate (run 1), the final secondary alcohol product was about 97% *threo*-IV and 3% *erythro*-IV. From *erythro*-brosylate (run 2), the final secondary alcohol product was about 95% *erythro*-VI and 5% *threo*-IV. The rotations of the secondary alcohols obtained in these two runs indicate that the *threo*-alcohol obtained from *threo*-brosylate (run 1) is essentially racemic, whereas the *erythro*-alcohol obtained from *erythro*-brosylate (run 2) is essentially optically pure. Although the infrared analysis was not performed on the alcohol from run 1 (acetolysis of *threo* isomer) the formolysis, the similarity of the magnitudes of rotation in runs 1 and 3 and in runs 2 and 4 indicate the results to be similar. In runs 2 and 4 mixed melting point comparisons of the *erythro*-alcohol obtained with authentic material further established the above contentions. In runs 1, 3 and 4, *p*-nitrobenzoates of the secondary alcohols were prepared, and mixed melting point and rotational comparisons between these compounds and the appropriate authentic materials also supported these conclusions (see Experimental). Insufficient material was obtained in run 2 to permit this derivative to be prepared.

Tertiary Alcohols Obtained from Solvolyses.—The infrared spectra of tertiary alcohols, V, VI and VII were not sufficiently different to permit an infrared analysis to be made of the tertiary alcohols from the solvolyses. The infrared spectra of the tertiary alcohols from the solvolyses were almost identical to that of alcohol V. Indeed, the rotation of the alcohol from run 2 (acetolysis of *erythro*-isomer) compares well with that obtained synthetically ($\alpha^{25}D$ −1.75°, l = 1 dm., neat *vs.* $\alpha^{25}D$ +1.81°, l = 1 dm., neat, respectively). This fact suggests this product to consist largely of optically pure V. Unfortunately insufficient material was available from this run to permit formation of a solid derivative. The alcohol from run 4 (formolysis of *erythro*-isomer) was converted to its 3,5-dinitrobenzoate derivative, which upon crystallization and recrystallization gave almost optically pure derivative of V as shown by comparison with an authentic sample. From the filtrates was obtained ester which appeared to be a mixture of ester of V and some other ester, probably of VII.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

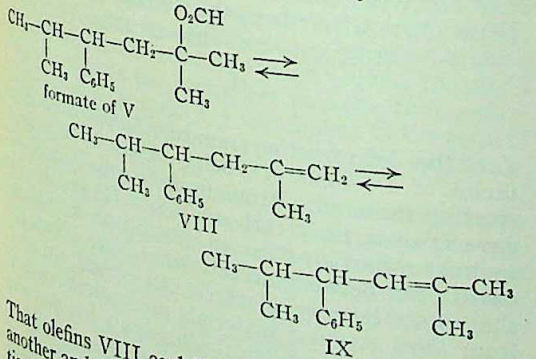
Digitized by Arya Samaj Foundation Chennai and eGangotri

gave 3,5-dinitrobenzoate ester of partially racemized V and possibly some other ester. The alcohol from run 3 (formolysis of *threo* isomer) gave 3,5-dinitrobenzoate ester of partially racemized V. From the filtrates was isolated the 3,5-dinitrobenzoate ester of racemic VII, as shown by comparison with an authentic sample. The above evidence suggests that optically pure V is produced in both acetolysis and formolysis runs of the *erythro* derivative but that somewhat racemized V was produced from the *threo* derivative. Alcohol VII was demonstrated to arise in the formolysis of *threo* material, and its presence was likely in the formolysis of *erythro* and possible in the acetolysis of the *threo*-brosylate.

Attempts to form the 3,5-dinitrobenzoate of VI failed. The absence of liquid residues from the formation of this derivative of the tertiary alcohols from the solvolysis points to the absence of VI in these mixtures. Even had the formate of VI formed in the formolyses, it probably would have gone to olefin since even the acetate of V slowly went to olefin in formic acid.

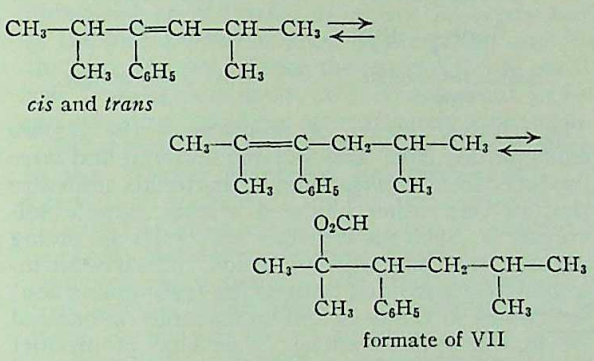
Olefins Obtained from Solvolyses.—During attempts to measure k_a for the formolysis of either *threo*-IV-Bs or *erythro*-IV-Bs, it became clear that two reactions were occurring in series with one another, each of which changed the rotation of the solution. The first and faster of these was the ionization of the brosylate, and the second was a reshuffling of certain of the initially formed (kinetically controlled) products. This result contrasts with that observed in the acetolyses where the products, once formed, persisted (see Experimental). To establish what secondary reactions were occurring in the formolyses, the following experiments were conducted.

Unfortunately the formate of V could not be prepared in a pure state. The acetate of active V was prepared and was found to give mixtures of olefins VIII and IX in formic acid under the conditions of the formolyses. Since formate is a better leaving group than acetate, it seems probable that the formate of V can interconvert with olefins VIII and IX under conditions of the formolysis.



That olefins VIII and IX can equilibrate with one another and with the formate of V under the conditions of the formolysis is suggested by the following experiment. The two olefin mixtures from acetolysis runs 1 and 2 were dissolved in the formolysis solutions and allowed to stand at 25° for the lifetime of a run. The rotations increased markedly and an ester band appeared in the infrared of the material isolated from this treatment.

Conjugated olefins were also produced during the solvolyses as shown by the ϵ's of the olefinic fraction at λ 232 mμ (see Table II). The total ultraviolet spectrum of these fractions showed no λ_{max} but only a general increase in absorption from 260 to 220 mμ. The same was true for the product obtained by treating IV-Bs with sodium ethoxide.[6] The absence of a maximum in this styrene region (230–250 mμ) undoubtedly is due to steric inhibition of resonance of the conjugated olefins. During the above equilibration of olefins in the formic acid solvolysis solutions, the ϵ's of the mixture at λ 232 mμ increased by about one-third. This result suggests that in formic acid the three conjugated olefins equilibrate with one another and that the increase of ϵ is associated with an accumulation of the more thermodynamically stable isomer, the isomer with the least degree of steric inhibition of resonance and the highest ϵ. When the equilibrating solutions were allowed to stand for a much longer time, both the rotations and the ϵ's stopped changing. This result demonstrates that the conjugated and unconjugated systems of olefins are not interconverting at any appreciable rate. Although not demonstrated, the formates of VII and possibly of VI also probably are involved in the equilibration of the conjugated olefins. These results are in harmony with those obtained with the simpler and more studied 2-phenylbutene system of olefins.[8] Attempts to reduce these olefins to 2,5-dimethyl-3-phenylhexane failed.



Discussion

Phenonium Ions as Intermediates in the Production of Secondary Acetate and Formate in Systems such as I.—The character of the secondary acetates and formates obtained from the solvolyses of the optically active diastereomers of 2,5-dimethyl-4-phenyl-3-hexyl brosylate indicate that in this reaction a bridged phenylcarbonium ion (a phenonium ion) intervenes as the chief intermediate leading to secondary ester. With one diastereomer, essentially completely racemized ester of the *same* diastereomeric configuration was obtained. With the other diastereomer the product possessed the same configuration as the reactant. Clearly the first diastereomer possesses the *threo* and the second the *erythro* configuration.

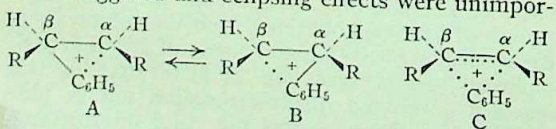
The relative absence of products of the *erythro* configuration from *threo* starting material and *threo* products from *erythro* starting materials indicates that in this rather hindered system, simple solvolysis is much slower than solvolysis involving phenyl participation in ionization. Clearly an internally compensated bridged ion (phenonium ion) intervened in the *threo* and an asymmetric bridged ion in the *erythro* system. This kind of product pattern resembles more that observed in the 3-phenyl-2-butyl than that of the 4-phenyl-3-hexyl system. In the former, *simple* acetolysis accounted for about 4–5% of the secondary acetates, and with the *threo* isomer inversion predominated over retention. In the 4-phenyl-3-hexyl system, *simple* acetolysis of the *threo* isomer accounted for about 15% of the secondary acetates, and retention predominated over inversion by a factor of about 5. In the 2,5-dimethyl-4-phenyl-3-hexyl system, *simple* acetolysis gave rise to about 3% of the secondary acetates, inversion being comparable to retention. Thus the most and least-hindered systems resemble each other more with regard to the amounts and direction of simple substitution than they resemble the intermediate system.

Two alternative hypotheses were offered for the marked predominance of retention over inversion in simple solvolysis in the *threo*-4-phenyl-3-hexyl system.[3] (1) A dynamic equilibrium between two unsymmetrical phenonium ions (A and B) might be substituted for the single symmetrical phenonium ion (C). In A and B the R groups were somewhat staggered and eclipsing effects were unimportant as compared to those in C, a species which might be either an intermediate or a transition state. As the bulk of R was increased, the activation energy for A → B would increase, and the competing simple solvolysis occurring with over-all retention at C_α would consume more of A. (2) Steric control of asymmetric induction by the substituents of the benzyl carbon atom might provide a larger amount of the *erythro* product in the simple solvolysis reaction involving an open carbonium ion.



The results of the solvolysis of the more hindered 2,5-dimethyl-4-phenyl-3-hexyl system make explanation (1) untenable, and are not inconsistent with (2). Since isopropyl is bulkier than ethyl, eclipsing effects in C should become more important. On the basis of (1), simple substitution with retention would become more prominent. The results are in the opposite direction. On the basis of (2), the ratio of *threo* to *erythro* product should vary with the steric situation at the benzyl carbon, and as phenyl and R approach each other in bulk, the degree of asymmetric induction might decrease.

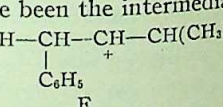
No evidence now exists which either suggests or demands the substitution of a dynamic equilibrium between unsymmetrical bridged carbonium ions for a single symmetrical bridged carbonium ion in systems where C_α and C_β carry the same substituents. Bridged ions such as C can provide a simpler and therefore better explanation of the facts until new evidence intrudes.

The Involvement of C_β–H in Production of Rearranged Tertiary Acetate and Formate in the 2,5-Dimethyl-4-phenyl-3-hexyl System.—A number of internal consistencies appear in the data of Table II which provide clues as to the mechanisms of olefin and tertiary ester formation. In runs 1 and 2 (acetolyses) where the products were kinetically controlled, the values of the ratios formulated are independent within experimental error of the configurations of the starting material. These data strongly imply that the tertiary ester and olefin had common intermediates, these intermediates being the same for each diastereomeric starting material.[9] The open secondary carbonium ion

CHART II

	$\frac{\alpha \text{ of olefin}}{\alpha \text{ of tert. alcohol}}$	$\frac{\text{Yield of olefin}}{\text{Yield of tert. alcohol}}$
threo acetolysis (run 1)	42	4.4
erythro acetolysis (run 2)	41	3.7
threo formolysis (run 3)	82	1.3
erythro formolysis (run 4)	77	0.23

(F) could not have been the intermediate since the



ϵ's of the olefin fraction from runs 1 and 2 differ by a factor of 4 (Table II), being higher for the *threo* starting material. More probably the brosylates gave open tertiary carbonium ions (G and H) by hydrogen participation in ionization, and these partitioned between acetate and olefin. The facts that both tertiary alcohols and olefins obtained from *threo* starting materials are optically active indicate that symmetrical phenonium ion was not

(9) A second condition for the equality of the ratios involving rotations is that the contributions of the active components to the rotation of the mixture are either proportional to their concentrations, or that deviations from proportionality are governed by the same factor in passing from mixtures obtained from run 1 to those of run 2. In the case of solutions of active 3-phenyl-1-butene in mixtures of *cis*- and *trans*-2-phenyl-2-butene and 2-phenyl-1-butene, the rotations were linear with concentration of the active component.[8] See Experimental for the rotation of a synthetic mixture of tertiary alcohols.

an important precursor in the production of these materials.

The rotation of the tertiary alcohol obtained in run 2 (*erythro*-acetolysis) was 97% that of optically pure V, so apparently $k_1 >> k_2$ with this diastereomer in this solvent. In run 1 (*threo*-acetolysis) the rotation was only about 60% that of optically pure V. With this isomer the starting brosylate ester racemizes at a rate which would make about 20% of alcohol V and of the active olefins racemic. Clearly in this run both the partially inactive tertiary alcohol and olefin fractions are diluted by about the same factor with optically inactive materials arising from the benzylcarbonium ion, G. The higher ϵ of the olefin (Table II) from run 1 also supports this thesis. Thus for the acetolysis of *threo*-brosylate, $k_1 \sim k_2$ and $k_5/(k_5 + k_6) \sim k_3/(k_3 + k_4)$ (this latter relationship is required by the constancy of the ratios of runs 1 and 2 in Chart II).

The results of the formolysis runs are complicated by the fact that the tertiary alcohol and olefin fractions once formed can interconvert to some extent. Runs 3 and 4 were allowed to go for 5 titrimetric half-lives, but since the *erythro* isomer solvolyzed 8 times as fast as the *threo*, the products once formed from the *threo*-brosylate (run 3) had a much longer period in which to approach equilibrium than did those from the *erythro*-brosylate (run 4). This fact accounts for the large differences in the yield ratios of Chart II for runs 3 and 4. That the rotation ratios are rather close for runs 3 and 4 suggests either that the two optically active olefins (VIII and IX) are produced in about the same ratio in a kinetically as a thermodynamically controlled process, or that both reaction times were long enough to allow these two olefins (not the tertiary formate) to equilibrate. The equilibration experiments conducted in formic acid on the olefin fractions from the acetolyses indicate that equilibration of VIII and IX is incomplete in the time of run 4. Thus the former interpretation appears to apply.

Perhaps the most striking internal consistency in the rotation data from the four runs is the constancy of the ratios of rotations of olefins obtained in runs 4 and 2 on the one hand and 3 and 1 on the other. The yields of these olefins varied by as much as a factor of 5, the rotations by as much as a factor of 2, and the starting materials in the formolyses and acetolyses were enantiomerically related. This similarity in ratios again emphasizes that the olefins are produced from the same intermediates (open carbonium ions) even though the starting materials are diastereomeric. Further, the fraction of olefinic product having arisen from racemized as compared to active brosylate ester in the *threo*-solvolysis must be about the same for the two solvents. Since the amount in the acetolysis (run 1) was about 20%, the amount in formolysis must have been approximately the same.

$$\frac{\text{(run 3) } \alpha \text{ olefin formolysis}}{\text{(run 1) } \alpha \text{ olefin acetolysis}}_{\textit{threo}\text{-solvolyses}} = 1.27$$

$$\frac{\text{(run 4) } \alpha \text{ olefin formolysis}}{\text{(run 2) } \alpha \text{ olefin acetolysis}}_{\textit{erythro}\text{-solvolyses}} = 1.29$$

Differences in Reactivity between Diastereomers in the Wagner–Meerwein Rearrangement.—The kinetic and yield data for the three systems (II, III and IV) when put together allow an analysis of reactivity differences between diastereomers to be examined as a function of the steric constraints of each system. Two general comparisons will be made. Partial rate factors for the various processes can be calculated in all three *threo* systems, and certain ratios compared with one another. The partial rate factors of the two diastereomers of each system will be compared with one another.

Chart III defines the partial rate factors and the configurational relationships involved, and Table III records the ratios of the partial rate factors of interest. Equations 2 and 3, coupled with the appropriate yield data,[3] were employed in converting the measured titrimetric (k_t) and polarimetric (k_α) rate constants into these ratios (ref. 3 provides sample calculations).

$$k_\alpha = k_0 + k_s + k_p \quad (2)$$

$$k_t = k_0 + k_s + k_p[k_c/(k_e + k_c)] \quad (3)$$

As the system becomes progressively more hindered, in acetic acid the value of $k_c/(k_c + k_e)$ passes from 0.12 for system II to 0.58 for system IV. In other words, ion-pair collapse becomes less favored. By contrast, in formic acid a slight trend in the opposite direction is evident, and in the most hindered system the values are rather close together. This pattern of results indicates that the exchange of an anion of an ion-pair with a solvent molecule is subject to a number of effects, some of which oppose one another.[10]

Of the other ratios of rates of Table III, the most interesting trend is that of $C_{\beta'}$–H (see part structure J) to become more involved in the solvolysis and for C_β–C_6H_5 to become less involved in passing from the least to the most ramified system (II to IV). This trend at least partially reflects the fact that $C_{\beta'}$–H can best participate in ionization at C_α

(10) Chloroform was present in the solvent in the formolysis of systems III and IV, so comparisons of these runs with those of II suffer somewhat. However, the dramatic changes in this ratio occur in passing from system III to IV, and about the same concentration of chloroform was present.

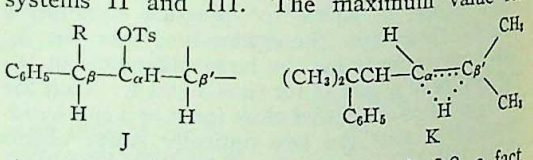
20	IV	25	HCOOH[e]	~ .5[f]	~ .3[g]	~ .7[g]	~ .0[g]

[a] $k\alpha = k_p + k_h + k_o + k_s$. [b] Temperature difference of 0.14° between runs 5 and 6, $k\alpha$ being the higher. [c] Temperature difference of 0.20° between runs 13 and 14, $k\alpha$ being the higher. [d] Actually a 3.33/1 mixture by volume of HCOOH–$CHCl_3$. [e] Actually a 2.86/1 mixture by volume of HCOOH–$CHCl_3$. [f] This ratio was calculated assuming that the same fractions of products were produced *via* racemized brosylate in formolysis and acetolysis, an assumption supported by the rotations of the olefins. [g] Calculations based on same assumptions as in (*f*).

Table IV compares the kinetics of the two diastereomers of each system in terms of the partial rate factors k_p (phenyl participation in ionization) and $k_h + k_o$ (a rough measure of hydrogen participation). The virtue of comparing reactivity differences between diastereomers lies in the fact that any differences must derive fundamentally from geometry. Unfortunately k_p cannot be calculated directly for the *erythro* runs, since the ratio $k_e/(k_e + k_e)$ cannot be determined. The best that can be done, therefore, is to calculate k_p (*erythro*) by assuming that the values of $k_e/(k_e + k_e)$ do not vary much between the diastereomers. This assumption is supported by the fact that although the values of k_α/k_t (Table IV) vary by factors of 4 and 2.5 in passing from acetic to formic acids (for systems II and III), the values of k_p (*erythro*)/k_p (*threo*) vary by factors of only 1 and 1.4 for the respective systems. Furthermore, when the values of $k_e/(k_e + k_e)$ are greater than 0.5, k_p becomes rather insensitive to the value of this ratio. Fortunately $(k_h + k_o)$ *erythro* can be calculated directly.

Quite reasonably, the values of k_t (*erythro*)/k_t (*threo*) depart more and more from unity as the system involved becomes more sterically constrained. The ratios of k_p (*erythro*)/k_p (*threo*) show about the same departure from unity in II and III as the ratios of k_t's, whereas the $(k_h + k_o)$ (*erythro*)/$(k_h + k_o)$ (*threo*) ratios are close to unity. In the much more hindered system, IV, the value of k_p (*erythro*)/k_p (*threo*) is about unity, and the $(k_h + k_o)$ (*erythro*)/$(k_h + k_o)$ (*threo*) ratio becomes about 9. On the basis of simple conformational *analysis*,[11] the *threo* isomers of systems II, III and IV are the more stable.[12] A comparison of the eclipsing effects[13] in each diastereomeric pair indicates that neighboring phenyl or hydrogen participation in ionization (from C_β) is more sterically feasible for the *erythro* than for the *threo* isomer (see Table IV). So both the starting states as well as the transition states for neighboring group participation would tend to favor k_p *erythro*/k_p *threo* > 1, and also to favor $(k_h + k_o)$ *erythro*/$(k_h + k_o)$ *threo* > 1 as long as $k_h + k_o$ measures mostly hydrogen involvement from the carbon carrying phenyl (C_β–H). This latter condition applies only to systems II and III. The maximum value for



these ratios in these two systems is 2.8, a fact which indicates both that eclipsing effects are small and that the differences in energy between the starting states are small. In IV, the ratio of k_p's remains near unity, but $(k_h + k_o)$ *erythro*/$(k_h + k_o)$ *threo* amounts to about 9. In this more hindered system, $k_h + k_o$ measures mostly involvement of $C_{\beta'}$–H. Since $C_{\beta'}$ carries two methyls, eclipsing effects in the transition state K should be about the

(11) (a) D. J. Cram and F. A. Abd Elhafez, THIS JOURNAL, **75**, 339 (1953); (b) D. J. Cram and F. D. Greene, *ibid.*, **75**, 6005 (1956)] D. H. R. Barton and R. C. Cookson [*Quarterly Reviews*, **10**, 48 (1956)] have also recognized these principles and quote as an example the work of R. P. Linstead and M. Whalley [*J. Chem. Soc.*, 3722 (1954)] on the relative stability of *meso*- and DL-2,3-disubstituted succinic acids. In this and similar systems as well as those such as the stilbene dibromides [*e.g.*, R. E. Buckles, W. E. Steinmetz and N. G. Wheeler, THIS JOURNAL, **72**, 2496 (1950)], dipole–dipole interactions may play a much more important role than simple steric effects. In these types of systems, the electronic and steric effects happen to reinforce one another. The only tests of the purely steric principles (of which the authors are aware) are those quoted in ref. 11a and 11b.

(12) In the analysis of IV, phenyl is selected as being effectively more bulky than isopropyl, a choice supported by the direction of asymmetric induction in the preparation of the system (ref. 6).

(13) See D. Y. Curtin [*Record Chem. Progress*, **15**, 111 (1954)] for a general discussion.

[a] The run numbers obviously had to be different for this calculation—data are in Table I. [b] The bridges referred to here are those involving (either as transition states or intermediates) the hydrogen on the C_β carrying the phenyl. [c] The yield data were obtained at 75° and the rates at 50°. It was assumed that the yields in the two diastereomers varied the same way over the 25° range of temperature. [d] k_α could not be obtained in formic acid.

same for the two diastereomers. Therefore, the factor of 9 is mainly attributable to differences in energy of the two diastereomeric starting states. The proximity of k_p (*erythro*)/k_p (*threo*) to unity therefore implies that the geometries of the transition states for phenyl participation resemble those of the starting states, and that phenyl provides only a small driving force for ionization in this particular system. The relative absence of eclipsing effects in IV recalls the data obtained in a study of the E_2 reaction in the 1,2-diphenyl-1-propyl-X system. The ratio k_{E_2} (*threo*)/k_{E_2} (*erythro*) in this system could be varied from $\sim$ 1 to 57, depending on the strength of the base, the character of the solvent and of the leaving group.[14] In system IV and probably in II and III as well, the transition states for phenyl migration still leave the substituents on C_α and C_β well staggered, and the three-membered ring only slightly formed.

Experimental

Preparation of the Brosylates of the Stereoisomers of 2,5-Dimethyl-4-phenyl-3-hexanol (IV).—The ordinary methods of preparation of either tosylates or brosylates in this system failed. The following procedure was found applicable to the preparation of all four stereomers. The starting four alcohols were reported previously in an optically pure state, as well as in their two racemic forms.[6] To 25 ml. of benzene (distilled from potassium) were added 1.23 g. (1.42 ml.) of sodium–potassium alloy and 2.58 g. of (−)-*threo*-IV. The mixture was stirred under dry, pure nitrogen at 25° for one hour and at reflux for 4 hours. Control experiments indicated this to be the minimum time for formation of the alcoholate. The reaction mixture was cooled to 0°, the remaining alloy removed (under nitrogen), and a solution of 3.26 g. of pure *p*-bromobenzenesulfonyl chloride in 15 ml. of dry benzene was added rapidly. The resulting mixture was permitted to warm to 15° during the first hour and then stirred at 25° for an additional hour. A few drops of solution gave a neutral test with phenolphthalein solution. The reaction mixture was washed with water, dried (sodium carbonate), treated with a few drops of pyridine and evaporated at 25° under diminished pressure. The resulting oil was crystallized at −20° from an equal volume of pentane (containing a few drops of pyridine). The liquor was decanted quickly, and the crystals were dissolved at 25° in a minimum amount of ether containing a few drops of pyridine and recrystallized by cooling to −20°. After two recrystallizations, the sulfonate ester was obtained (by decantation), dried under vacuum, wt. 3.70 g. (70% yield), m.p. indeterminate because of decomposition.

Anal. Calcd. for $C_{20}H_{25}O_3SBr$: C, 56.46; H, 5.90. Found: C, 56.64; H, 6.12.

The other three stereomers were prepared in from 50–70% yields, and showed similar instability, which prevented the determination of any meaningful m.p.'s or rotations. The ester of (+)-*threo*-IV was not successfully analyzed because of its instability. The analyses of (+)-*erythro*-IV and (−)-*erythro*-IV, respectively, are as follows.

Anal. Calcd. for $C_{20}H_{25}O_3SBr$: C, 56.46; H, 5.90. Found: C, 56.54, 56.33; H, 5.88, 5.79.

Preparation of the Acetates of the Stereomers of 2,5-Dimethyl-4-phenyl-3-hexanol (IV).—In the hope that the acetates of the four stereomers of IV would have rotations that would aid in the analysis of unknown mixtures of stereomers, these esters were prepared by the usual pyridine method in yields of 85–93%. Isomer (+)-*threo*-IV gave $n^{25}D$ 1.4868, $\alpha^{25}D$ +104.3° (l = 1 dm., neat).

Anal. Calcd. for $C_{16}H_{24}O_2$: C, 77.37; H, 9.74. Found: C, 77.59; H, 9.72.

Isomer (−)-*threo*-IV gave $n^{25}D$ 1.4868, $\alpha^{25}D$ −104.4° (l = 1 dm., neat). *Anal.* Found: C, 77.31; H, 9.47.

Isomer (+)-*erythro*-IV gave m.p. 45–46°, $\alpha^{25}D$ +85.7° (l = 1 dm., neat). *Anal.* Found: C, 77.15; H, 9.52.

Isomer (−)-*erythro*-IV gave m.p. 45–46°, $\alpha^{25}D$ −85.7° (l = 1 dm., neat). *Anal.* Found: C, 77.58; H, 9.64.

Kinetics of Solvolysis of the Brosylates of the Stereomers of IV.—The acetolysis solutions were prepared from C.P. acetic acid, anhydrous potassium carbonate and sufficient acetic anhydride to consume the water produced and leave a 1% excess. The ampoule technique was employed in both the titrimetric and polarimetric runs. The titration reagents and procedures have been reported previously.[4b] The polarimetric readings were taken in a thermostated 2-dm. tube at 25°. In all cases from 8 to 12 points were taken, and the reactions followed to 85–95% completion. A fixed infinity reading was obtained in the polarimetric runs.

The formic acid used in formolysis was purified as before[4c] (100.01% by titration with Karl Fischer reagent), and the requisite amounts of anhydrous sodium formate and of ethanol-free anhydrous chloroform were added. The amount of chloroform needed was determined by trial experiments, homogeneity throughout the run being the criterion. The titrimetric runs were followed by withdrawing 5-ml. aliquots of solution from the reaction and quenching this in 50 ml. of purified dioxane, and titrating this solution with standardized perchloric acid–dioxane solution (method of Winstein and Heck).[15] The indicator was bromcresol green and the light yellow end-point was always compared to a standardized end-point obtained by mixing equivalents of standard solutions together. Fifteen points were taken per run, and the reactions were followed to about 90% completion. The polarimetric formolyses were carried out in a 4-dm. thermostated polarimeter tube, fifteen points, a fixed infinity reading being taken.

4-Methyl-3-phenylpentanoic Acid.—Hydrolysis of 40 g. of 3-methyl-2-phenylbutyronitrile[6] with 56 g. of potassium hydroxide in 300 ml. of diethylene glycol (105° for 72 hours) gave 36 g. (81% yield) of 3-methyl-2-phenylbutanoic acid (recrystallized from pentane), m.p. 60.5–62.5° (reported[16] 62–63°). A solution of 20 g. of this acid in 16 g. of thionyl chloride was allowed to stand for 10 hours at 25°. The excess thionyl chloride was removed under reduced pressure, and the remaining liquid residue was distilled at 125° (13 mm.) to give 21.6 g. (98% yield) of acid chloride, $n^{25}D$ 1.5050. A solution of 20.4 g. of diazomethane in 500 ml. of dichloromethane was prepared from 50 g. of N-nitrosomethylurea.[17] To 400 ml. of this solution at 0° was added dropwise a solution of 20.6 g. of the above acid chloride in 50 ml. of dichloromethane (75 minutes). The resulting mixture was allowed to warm to 25°, the excess solvent was removed at 30 mm., and the bath temperature was raised to 35°. The remaining liquid residue was cooled, dissolved in 150 ml. of methanol, and 0.7 g. of powdered silver oxide was added. The resulting exothermic reaction was permitted to continue with occasional cooling until the reaction had subsided, when more oxide was added, and the mixture was refluxed for one hour. The mixture was cooled, filtered, evaporated (30 mm.), and the oil was distilled at 105–110° (pot temperature) at 2 mm. to give 19.3 g. (89% yield) of crude ester. Hydrolysis of the substance with 20 g. of potassium hydroxide in 150 ml. of diethylene glycol at 130° for 38 hours gave acid, which was recrystallized three times from pentane to give 12.8 g. (63% yield) of 4-methyl-3-phenylpentanoic acid, m.p. 48–49°. This acid has been reported previously as an oil.[18]

Anal. Calcd. for $C_{12}H_{16}O_2$: C, 74.96; H, 8.39; neut. equiv., 192. Found: C, 75.26; H, 8.37; neut. equiv., 192.

The anilide was prepared in the usual way, m.p. 114.5–116° (ethyl acetate).

Anal. Calcd. for $C_{18}H_{21}NO$: C, 80.86; H, 7.92. Found: C, 80.80; H, 7.92.

The above acid was also prepared by the following inferior sequence. The brosylate of 3-methyl-2-phenyl-1-butanol[6] was treated with potassium cyanide, and the resulting nitrile was hydrolyzed to acid, m.p. 48.5–49.5°, undepressed by admixture with an authentic sample.

This acid was resolved through its quinine salt as follows. A solution of 35.7 g. of acid and 52.7 g. of quinine was dissolved in a minimum amount of ethanol and held at 0°. The resulting solid was recrystallized 13 times (ethanol), the salt was converted to the acid to give m.p. 44–45°, $[\alpha]^{25}D$ +33.99° (c 3.3, $CHCl_3$). The acid was again converted to its quinine salt which was recrystallized three more times from methanol, and the resulting salt was again converted to the acid. This acid (recrystallized from pentane) gave wt. 0.0839 g., m.p. 44–45°, $[\alpha]^{33}D$ +34.4° (c 3.3, $CHCl_3$). Extensive recycling of the second crops gave more optically pure material of identical physical properties, enough to provide 0.88 g. of optically pure acid.

Anal. Calcd. for $C_{12}H_{16}O_2$: C, 74.96; H, 8.39. Found: C, 75.21; H, 8.59.

2,5-Dimethyl-4-phenyl-2-hexanol (V).—A solution of 4.92 g. of 4-methyl-3-phenylpentanoic acid (racemic) in 26 ml. of absolute methanol containing 1.3 ml. of concd. sulfuric acid was refluxed for 10 hours. The ester was isolated in the usual way and distilled at a pot temperature of 118° (4.6 mm.) to give 4.91 g. (93% yield), $n^{25}D$ 1.4932.

Anal. Calcd. for $C_{13}H_{18}O_2$: C, 75.69; H, 8.79. Found: C, 75.64; H, 8.85.

To a solution of methylmagnesium iodide prepared from 42.7 g. of methyl iodide and 8.0 g. of magnesium turnings, was added a solution of 3.0 g. of methyl 4-methyl-3-phenylpentanoate in 50 ml. of ether. The reaction mixture was stirred for 10 hours and then refluxed vigorously for one hour before decomposing the reaction mixture with 200 ml. of ice-cold saturated ammonium chloride solution. The phases were separated, and the aqueous phase was acidified with sulfuric acid and then extracted with ether. The ether extract was washed, dried, evaporated, and the remaining oil was absorbed on 200 g. of basic alumina of activity I.[19] After elution of the column with pentane had produced no residue, the product was eluted with 50% methanol in ether. The eluent was evaporated, and the liquid residue was dissolved in pentane, washed with water and dried. The pentane was evaporated, and the liquid residue was distilled at 100° pot temperature (1.4 mm.) to yield 2.76 g. (92% yield) of 2,5-dimethyl-4-phenyl-2-hexanol (V), $n^{25}D$ 1.5021.

Anal. Calcd. for $C_{14}H_{22}O$: C, 81.50; H, 10.75. Found: C, 81.58; H, 10.60.

The 3,5-dinitrobenzoate of V was prepared from 0.10 g. of V, 0.3 ml. of reagent pyridine and 0.12 g. of freshly prepared 3,5-dinitrobenzoyl chloride at 90° (2 hours). The product was isolated in the usual way and recrystallized twice from ether–pentane to give 0.15 g. (77% yield) of light yellow needles, m.p. 89.5–90.5°.

Anal. Calcd. for $C_{21}H_{24}O_6N_2$: C, 62.99; H, 6.04. Found: C, 63.06; H, 6.13.

Hydrolysis of the above derivative in a mixture of 0.05 g. of potassium hydroxide in one ml. of water and 4 ml. of ethanol at 95° for 8 hours gave back the original alcohol V in almost quantitative yield.

The acetate of V proved difficult to prepare, the following method giving the best result. A mixture of 0.109 g. of V, 0.5 ml. of pure acetic anhydride and 0.4 ml. of pure pyridine was held at 50° for 12 days. The product was isolated in the usual way, absorbed on a column of 50 g. of neutral alumina of activity I[19] made up in pure pentane. The product was eluted with 350 ml. of 12% ether in pure pentane, the solvent first was evaporated at 30 mm., and then at 1 mm. The acetate was not distilled due to the possibility of slight decomposition but was analyzed directly, $n^{25}D$ 1.4864.

Anal. Calcd. for $C_{16}H_{24}O_2$: C, 77.37; H, 9.74. Found: C, 77.28; H, 9.80.

Attempts to form the formate of V gave a mixture of olefin and formate.

Utilizing the above procedure, optically pure 4-methyl-3-phenylpentanoic acid (0.875 g.) was converted to its methyl ester (0.870 g.), $n^{25}D$ 1.4931, $\alpha^{25}D$ +33.47 (l = 1 dm., neat).

Anal. Calcd. for $C_{13}H_{18}O_2$: C, 75.69; H, 8.79. Found: C, 75.64; H, 8.84.

The above ester (0.87 g.) was divided into two portions, the first being converted to alcohol V (see above) to give after distillation at 118° (pot temperature) and 2 mm. 0.34

g. of alcohol, $n^{25}D$ 1.5019, $\alpha^{25}D$ +2.02 (l = 1 dm., neat). The other portion was subjected to the same procedure but the chromatographic step was omitted, 0.23 g. of V being obtained, $n^{25}D$ 1.5022, $\alpha^{25}D$ +2.68° (l = 1 dm., neat). The variation in rotation of these two preparations suggested contamination with small amounts of the highly rotating olefins derived from this tertiary alcohol. Therefore the combined alcohol portions were converted to the solid 3,5-dinitrobenzoate derivative (see above), which after a charcoal treatment and two recrystallizations from absolute ethanol gave 0.226 g. of ester, m.p. 89.5–90.5°, decomposition point 160–161° (dependent on heating rate), $[\alpha]^{25}D$ +15.01° (c 3.3, $CHCl_3$), m.m.p. with same derivative of racemic V, 80.5–82°.

Anal. Calcd. for $C_{21}H_{24}O_6N_2$: C, 62.99; H, 6.04. Found: C, 62.78; H, 6.07.

A second independent preparation of active alcohol V gave $\alpha^{25}D$ +2.79° (l = 1 dm., neat), and its 3,5-dinitrobenzoate gave $[\alpha]^{25}D$ +15.48° (c 3.3, $CHCl_3$). A total of 0.509 g. of this derivative of active V was hydrolyzed (see above) to give V as an oil which was submitted to chromatography on 50 g. of neutral alumina made up in pentane. A trace of olefin was eluted with pure pentane and alcohol was eluted with pure ether to give after distillation (90–95°, pot temperature, 0.9 mm.) 0.17 g. of optically pure V, $\alpha^{26}D$ +1.83° (l = 1 dm., neat). Another independent preparation gave $\alpha^{26}D$ +1.79° (l = 1 dm., neat).

Anal. Calcd. for $C_{14}H_{22}O$: C, 81.50; H, 10.75. Found: C, 81.22; H, 10.71.

2,5-Dimethyl-3-phenyl-3-hexanol (VI).—To a solution of 0.254 mole of isopropyllithium in 15.8 ml. of pentane[6] was added dropwise a solution of 25 g. of isovalerophenone in 75 ml. of pentane. The mixture was stirred for 10 hours, treated with ice-water, and the product isolated in the usual way. Distillation of the alcohol gave 20.6 g. (65% yield) of VI, b.p. 97–101° (3 mm.), $n^{25}D$ 1.5029–1.5016. This material (3.64 g.) was treated with a suspension of 0.9 g. of lithium aluminum hydride in ether, and worked up in the usual way. The resulting oil was treated with 4.0 g. of phthalic anhydride and 3 ml. of pure pyridine at 105° for 46 hours. The resulting solution was shaken with ether and dilute, cold hydrochloric acid, and the ether layer was washed with water, extracted with sodium bicarbonate solution and again with water. This operation removed the secondary alcohol present which had come from unreacted ketone. The ether layer was dried, evaporated, taken up in pure pentane and chromatographed on 200 g. of neutral alumina of activity I[19] in pure pentane. Elution of the column with pure pentane gave 0.43 g. of olefin (distilled at 90–95° pot temperature at 6 mm.), $n^{25}D$ 1.4981, λ_{232} (arbitrary), ϵ 4,805. Elution of the column with 9 liters of 32% ether in pure pentane gave alcohol VI which was distilled at pot temperature of 115–117° (4 mm.) to give 1.94 g. of V, $n^{25}D$ 1.5018.

Anal. Calcd. for $C_{14}H_{22}O$: C, 81.50; H, 10.75. Found: C, 81.41; H, 10.57.

Repeated attempts to form a 3,5-dinitrobenzoate of this compound failed to yield any solid derivative.

4-Methyl-2-phenylpentanoic Acid.—To 100 ml. of absolute ethanol was added 5.1 g. of sodium, and the resulting solution was cooled to 50°. Diethyl phenylmalonate[20] (47.2 g.) was added (40 minutes), the mixture was maintained at 50°, and 30.4 g. of isobutyl bromide was added (90 minutes). The solution (pH 10) was brought to reflux, and within 10 minutes solid separated. After 19 hours of reflux the reaction mixture approached pH 7, and the excess ethanol was evaporated. The remaining material was diluted with water, extracted with ether, and the extract was washed, dried and evaporated. The resulting oil was distilled (10 mm.): 1st fraction, b.p. 101–105°, wt. 24.7 g., $n^{25}D$ 1.4921; 2nd fraction, b.p. 130–150°, wt. 6.28 g., $n^{25}D$ 1.4848 (diethyl phenylmalonate, b.p. 156–158° at 9.3 mm., $n^{25}D$ 1.4896); 3rd fraction, b.p. 165–167°, wt. 4.29 g., $n^{25}D$ 1.4861. Hydrolysis of the first fraction gave phenylacetic acid. The third fraction was hydrolyzed with 60 ml. of an aqueous 40% potassium hydroxide solution (20 hours), and the resulting acid was recrystallized once from ether–pentane to give 1.63 g. of 4-methyl-2-phenylpentanoic acid, m.p. 75.5–76.5° (reported[21] 78–79°).

Anal. Calcd. for $C_{12}H_{16}O_2$: C, 74.96; H, 8.39. Found: C, 75.06; H, 8.47.

2,5-Dimethyl-3-phenyl-2-hexanol (VII).—A solution of 1.63 g. of 4-methyl-2-phenylpentanoic acid and 0.5 ml. of concd. sulfuric acid in 15 ml. of methanol was refluxed for 10 hours, and the resulting solution was worked up as usual. The resulting liquid was distilled at a pot temperature of 110–115° (2.5 mm.) to give 1.70 g. (97% yield) of 4-methyl-2-phenylpentanoate, $n^{25}D$ 1.4882.

Anal. Calcd. for $C_{13}H_{18}O_2$: C, 75.69; H, 8.79. Found: C, 75.87; H, 8.74.

This ester (1.70 g.) was treated with methylmagnesium iodide (5 g. of magnesium and 29.6 g. of methyl iodide) in the usual way to give VII, wt. 1.53 g. (90% yield), distilling at a pot temperature of 118–122° (3 mm.), $n^{25}D$ 1.5009. A portion (0.8 g.) of this alcohol was chromatographed on 250 g. of neutral alumina of activity I[19] in pentane, and the column was eluted with 8 liters of 32% ether in pentane. The solution containing the alcohol fraction was washed with sodium sulfite solution to remove ether peroxides, and the alcohol was distilled at 122–126° (pot temperature), wt. 0.56 g., $n^{25}D$ 1.5009.

Anal. Calcd. for $C_{14}H_{22}O$: C, 81.50; H, 10.75. Found: C, 81.27; H, 10.64.

A small portion of this alcohol was converted to the 3,5-dinitrobenzoate derivative, m.p. 133.5–134.5°, dec. 170.5–171.5° (depending on rate of heating somewhat), m.m.p. with the same derivative of 2,5-dimethyl-4-phenyl-2-hexanol 81–102°.

Anal. Calcd. for $C_{21}H_{24}O_6N_2$: C, 62.99; H, 6.04. Found: C, 63.10; H, 6.15.

The acetate of VII was prepared in 57% yield by the same method utilized in the preparation and purification of the acetate of V. The ester distilled at 110–115° (pot temperature) and 2 mm., $n^{25}D$ 1.4850.

Anal. Calcd. for $C_{16}H_{24}O_2$: C, 77.37; H, 9.74. Found: C, 77.14; H, 9.52.

Preparation of Acetolysis Stock Solution.—Glacial acetic acid was distilled (b.p. 115–116°), titrated with standardized Karl Fischer reagent and found to contain 5.46 g. of water per 1400 ml. of acid. A solution of 1400 ml. of this acid, 11.090 g. of anhydrous potassium carbonate (dried for 48 hours at 125°) and 58 ml. of freshly distilled acetic anhydride was refluxed to yield an acetolysis medium, 0.110 molar in potassium acetate and containing 1% excess acetic anhydride (by volume).

Acetolysis of the Brosylate of (+)-*erythro*-2,5-Dimethyl-4-phenyl-3-hexanol (Run 2 of Table II).—This brosylate (5.60 g.) was dissolved in 137 ml. of acetolysis stock solution (0.096 molar in brosylate), and held at 49.97 ± 0.05° for 291 minutes (8 titrimetric half-lives). The solution was then shaken with 1 liter of ice-water and four successive 250-ml. portions of pure pentane. The aqueous layer was then extracted with 150 ml. of pure ether. The organic extracts were combined, washed with water, sodium bicarbonate solution and again with water. The solution was dried, evaporated through a 75-cm. Vigreux column. (All subsequent evaporations of solvent were through this column, and pure, peroxide-free ether and kerosene-free pentane were utilized throughout.) The residual oil was distilled at a pot temperature of 90–115° (2 mm.) to give 2.64 g. of oil and 0.10 g. of pot residue. A solution of the oil in 25 ml. ether was added dropwise to a suspension of 0.624 g. of lithium aluminum hydride in ether. After being stirred for 3.5 hours, the mixture was decomposed with 70 ml. of wet ether and then 50 ml. of ice-water. The product was isolated in the usual way, and the resulting oil was chromatographed on 175 g. of neutral alumina of activity I[19] in pentane. The residues from the pentane eluates were distilled at a pot temperature of 90° (3 mm.) to give 1.74 g. of olefin (see Table II). The residues from the ether eluates were combined with the aid of pentane, and the resulting solution was washed free of peroxides with sodium sulfite solution and water. The pentane layer was dried, evaporated, and the resulting alcohol fraction was distilled at a pot temperature of 102–105° (1.5 mm.) to give 0.57 g. of alcohol. At this point 91% of the starting brosylate ester

[a] Beckman IR2T infrared spectrophotometer. The readings were taken successively in a 0.03-mm. cell, homogeneous liquid films, NaCl prism.

was accounted for. This mixture was submitted to infrared analysis (see later section).

The alcohol fraction was chromatographed on 171 g. (3 cm. by 35 cm.) of neutral alumina of activity I[19] in pentane, the chromatograph column being wrapped in heavy paper to exclude light. The column was developed with 32% ether in pentane (ether was washed free of peroxides just prior to use and carefully distilled). The results are tabulated (the chromatograph was run continuously for 27 hours). The residues from cuts 1–19 were combined with pentane and dried to give 0.0426 g. of solid material, m.p. 65–68°, $[\alpha]^{25}D$ +17.3° (*c* 4.3, $CHCl_3$). Recrystallization of the material from pentane gave 0.0243 g., m.p. 68.4–69.2°, $[\alpha]^{25}D$ +20.7° (*c* 1.7, $CHCl_3$), undepressed by admixture with an authentic sample of optically pure (+)-*erythro*-IV.

Eluent	Vol. of eluent, ml.	Cut	Characteristics
32% ether in pentane	1550	1–10	Blank
	1350	11–19	Crystals
	450	20–22	Blank
	1000	23–28	Droplets
100% ether	500	29–30	Liquid
	800	31	Blank

The liquid residues from cuts 21–31 were dissolved in pentane, the solution was washed with sodium sulfite solution, water, dried and evaporated. Distillation of the oil at a pot temperature of 102–103° (2 mm.) gave 0.47 g. of tertiary alcohol fraction. See Table II for properties. The infrared spectrum of this material proved to be identical to that of 2,5-dimethyl-4-phenyl-2-hexanol and was demonstrated through comparisons of this spectrum with that of a synthetic mixture of V containing 2% of IV to contain less than 2% of this secondary alcohol. Unfortunately this material was lost before a derivative could be prepared.

Acetolysis of the Brosylate of (+)-*threo*-2,5-Dimethyl-4-phenyl-3-hexanol (Run 1 of Table II).—The brosylate ester (6.123 g.) of optically pure alcohol was acetolyzed as in run 2 in 150 ml. of stock solution for 31 hours (8 titrimetric half-lives). The products were isolated as in run 2 to give 3.03 g. of olefin–ester mixture, which gave 1.43 g. of olefin and 1.20 g. of a mixture of secondary and tertiary alcohol (see Table II for physical properties). This mixture was submitted to infrared analysis (see later section). The secondary and tertiary alcohol fractions were separated by chromatography, 1750 ml. of solvent developer coming through the column without any dissolved alcohol in between the secondary and tertiary alcohol fractions. The secondary alcohol fraction amounted to 0.69 g., its infrared spectrum being identical to that of racemic *threo*-IV. This material (0.161 g.) was converted to its *p*-nitrobenzoate derivative,[6] 0.197 g. (71% yield) being obtained after being crystallized once from ethanol, m.p. 115.5–118° (undepressed by admixture with an authentic sample),[6] $[\alpha]^{25}D$ +0.45° (*c* 3.3, $CHCl_3$). The same derivative of (+)-*threo*-IV has m.p. 145–146°, $[\alpha]^{25}D$ +105° (*c* 3.3, $CHCl_3$).[6]

Mixed melting points of the following *p*-nitrobenzoates were obtained: (1) 5% derivative of (−)-*threo*-IV +95% racemic derivative, 118.5–123°; (2) 0.5% derivative of (−)-*threo*-IV + 99.5% racemic derivative, 117.5–119.5°; 1% derivative of (+)-*erythro*-IV + 99% racemic derivative of *threo*-IV, m.m.p. 110.5–140°.

The tertiary alcohol fraction amounted to 0.24 g., and its infrared spectrum was almost identical to that of authentic alcohol V. This fraction (0.160 g.) was converted to its 3,5-dinitrobenzoate derivative (see previous section) to give upon crystallization from ethanol 0.1554 g. (50% yield) of orange derivative. This material was crystallized three times from ethanol (charcoal treatment) to give 0.048 g. of derivative, m.p. 82.5–84° (decomposition, 162.5–163.5°), $[\alpha]^{25}D$ −8.37 (*c* 3.3, $CHCl_3$). The same derivative of optically pure V (m.p. 89.5–90.5°) gave $[\alpha]^{25}D$ +15.01° (*c* 3.3 $CHCl_3$). The mixed melting point of this derivative of active and racemic V gave 80.5–82°. Fractional crystallization of the filtrates from the above purification gave no material that melted above the melting point of the derivative of optically pure V (89.5–90.5°).

Infrared Analysis of Secondary–Tertiary Alcohol Mixtures from Runs 1 and 2.—The infrared spectra of pure *threo*-IV, *erythro*-IV and V were determined, and the most advantageous wave lengths for analysis selected. The absorbance of the two unknown mixtures at these wave lengths was determined. Two independent sets of three simultaneous equations were solved to give estimates of the three components. Synthetic mixtures of approximately the same composition were prepared and similarly analyzed, and the unknown mixtures were corrected to the known for deviations from Beer's law. Table V records the pertinent data. For run 2, the first set of equations gave 1% *threo*-IV, 17% *erythro*-IV and 83% V, and the second set gave 1% *threo*-IV, 19% *erythro*-IV and 80% V. For run 1, the first set of equations gave 70% of *threo*-IV, 2% of *erythro*-IV and 28% of V, whereas the second set gave 66% of *threo*-IV, 3% of *erythro*-IV and 30% of V. These values compare well with those obtained for the balance of secondary and tertiary alcohol obtained from the chromatograms.

Preparation of Formolysis Stock Solution.—Formic acid was purified by the method of Winstein and Marshall,[16] and the chloroform was purified immediately before use. A mixture of 105 ml. (1.55 g.) of chloroform in 300 ml. of formic acid was prepared, and the solution made 0.040 *N* in sodium formate with anhydrous, analytical grade reagent.

Formolysis of the Brosylate of (−)-*erythro*-2,5-Dimethyl-4-phenyl-3-hexanol (Run 4 of Table II).—A mixture of 4.78 g. of brosylate in 320 ml. of stock formolysis solution was shaken vigorously until solution was complete, and the resulting solution was held at 25.00 ± 0.01° for 23 minutes (5 titrimetric half-lives). The products were isolated as in run 2 to give 0.295 g. of olefin and 1.552 g. of a mixture of the secondary and tertiary alcohols (81% yield of products at this point). The alcohol mixture was submitted to chromatographic separation to give a secondary and tertiary alcohol fraction with a large blank fraction intervening.

The secondary alcohol fraction came to 0.137 g. of material, m.p. 68.4–69°, m.m.p. with authentic (−)-*erythro*-IV, 69.5–70.5° (see Table II for other properties). A sample of this fraction (0.0795 g.) was converted to its *p*-nitrobenzoate derivative[6] to give 0.0913 g. (67% yield) of material, m.p. 168.5–169.5° (undepressed by admixture with authentic material), $[\alpha]^{25}D$ −46.1° (*c* 3.3, $CHCl_3$). Authentic material[6] gave m.p. 168.5–170.0°, $[\alpha]^{25}D$ −47.0° (*c* 3.3, $CHCl_3$).

The tertiary alcohol fraction came to 1.189 g. (see Table II for properties). Its infrared spectrum indicated the presence of less than 2% of *erythro*-IV. A sample (0.203 g.) of this material was converted to its 3,5-dinitrobenzoate (see previous section) to give 0.257 g. (65% yield) of crude orange

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

product, m.p. 87–89°, $[\alpha]^{25}D$ +12.91° (*c* 3.3, $CHCl_3$). One recrystallization of this material from ethanol (charcoal) gave 0.145 g. of pure material, m.p. 89.3–90.2°, m.m.p. with an authentic sample, 89.5–90.5°, $[\alpha]^{25}D$ +14.2° (*c* 3.3, $CHCl_3$). Fractional crystallization of the filtrates gave crops melting above the melting point of the 3,5-dinitrobenzoate of V, *e.g.*, m.p. 87–104°. This material was probably contaminated ester of VII (m.p. 133.5–134.5°).

Formolysis of Brosylate of (−)-*threo*-2,5-Dimethyl-4-phenyl-3-hexanol (Run 3 of Table II).—A mixture of 5.0 g. of the above ester and 335 ml. of formolysis stock solution was shaken until homogeneous, and the resulting solution (0.035 molar in ester and 0.041 in sodium formate) was held at 25.00 ± 0.01° for 190 minutes (5 titrimetric half-lives). The products were isolated as in run 2 to give 0.960 g. of olefin (see Table II) and 1.141 g. of alcohol fraction (91% yield of products at this point). The alcohol mixture was chromatographically separated into secondary and tertiary alcohol components with a large blank fraction intervening.

The secondary alcohol fraction came to 0.226 g. (see Table II), and possessed an infrared spectrum identical to that of *threo*-IV. Its *p*-nitrobenzoate[6] was prepared from 0.129 g. of alcohol to give 0.158 g. (71% yield), m.p. 119–122° (undepressed by admixture with an authentic sample of derivative of racemic *threo*-IV), $[\alpha]^{25}D$ −2.13° (*c* 3.3, $CHCl_3$).

The tertiary alcohol fraction came to 0.536 g., and its infrared spectrum showed the presence of not more than 3% *threo*-IV. This fraction (0.201 g.) was converted to its 3,5-dinitrobenzoate derivative to give 0.270 g. (69% yield) of light orange crystals, m.p. 72–83°, $[\alpha]^{25}D$ +9.38° (*c* 3.3, $CHCl_3$). Three recrystallizations of this material from ethanol (charcoal treatment) gave 0.0348 g. of material, m.p. 83–87°, $[\alpha]^{25}D$ +13.1 (*c* 3.3, $CHCl_3$). This material was partially racemized derivative of V. Fractional recrystallization of the second crops gave 0.001 g. of the *p*-nitrobenzoate of 2,5-dimethyl-3-phenyl-2-hexanol (VII), m.p. 131.5–132.5°, m.m.p. with authentic material, 132–133.5°.

Controls on the Olefin Products of Acetolysis and Formolysis.—A solution of 0.208 g. of olefin from acetolysis run 1 in 20 ml. of acetolysis stock solution was held at 50° for 31 hours (8 titrimetric half-lives for acetolysis of the brosylate of *threo*-IV) and reisolated (a chromatographic step was included). This treatment changed the rotation of the olefin only slightly, from $\alpha^{25}D$ −42.91° (*l* = 1 dm., neat) to −43.94° (*l* = 1 dm., neat). A similar treatment of the olefin fraction from the formolysis run 3 only changed its rotation from $\alpha^{25}D$ +54.83° (*l* = 1 dm., neat) to $\alpha^{25}D$ +55.43° (*l* = 1 dm., neat).

A solution of 0.207 g. of olefin from acetolysis run 1 in 60 ml. of formolysis stock solution was held at 25° for 190 minutes (5 titrimetric half-lives for the formolysis of the brosylate of *threo*-IV). The olefin was reisolated, but showed a strong band in the infrared corresponding to formate ester at 1715 $cm.^{-1}$. This material was treated with lithium aluminum hydride, and the product chromatographed to give 0.0027 g. of an alcohol fraction. A similar experiment with the olefin from formolysis run 3 gave similar results.

A solution of 0.207 g. of olefin from acetolysis run 2 in 65 ml. of formolysis stock solution was held at 25° for 190 minutes (5 titrimetric half-lives for the formolysis of the brosylate of *threo*-IV). The product was isolated, treated with lithium aluminum hydride and the olefin fraction isolated by chromatography as before to give 0.16 g. of material. During this treatment the properties of the olefin changed as follows: at the start, $n^{25}D$ 1.4994, $\alpha^{25}D$ −72.09° (*l* = 1 dm., neat), λ_{232} gave ε 474 (cyclohexane); at the end, $n^{25}D$ 1.5016, $\alpha^{25}D$ −84.49° (*l* = 1 dm., neat), λ_{232} gave ε 595 (cyclohexane). A second experiment was carried out identical to that above except the reaction was permitted to proceed for 14 hours (20 titrimetric half-lives). The recovered olefin fraction gave $n^{25}D$ 1.5020, $\alpha^{25}D$ −88.12° (*l* = 1 dm., neat), λ_{232} gave ε 575 (cyclohexane).

A solution of 0.210 g. of olefin from acetolysis run 1 in 70 ml. of formolysis stock solution was held at 50° for 190 minutes. The product was isolated, treated with lithium aluminum hydride, chromatographed, and the olefin fraction was reisolated. During this treatment the properties of the olefin changed as follows: at the start, $n^{25}D$ 1.4992, $\alpha^{25}D$ −42.91° (*l* = 1 dm., neat), λ_{232} gave ε 1594 (cyclohexane); at the end, $n^{25}D$ 1.5007, $\alpha^{27}D$ −47.24° (*l* = 1 dm., neat), λ_{232} gave ε 2040 (cyclohexane).

Controls on the Stability of the Tertiary Esters Formed in the Solvolyses.—The formate of V could not be prepared, so the more stable acetate of V was used in the control experiment. A solution of 0.201 g. of material was dissolved in 40 ml. of formolysis stock solution and maintained at 25° for 190 minutes. The product was isolated in the usual way, treated with lithium aluminum hydride and chromatographed to give 0.0347 g. of olefin and 0.0749 g. of an alcohol fraction. Clearly the formate of V would have been unstable under the conditions of its formation in the formolyses.

A solution of 0.0346 g. of the acetate of 2,5-dimethyl-3-phenyl-2-hexanol (VII) in 5 ml. of acetolysis stock solution was held at 50° for 31 hours (8 titrimetric half-lives of the acetolysis of brosylate of *threo*-IV). The product was isolated, treated with lithium aluminum hydride, and the alcohol and olefin separated by chromatography. The olefin fraction amounted to 0.0013 g. and the alcohol fraction to 0.0225 g. (69% recovery). This acetate appeared to decompose only slightly under the conditions of its possible formation. The similarities in structure between V and VII indicate the acetate of V should be equally stable under the acetolysis conditions.

A solution of 0.0989 g. of the acetate of VII in 30 ml. of formolysis stock solution was held at 25° for 190 minutes. Work-up of the mixture gave 0.0066 g. of alcohol (37% recovery) and 0.0214 g. of olefin. This experiment indicates that the formate of VII would have been unstable under the conditions of the formolyses, probably equilibrating with the conjugated olefins.

Control on the Dilution Effect of Racemic 2,5-Dimethyl-3-phenyl-2-hexanol (VII) in Optically Pure 2,5-Dimethyl-4-phenyl-2-hexanol (V).—A solution of 0.0392 g. of pure racemic VII in 0.0832 g. of optically pure V ($\alpha^{25}D$ +1.81°, (*l* = 1 dm., neat) was prepared and gave $n^{25}D$ 1.5013, $\alpha^{25.6}D$ +0.82 ± 0.06° (*l* = 1 dm , neat). The infrared spectrum of this mixture was essentially identical with that of an authentic sample of V.

Control on the Extent of Resolution During the Fractional Crystallization of the 3,5-Dinitrobenzoate of Partially Active 2,5-Dimethyl-4-phenyl-2-hexanol (V).—Partially optically active 4-methyl-3-phenylpentanoic acid (1.06 g., m.p. 46–47.5°) was esterified to give 1.05 g. of methyl ester, $n^{25}D$ 1.4931, $\alpha^{25}D$ −17.77° (*l* = 1 dm., neat), 53% optically pure. This material gave 0.90 g. of V, $n^{25}D$ 1.5021, 0.305 g. of which was converted to its 3,5-dinitrobenzoate. This derivative was recrystallized from ethanol. The first crop of 0.33 g., m.p. 81.5–86°, $[\alpha]^{25}D$ −7.33° (*c* 3.3, $CHCl_3$), was recrystallized to yield 0.119 g., m.p. 81–87°, $[\alpha]^{26}D$ −7.25° (*c* 3.3, $CHCl_3$). A second crop of 0.090 g., m.p. 81–84, $[\alpha]^{24}D$ −8.58° (*c* 3.3, $CHCl_3$), was recrystallized to yield 0.0483 g., m.p. 81.5–83.5°, $[\alpha]^{25}D$ −9.37° (*c* 3.3, $CHCl_3$). The mother liquor after removal of the second crop gave material, 0.0251 g., $[\alpha]^{26}D$ −7.97° (*c* 2.5, $CHCl_3$). The percentage increase in resolution with each crystallization appears to be about +5 ± 12%.

Eluent	Volume of eluent, ml.	Cut	Characteristics
32% ether in pentane	1000	1– 52	Blank
	525	53– 75	Liquid
	1800	76–147	Solid
	75	148–150	Blank
	600	151–153	Blank
100% ether	800	154–155	Liquid
	400	156	Blank

Control on the Chromatographic Separation of 2,5-Dimethyl-4-phenyl-3-hexanol (IV) and 2,5-Dimethyl-4-phenyl-2-hexanol (V).—A mixture of 0.225 g. of (−)-*erythro*-IV, $[\alpha]^{25}D$ −19.02° (*c* 3.3, $CHCl_3$) and 0.232 g. of (−)-*threo*-IV, $[\alpha]^{25}D$ −7.25° (*c* 5, $CHCl_3$) was melted and well mixed, $[\alpha]^{25}D$ −12.69° (*c* 5, $CHCl_3$). A portion (0.3083 g.) of this mixture was diluted with 0.2465 g. of racemic V, and the resulting sample was chromatographed on 166 g. of neutral alumina (3 cm. by 25 cm. column) of activity I[19] made up in pentane. The secondary alcohol was eluted from the column with 32% ether, and the tertiary with 100% ether

Stereochemistry of the Primary Carbon. VI. The Reaction of Optically Active 1-Aminobutane-1-*d* with Nitrous Acid. Mechanism of the Amine–Nitrous Acid Reaction[1]

BY ANDREW STREITWIESER, JR., AND WILLIAM D. SCHAEFFER[2,3]

RECEIVED OCTOBER 2, 1956

The reaction of *n*-butylamine with sodium nitrite in acetic acid gives a mixture of esters in which the ratio of *n*-butyl acetate to *sec*-butyl acetate is 2:1 and a small amount of alkyl nitrates. The 1-butyl-1-*d*-acetate obtained from optically active 1-aminobutane-1-*d* is 69 ± 7% inverted, 31 ± 7% racemized. A mass spectral investigation of the product from 1-aminobutane-1,1-d_2 shows that 0% ethyl rearrangement occurs. These results in conjunction with other data lead to a complete theory for the product-determining steps of the amine–nitrous acid reaction. The fundamental tenet of this hypothesis is that the alkyldiazonium ion, the last *common* intermediate in the reaction, can undergo a number of competing reactions because of its great instability.

Introduction

Since the first example of Piria[4] and the later extended investigations of Linnemann[5] the reaction of aliphatic primary amines with nitrous acid has been used extensively in preparative and theoretical organic chemistry. In aqueous solution, the reaction generally produces alcohols and olefins, frequently with rearrangement. Although the kinetics of the reaction has been investigated[6] it pertains only to the initial phase of the reaction of the amine with a nitrous acid moiety; the product-determining steps occur later in the reaction sequence and are not amenable to direct kinetic approaches. Analogy to the aromatic series strongly suggests that diazonium ions are intermediates in the reaction.[7] The nature of the reaction products and particularly the similarity of the many rearrangement products to products of typical carbonium ion reactions have led to the interpretation of the product-determining steps of the amine–nitrous acid reaction in terms of solvolytic displacement reactions. The commonly accepted mechanism of the reaction is a competing direct displacement (SN2) on the alkyldiazonium ion by solvent (reaction 1) and a unimolecular fission of the diazonium ion (SN1) to a carbonium ion which subsequently may react with solvent to form product, eliminate a proton to yield olefin or rearrange a hydrogen or a carbon function to a new carbonium ion which ultimately results in products of such rearrangement (reaction 2).[8–11]

$$H_2O \longrightarrow R\overset{\frown}{\text{—}}N_2^+ \longrightarrow ROH + H^+ + N_2 \quad (1)$$

$$R\text{—}N_2^+ \longrightarrow N_2 + R^+ \begin{cases} \xrightarrow{H_2O} ROH + H^+ + N_2 \\ \longrightarrow \text{Olefin} + H^+ + N_2 \\ \longrightarrow N_2 + R'^+, \text{ etc.} \end{cases} \quad (2)$$

In several cases the experimental observations are in accord with this hypothesis; *e.g.*, the reactions with aqueous nitrous acid of crotylamine, α-methylallylamine, α,α-dimethylallylamine and γ,γ-dimethylallylamine yield, respectively, the same mixtures of isomeric allylic alcohols as the silver ion-catalyzed aqueous solvolyses of the corresponding chlorides[12,13]; cyclopropylcarbinylamine and cyclobutylamine on treatment with aqueous nitrous acid give similar mixtures of cyclobutanol, cyclopropylcarbinol and allylcarbinol.[12] However, in some other examples, this interpretation is clearly not a happy one. *n*-Propyl-, *n*-butyl- and *n*-amylamines, etc., give rather large amounts of secondary carbinol, the product of a rearrangement.[5,b,c,f,14] In solvolytic displacement reactions, rearrangement of *n*-primary to second-

ary compounds is observed only by the action of strong Lewis acids; *e.g.*, Friedel–Crafts reactions with aluminum halides and alkyl halides or with boron trifluoride and alcohol. These conditions are such that either the carbonium ion intermediate is formed repeatedly or the reactivity of the nucleophilic reagent is so low that reaction with the carbonium ion is slower than the rearrangement. These conditions are not likely to be met in aqueous nitrous acid. Moreover, in the reaction of optically active secondary carbinylamines, the product alcohol possesses some optical activity.[10,15] There is an apparent inconsistency in the interpretation of the net inversion of configuration observed as resulting from direct displacement by solvent (reaction 1) for the reaction of *sec*-butylamine with nitrous acid in water yields 2-butanol with 22% net inversion although in the far less nucleophilic solvent, acetic acid, 2-butyl acetate is formed with 28% net inversion.

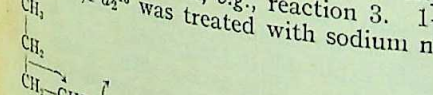
In order to specify in more detail these difficulties of the accepted mechanism, we chose to investigate the stereochemistry of a simple system in which partial rearrangement is known to occur.

Results

Treatment of a solution of *n*-butylamine in 1 *N* hydrochloric acid with sodium nitrite is reported to yield a mixture of 25% 1-butanol, 13% 2-butanol, 5% *n*-butyl chloride, 3% *sec*-butyl chloride, 30% butenes and a trace of butyl nitrites.[14f] The reaction of *n*-butylamine with sodium nitrite in acetic acid yields butenes and a mixture of *n*-butyl acetate and *sec*-butyl acetate which contains 4–8% of butyl nitrates. Reduction of this mixture with lithium aluminum hydride yields a mixture of 65% 1-butanol and 35% 2-butanol. The ratio of primary to secondary products in acetic acid is virtually identical to that found by Whitmore and Langlois[14f] in water.

Optically active 1-aminobutane-1-*d* has been described previously.[16] The 1-butyl-1-*d* acetate obtained by treatment with sodium nitrite in acetic acid corresponded to 69 ± 7% net inversion of configuration.[17] This result is remarkably similar to that obtained from *sec*-butylamine (*vide supra*).

Roberts and Halmann[14e] have reported that the *n*-propyl alcohol obtained by treatment of *n*-propylamine with nitrous acid has undergone 8.5% of methyl group rearrangement. It was necessary to establish whether an ethyl group rearrangement in the *n*-butyl case contributed importantly to the racemization observed, *e.g.*, reaction 3. 1-Aminobutane-1,1-d_2[16] was treated with sodium nitrite in



products (3)

acetic acid and the resulting mixture of esters was converted to alcohols. The primary alcohol obtained by fractionation was compared mass spectrographically with the 1-butanol-1,1-d_2 used to prepare the amine. Rearrangement of an ethyl group would produce 1-butanol-2,2-d_2 which could be detected easily in the mass spectrum, even in rather small amount. The analysis of the cracking patterns (see Appendix) indicated that none of the rearranged alcohol was present, hence 0% ethyl rearrangement had taken place in the amine–nitrous acid reaction.

It is unlikely that a significant amount of the observed racemization was due to the formation of a diazoalkane which had reacted with solvent to give racemic acetate. This reaction has been shown to be of minor importance with ethylamine[18] and is undetectable with allylic amines.[19] The mass spectral investigation of the product from 1-aminobutane-1,1-d_2 establishes that diazoalkane formation accounts for no more than about 1% of the reaction (see Appendix).

Discussion

The present stereochemical results may be compared with the results of some typical solvolyses. The acetolysis of 1-butyl-1-*d* *p*-nitrobenzenesulfonate at 114° yields 1-butyl-1-*d* acetate with 85 ± 2% net inversion. In 90% nitrobenzene–10% acetic acid at 91° the product shows 59 ± 2% net inversion and in 75% dioxane–25% acetic acid at 97°, 46 ± 2% inversion.[20] In all of these cases the amount of racemization observed is comparable to that observed in the corresponding amine–nitrous acid reaction and probably is due to the intervention of intermediates of the carbonium ion type[21]; yet, *in all of these solvolyses, no trace of rearrangement to sec-butyl compounds could be detected.* It follows that the product-determining intermediates in the amine–nitrous acid reaction must differ at least in part from the intermediates in the sulfonate acetolyses. The same conclusion may be derived from the observation that the composition of the butene mixture obtained from the reaction of *sec*-butylamine differs from that obtained by solvolysis of *sec*-butyl tosylate (*vide infra*).

If the racemized product in the acetolyses of 1-butyl-1-*d* *p*-nitrobenzenesulfonate arises from a carbonium ion intermediate which has lost asymmetry, it follows that the reaction of this intermediate with acetic acid must be considerably more rapid than a rearrangement to a secondary carbonium ion; *i.e.*, the free energy of activation for rearrangement is significantly higher than that for solvolysis. It also follows that a concerted rearrangement and expulsion of the leaving group, reaction 4, also requires considerably more energy than the direct formation of a primary carbonium ion.

(16) A. Streitwieser, Jr., and W. D. Schaeffer, This Journal, **78**, 5597 (1956).

(17) This number is obtained by a direct comparison of the rotation of the product acetate with that of acetate prepared from a sample of the same 1-butanol-1-*d* from which the amine was prepared. As discussed in the earlier paper[16] the latter preparation probably went with a single inversion of configuration and no racemization.

$$C_2H_5-\overset{H}{\underset{|}{CH}}-\overset{\curvearrowright}{CH_2}-X \longrightarrow C_2H_5\overset{+}{C}HCH_3 + X^- \quad (4)$$

In the reaction of *n*-butylamine with nitrous acid, if the *sec*-butyl products obtained are due to a process such as reaction 4 (X = N_2^+), it follows that the difference in free energies of activation between this process and the formation of a primary carbonium ion is much smaller than the corresponding difference in sulfonate solvolysis. To account for this change, we propose the following theory for the course of the product-determining steps in the amine–nitrous acid reaction.

Diazonium ions on the whole are rather unstable; because of the stability of the nitrogen molecule, the decomposition of an alkyldiazonium ion into nitrogen and a carbonium ion undoubtedly does not have high energy requirements and, indeed, may even be somewhat exothermic.[22] The activation energy is correspondingly rather small, perhaps of the order of 3–5 kcal./mole, compared to the corresponding dissociation of a primary alkyl sulfonate into carbonium ions for which the activation energy is about 30 kcal./mole.

The transition state for the decomposition of an alkyldiazonium ion more closely resembles the reactant than does the transition state for solvolysis of an alkyl sulfonate.[23] Correspondingly, the scale of energy differences for competing reactions would reasonably be expected to be compressed. Consider the following example (Fig. 1) of a system in which a

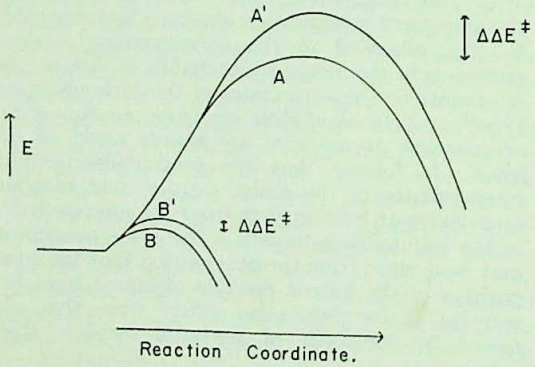

Fig. 1.—Illustrating the effect of total activation energy on the position of the transition state along a reaction coordinate and on the difference in activation energies between competing reactions.

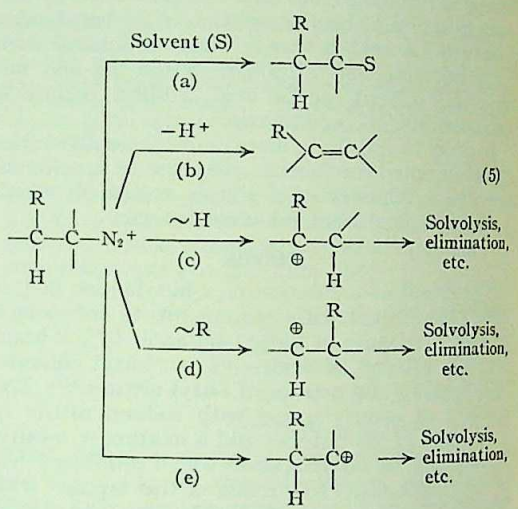
competing concerted rearrangement (A′) requires 5 kcal./mole more energy than a "normal" solvolysis (A) having an activation energy of 25 kcal./mole; in the corresponding diazonium reaction for which the "normal" process (B) has an activation energy of, say, 5 kcal./mole, the rearrangement (B′) would require only 1 kcal./mole more energy to a first approximation. (In both cases the difference amounts to 20% of the activation energy of the "normal" reaction.) At room temperature, in the former case the rearrangement accounts for 0.02% of the product; in the latter case, 16%. Thus, a rearrangement which is not observed in solvolyses of halides and sulfonates can form a significant part of the product in the corresponding amine–nitrous acid reaction.

Because of this compressed scale of energy differences, *a number of different reactions can compete more or less successfully in various systems.* These reactions, *which derive from the diazonium ion as the common intermediate*, are summarized in reaction 5. The relative importance of each reaction is more or less predictable from modern organic chemical theory and by analogy with other reactions. In the following discussion, the theory is applied to the present results.



Reaction 5a: Direct Displacement.—One of the reactions which can compete with normal carbonium ion formation is direct displacement by solvent. The hypothesis that the structure of the transition state resembles the reactants carries the implication that the bond to the attacking solvent molecule at the transition state for displacement is long and weak. Steric hindrance effects are reduced and relatively small stereochemical differences are to be expected between primary and secondary systems. In acetic acid, *n*-butylamine reacts with 69% inversion, *sec*-butylamine with 28% inversion (*vide supra*). Since the bond to the solvent is relatively long and weak, the extent of the inversion process is expected to be relatively insensitive to the nucleophilicity of the solvent. The similarity of the stereochemical results observed for *sec*-butylamine in water and in acetic acid may be explicable in these terms.

Reaction 5b: Elimination.—The olefin obtained from *sec*-butylamine in aqueous nitrous acid consists of 25% 1-butene, 19% *cis*-2-butene and 56% *trans*-2-butene (Table I). This composition would not be expected to change significantly in acetic acid. The composition of this mixture differs greatly from the mixture of butenes obtained by the acetolysis of *sec*-butyl tosylate (Table I).[24] Of particular importance is the difference in the *cis/trans* ratio in the two cases. The olefin in the

Table I

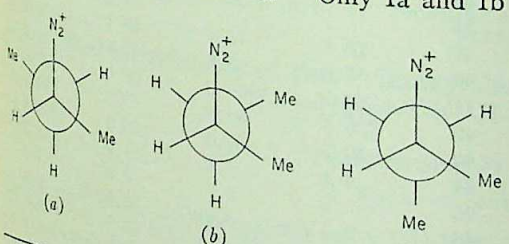
Composition of Butenes from Solvolysis and Amine–Nitrous Acid Reactions

Reaction	Butene composition, % 1-	*cis*-2	*trans*-2	Ratio *trans*/*cis*
s-BuOTs + AcOH[a]	10.3	43.2	46.5	1.1
s-BuNH$_2$ + HNO$_2$[b]	(25)[c]	19	56	2.9
n-BuNH$_2$ + HNO$_2$[b]	71	9	20	2.2
Equilibrium[d]	2	23	75	3.2

[a] At 70°; from ref. 24. [b] At room temperature. [c] By difference; direct analysis by infrared was prevented by the presence of a trace of butanol. Analysis of 2-butenes is not affected by the butanol. Less than 2% of isobutylene was present. [d] Gas at 25°; calculated from ref. 25.

sec-butyl tosylate and in similar solvolyses is considered to arise from a common carbonium ion intermediate because the olefin proportion and composition is the same when different leaving groups are used.[21,24,26] Consequently, the failure of this criterion with *sec*-butylamine demonstrates that at least part of the olefin formed in the amine–nitrous acid reaction does not arise from a carbonium ion intermediate.

An alternative is reaction 5b, a concerted elimination of a *trans*-hydrogen and nitrogen from the diazonium ion. Because the activation energy is presumed to be comparable to or less than the energy required for rotation about a carbon–carbon bond (3–4 kcal./mole for the central bond in *n*-butane[27]; undoubtedly more where groups bulkier than methyl are involved), the rates of such rotation will be of about the same magnitude or slower than the rate of decomposition. Hence, the relative populations of different conformations of the diazonium ion at the moment of formation will be important in determining the relative importance of possible subsequent reactions. In the case of 2-butylamine, three such conformations are important, Ia, b and c.[28] Ib is expected to be less populated than Ia and Ic.[29] Only Ia and Ib



I

can eliminate a *trans*-3-hydrogen; hence, consistent with the observed results, *cis*-2-butene which would arise from Ib is expected to be formed in smaller amount than *trans*-2-butene which arises from Ia. In elimination from a carbonium ion, the two types of hydrogen are conformationally equivalent and comparable amounts of the *cis*- and *trans*-olefins may be anticipated. Ic, which is relatively highly populated, cannot give a 2-butene by *trans* elimination. All three conformations (*i.e.*, the entire population of diazonium ions) can give rise to 1-butene; only a fraction of the entire population of diazonium ions (that part in Ia and Ib) can generate 2-butene; therefore, even if the specific rate constant for formation of 1-butene is somewhat lower than that for the more stable 2-butenes, a relatively large amount of 1-butene is produced in the reaction (Table I).

This hypothesis also serves to interpret the fact that in cyclohexyl systems, equatorial amines (in which there are no *trans*-hydrogens) give essentially no olefin although axial amines generally produce large amounts of olefin.[31]

Reactions 5c and 5d: Rearrangement.—Rearrangement of a hydrogen or carbon function is expected when the rearranging group is *trans* to the leaving nitrogen. However, rearrangement by reaction 5c and 5d apparently occurs only when a more stable carbonium ion results. In the case of *n*-butylamine a significant fraction of the total population of diazonium ion is expected to be in conformations having a *trans*-2-hydrogen. Such a hydrogen can eliminate (reaction 5b) or migrate (reaction 5c) perhaps by way of a common hydrogen-bridged intermediate. In cases in which the population of diazonium ions in conformations having *trans*-hydrogens is too small, no rearrangement is expected. The non-occurrence of hydrogen-rearranged products from 2,2-diphenylethylamine,[32] for example, is probably due to this cause.

It should be emphasized that because the total activation energy for reaction is presumed to be small, the rearrangements 5c and 5d should not be regarded as participations in the usual sense in which a neighboring group helps to *push* out the leaving group. Rather, these reactions are perhaps better regarded as resulting from the tendency of the leaving nitrogen to *pull* over the *trans*-group.

Reaction 5e: Carbonium Ion Formation.—The formation of a carbonium ion by loss of nitrogen, long thought to be the principal mode of decomposition of alkyl diazonium ions, is here regarded as being only one of several possible competing reactions. In the present case, the 31% racemization observed in the 1-butyl-1-*d* acetate obtained from 1-aminobutane-1-*d* is attributed to the formation in part of primary butyl-1-*d* cations which lose their asymmetry. We would expect that carbonium ions produced in the amine–nitrous acid reaction would be "normal" and would react in the

same manner as carbonium ions generated from other sources.[33]

Experimental

Reaction of *n*-Butylamine with Sodium Nitrite and Acetic Acid.—To a solution of 22 g. (0.30 mole) of *n*-butylamine in 200 ml. of acetic acid was added 40 g. of sodium nitrite over a period of 1 hr. at 0°. After stirring in the cold for an additional 2 hr. the mixture was allowed to warm to room temperature during 12 hr. The mixture was poured into an ice-cold solution of 200 g. of potassium hydroxide in 500 ml. of water. The resulting mixture was extracted four times with 100-ml. portions of pentane. After drying, the combined pentane extracts were distilled and yielded 13.6 ml. of material, b. 108–126°, which was a mixture of *n*-butyl acetate, *sec*-butyl acetate and *n*-butyl nitrate (identified by its intense absorption in the infrared at 6.13 μ; *sec*-butyl nitrate may have been present in small amount but was not identified), which presumably arose by a reaction with nitrate ion formed by the decomposition of nitrous acid. The nitrogen analysis (found: 0.96%)[36] corresponds to the presence of 8.2%[37] butyl nitrate. The mixture was hydrolyzed by refluxing with 25 g. of potassium hydroxide and 100 ml. of water for 24 hr. The product, 9.5 ml., b. 100–117°, still showed the presence of alkyl nitrate (infrared).

The nitrate present was cleaved with lithium aluminum hydride. After refluxing 9.2 ml. of the alcohol and nitrate mixture with 2.0 g. of lithium aluminum hydride in 35 ml. of ether, 7.9 ml. of butyl alcohols was obtained, b. 100–117°. The infrared spectrum of the mixture compared to those of the pure alcohols showed the presence of 65% of *n*-butyl alcohol and 35% of *sec*-butyl alcohol.

In a similar experiment, the butenes evolved were collected in a Dry Ice trap. Analysis of the mixture by infrared[38] gave the results in Table I. No isobutylene could be detected.

Reaction of Optically Active 1-Aminobutane-1-*d* with Sodium Nitrite in Acetic Acid.—Eleven grams (0.15 mole) of optically active 1-aminobutane-1-*d*[16] in 100 ml. of dry acetic acid was treated with 20 g. of sodium nitrite as described above. The product, 6.5 ml., b. 112–125°, had $\alpha^{25}D$ +0.206 ± 0.004° (*l* 4) and was a mixture of approximately 69% 1-butyl-1-*d* acetate, 23% 2-butyl-1-*d* acetate and 8% of alkyl nitrate. Distillation through a concentric tube column gave 2.2 ml., b. 123–126.5°, of a mixture having $\alpha^{25}D$ +0.120 ± 0.004° (*l* 2) and consisting of approximately 80% 1-butyl-1-*d* acetate, 13% 2-butyl-1-*d* acetate and 7% alkyl nitrate. The column did not function properly in this distillation. After thorough cleaning, a second fractionation gave 0.5 ml. of product having $\alpha^{25}D$ +0.052 ± 0.004° (*l* 1) and consisting of 75% 1-butyl-1-*d* acetate and 25% *n*-decane (used as a chaser in these distillations). The compositions were estimated by comparison of the infrared spectra with standard compounds. The final product, which contained no *sec*-acetate or alkyl nitrate, corresponds to a rotation for pure 1-butyl-1-*d* acetate of +0.069 ± 0.007° (*l* 1). The rotation of acetate prepared directly from the alcohol used to prepare the amine is $\alpha^{25}D$ +0.200 ± 0.004° (*l* 2).[39] Since the preparation of the amine from alcohol probably involved one inversion and no racemization,[16] it follows that the 1-butyl-1-*d* acetate formed in the amine–nitrous acid reaction is 69 ± 7% inverted, 31 ± 7% racemized.

Using this rotation for pure 1-butyl-1-*d* acetate product, the rotation of the initial product mixture corresponds to the presence of 75% of primary acetate since the 2-butyl-1-*d* acetate present is presumed to be racemic and if the rotation due to the small amount of nitrate present is neglected. Similarly, the rotation of the product from the first fractionation corresponds to the presence of 87% of 1-butyl-1-*d* acetate. These results are in reasonable agreement with the infrared spectra, especially if the nitrate present has about the same rotation as the *n*-acetate.

2-Butyl-1-*d* Acetate.—This material was prepared for infrared comparison purposes. 1,2-Epoxybutane (Dow) (6.85 g., 0.095 mole) was dropped into 1.0 g. (0.0238 mole) of lithium aluminum deuteride (Metal Hydrides, Inc., Beverly, Mass.) in 75 ml. of dry ether at a rate sufficient to maintain a gentle reflux. After refluxing for an additional two hours, the product was worked up in the usual manner. Distillation gave 5.5 g. (0.073 mole, 78%) of 2-butanol-1-*d*, b. 96–99°. The infrared spectrum of this alcohol shows important differences from 2-butanol. In addition to the C–D stretching band at 4.55 μ, other new bands appear at 7.84, 9.21 and 11.45 μ, although the peaks at 10.37 and 12.24 μ in 2-butanol are missing. In addition, other bands are changed in shape and intensity.

Part of the alcohol was converted to the acetate with acetyl chloride and pyridine.[40] In the ester, too, there are important differences in the infrared. New bands appear at 4.56 (C–D), 9.54, 10.17 and 11.76 μ; missing are the bands at 8.46, 10.04, 10.31, 11.56 and 11.95 μ present in 2-butyl acetate. There are many other differences in detail.

Reaction of 1-Aminobutane-1,1-d_2 with Sodium Nitrite in Acetic Acid.—Twenty-five grams (0.33 mole) of 1-aminobutane-1,1-d_2[16] in 226 ml. of dry acetic acid was treated with 45 g. of sodium nitrite as above and the products were isolated in the same manner. Distillation gave 16.0 g. (40% yield) of deuterated *n*- and *sec*-butyl acetates and nitrates. The mixture was reduced with 6.0 g. of lithium aluminum hydride in 100 ml. of ether and was refluxed for several hours. Distillation of the product through a glass

spiral column using 2-octanol as a chaser gave the following fractions: 1, b. 96–113°, 3.9 ml.; 2, b. 113–117°, 3.1 ml.; 3, b. 117–117.4°, 3.3 ml.; 4, b. 117.4–117.5°, 1.6 ml. The infrared spectrum of fraction 4, 1-butanol-1,1-d_2, indicated the absence of deuterated secondary carbinol; however, the mass spectral cracking pattern showed the presence of an impurity which is probably 2-octanol. This cracking pattern is discussed in the appendix.

Reaction of *sec*-Butylamine with Nitrous Acid.—The object of this experiment was the analysis of the butene mixture obtained. To a solution of 20 g. (0.27 mole) of *sec*-butylamine in 300 ml. of water and 143 ml. of 3 *N* sulfuric acid (0.216 mole) was added in portions and with stirring 52.5 g. (0.229 mole) of barium nitrite. The barium nitrite was added from a flask attached with a rubber tube. The mixture was stirred at room temperature for 20 hours and the butenes produced were passed through 20% potassium hydroxide and a potassium hydroxide tower and were collected in a Dry Ice trap. The analysis of the mixture by infrared is given in Table I.[38]

Appendix

Cracking patterns for 1-butanol-1,1-d_2, and, for comparison, 1-butanol and 1-butanol-1-d, are given in Table II at an ionizing voltage of 75 v.[41] Column 4 contains the pattern for the 1-butanol-1,1-d_2 used to prepare the amine.[16] Column 5 contains the pattern for the 1-butanol-1,1-d_2 obtained from the reaction of the amine with nitrous acid (fraction 4). This material apparently contains an impurity (perhaps 2-octanol used as a chaser in the distillation) which contributes to some of the peaks. In the absence of this contribution and with no rearrangement of an ethyl group or loss of deuterium, the two patterns should be identical. The amount of $CH_3CH_2CD_2CH_2OH$ (II, product of an ethyl group rearrangement) present in the $CH_3CH_2CH_2CD_2OH$ (III) may be estimated in two independent ways: an important process in the electron impact of primary carbinols is the cleavage of the bond to the carbinol carbon with the formation of CH_2OH^+ (mass 31). To the extent that II is present in III, the 31 peak will be increased and the 33 peak lowered by a corresponding amount. Reference to Table II shows that the 33 peak is lowered (by ~5%) but the 31 peak *is not* increased by a corresponding amount; in fact, it is also lower (by 7.5%). Hence, these peaks indicate 0% rearrangement. The other fragment from the carbinol cleavage in *n*-butyl alcohol is a propyl (or isopropyl) cation, $C_3H_7^+$ (mass 43). The abnormally high 43 peak in column 5 is probably due to a contribution by the impurity. The presence of II will be manifested by an increase in the 45 peak ($C_3H_5D_2^+$). This peak is increased by only 0.2 unit which corresponds to 0.2% rearrangement but which is within the limits of the experimental uncertainties. Hence, ~0% ethyl rearrangement has occurred.

An indication may also be had of the proportion of the amine–nitrous acid reaction which proceeded through a diazobutane intermediate since an atom of deuterium would be lost in the process. The presence of an increased amount of 1-butanol-1-d would be shown by an increase in the 32 peak ($CHDOH^+$). The observed increase, 0.7 unit, corresponds to 1% of 1-butanol-1-d. This is a maximum figure because of the unknown contribution of the impurity.

Stereochemistry of the Primary Carbon. VII. The Decomposition of N-(1-Butyl-1-*d*)-N-nitrosoacetamide[1,2]

BY A. STREITWIESER, JR., AND W. D. SCHAEFFER[3]

RECEIVED SEPTEMBER 24, 1956

The thermal decomposition of optically active N-(1-butyl-1-*d*)-N-nitrosoacetamide gives an optically inactive mixture of 22% *n*-butyl acetate, 56% 1-butyl-1-*d* acetate and 22% 1-butyl-1,1-d_2 acetate. The decomposition of N-(1-butyl)-N-nitrosoacetamide in the presence of deuteroacetic acid gives butyl acetate containing some 1-butyl-1-*d* acetate. The results are interpreted by a mechanism which involves diazoalkane intermediates.

Methods for converting aliphatic amines to the corresponding alcohol or alcohol derivatives are rather limited. The most common method, the amine–nitrous acid reaction, generally furnishes low yields of alcohols frequently contaminated by rearrangement products. Consequently, considerable interest recently has been shown in the thermal decomposition of N-alkyl-N-nitrosoamides, the first examples of which are due to Pechmann[4] and Chancel.[5] Recent studies[6–9] have demonstrated the generality of this reaction which yields esters and olefins; from primary carbinylamines the corresponding esters are obtained in good yield with little or no rearrangement. White[9d] has inter-

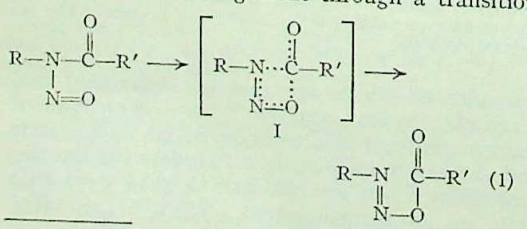
preted his stereochemical results in terms of a mechanism involving a set of cyclic transition states some of which are rather unusual and, to us, highly unlikely. It seemed clear that application of the reaction to the 1-aminobutane-1-*d* system could yield results which would be of significant interest from the standpoint of the reaction mechanism.

Results and Discussion

Optically active 1-aminobutane-1-*d*[10] was converted to N-(1-butyl-1-*d*)-N-nitrosoacetamide with acetic anhydride and nitrous acid. Since no bond to the asymmetric carbon is broken in these reactions, no loss in optical purity is expected in this sequence. The thermal decomposition of N-(*n*-butyl)-N-nitrosoacetamide in heptane solution at 85° is reported to yield 79% of *n*-butyl acetate and 16% of acetic acid.[9c] The decomposition of the deutero-nitrosoamide in cyclohexane solution at 80° gave 59% of deuterated butyl acetate having $\alpha^{25}D$ +0.005 ± 0.004° (*l* 2). 1-Butyl-1-*d* acetate of the same optical purity as the starting amine has $\alpha^{25}D$ +0.200 + 0.004° (*l* 2); hence 98 ± 2% of the optical activity has been lost. Analysis of the nitrosoamide decomposition product by comparison of its infrared spectrum with those of known mixtures showed it to consist of about 22% *n*-butyl acetate, 56% 1-butyl-1-*d* acetate and 22% 1-butyl-1,1-d_2 acetate. The analysis depended on the fact that *n*-butyl acetate is blank in the 4–5 μ region, 1-butyl-1-*d* acetate has a single intense C–D band at 4.54 μ, and 1-butyl-1,1-d_2 acetate has a C–D doublet at 4.46 and 4.63 μ, and on the differences between the three esters in the 8.5–9.0 μ region. The resulting analysis is probably better than ±5% in each component.

No mechanism involving only intramolecular transformations can account for the observed disproportionation of deuterium. A reasonable mechanism which accommodates both the complete loss of optical activity and the disproportionation of deuterium is one which involves a diazoalkane intermediate.

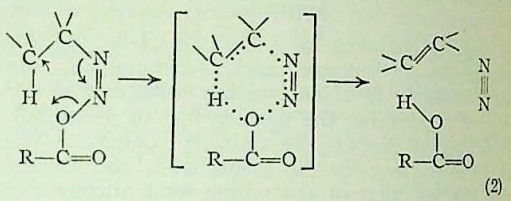
In the aromatic series the postulate that the first step in the decomposition of acylnitrosoarylamines involves an intramolecular rearrangement to the corresponding aryl diazoester[11] (equation 1) has been shown to be consistent with a variety of experimental observations.[12–15] Analogously the rearrangement through a transition



(1)

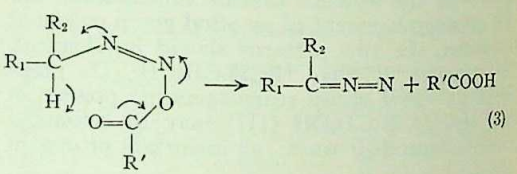
state such as I also has been postulated as the first and rate-determining step in the decomposition of aliphatic nitrosoamides.[4b,6b,9d,16,17] Huisgen and Reimlinger[17a] have recently shown that kinetic results may be accommodated readily on the basis of a rate-determining rearrangement to the diazoester; in particular, the rate pattern as a function of structure was shown to be in accord with reasonable hypotheses concerning the relative importance of steric and polar effects. Hence the reaction products may be regarded as resulting from subsequent reactions of the intermediate diazoester.

One of the subsequent reactions of the diazoester is an elimination to form olefins, nitrogen and the carboxylic acid for which the intramolecular mechanism proposed by White[9d] (reaction 2) is attractive, at least in non-polar solvents. A similar re-



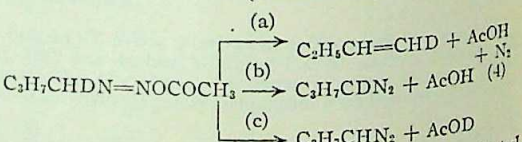
(2)

action with an α-hydrogen atom would result in the formation of a diazoalkane (reaction 3). Diazoalkanes are known to react rapidly with



(3)

carboxylic acids to form esters without rearrangement.[18,19,20] The postulate of a diazoalkane intermediate in the present case accounts for the loss of optical activity in an obvious manner. Furthermore, the deuterium migrations are readily accounted for. According to this mechanism 1-butyl-1-*d* diazoacetate can decompose by β-elimination to give acetic acid and olefin (reaction 4a), or by α-elimination to give either acetic acid and diazobutane-1-*d* (reaction 4b) or deuteroacetic acid and diazobutane (reaction 4c). The reaction



(4)

of diazobutane with acetic acid generates *n*-butyl acetate. Reaction of diazobutane-1-*d* with acetic acid or of diazobutane with deuteroacetic acid produces 1-butyl-1-*d* acetate. The reaction of diazobutane-1-*d* with deuteroacetic acid gives rise to 1-butyl-1,1-d_2 acetate.

June 5, 1957

The reaction of diazoalkanes with carboxylic acids is known to have a relatively large isotope effect; for example, the reaction of diphenyldiazomethane with acetic acid is about four times faster than the reaction with deuteroacetic acid.[21,22] Hence, if reactions 4b and 4c went at equal rates, excess deuteroacetic acid would remain at the end of the reaction (because of reaction 4a), and the product butyl acetate would manifest a net loss of some deuterium. The fact that such loss of deuterium is at most rather small suggests that the α-elimination reaction is also subject to an isotope effect; *i.e.*, reaction to 4b would seem to be faster than 4c. This point was not further investigated.

An obvious corollary of this mechanism is that the decomposition of undeuterated nitrosoamide in the presence of deuteroacetic acid should yield product ester containing some deuterium. The decomposition of N-(*n*-butyl)-N-nitrosoacetamide in cyclohexane containing 1.8 equivalents of deuteroacetic acid gave *n*-butyl acetate containing 26% of 1-butyl-1-*d* acetate; the decomposition in isopropyl ether containing 1.3 equivalents of deuteroacetic acid gave *n*-butyl acetate containing 21% of 1-butyl-1-*d* acetate.

The hypothesis also allows the interpretation of certain results in the decomposition of nitrosoamides in the presence of added salts. When N-(*n*-butyl)-N-nitrosoamide was allowed to decompose in cyclohexane in the presence of suspended sodium benzoate and calcium hydride, the ester produced was a mixture of butyl acetate and butyl benzoate. A rapid reaction of acetic acid with the sodium benzoate to form benzoic acid which reacts with the diazoester would account for the formation of butyl benzoate. The calcium hydride was used in this and in other experiments to react with the acid as produced. However, subsequent experiments demonstrated that the reaction of carboxylic acids with calcium hydride suspended in inert solvents is rather slow.

The postulate that diazoalkane intermediates are involved in the decomposition of aliphatic nitrosoamides was first offered by Heyns and Bedenberg.[8] These authors later discarded this mechanism on the basis of competition experiments[23]; for example, the thermal decomposition of a mixture of N-methyl-N-nitrosoacetamide and N-butyl-N-nitrosobutyramide without solvents gave a mixture of methyl acetate and butyl butyrate. The diazoalkane hypothesis predicts that a mixture of four esters should have resulted. Several aspects of the experimental procedure, however, seem to us to reduce the significance of these observations; *viz.*, the use of no solvent and of temperatures much higher than necessary to promote the reaction. Consequently, a competition experiment was run under conditions similar to those used generally in this investigation. When an equimolar mixture of N-ethyl-N-nitrosopropionamide and N-butyl-N-nitrosoacetamide was decomposed in hexyl ether solution at 80° for 24 hours, the product was a mixture containing comparable amounts of all four possible esters, ethyl acetate, ethyl propionate, butyl acetate and butyl propionate. A control experiment was also run in which a mixture of ethyl propionate and butyl acetate was heated in the presence of acetic acid and propionic acid in hexyl ether solution for 24 hours at 80°. The two starting esters were isolated in good yield with no evidence for the formation of ethyl acetate and butyl propionate. These results are completely consistent with the diazoalkane mechanism.

Comparison with Other Systems.—The mechanism of the nitrosoamide decomposition has been discussed by several authors, but no over-all picture has yet been presented consistent with all of the known facts. Although the present results indicate that essentially all of the decomposition of *primary* carbinyl nitrosoamides proceeds by reactions 2 and 3, the stereochemical results of White[9d] have conclusively demonstrated that these cannot be the exclusive modes of reaction in *secondary* carbinyl systems. Thus, in dioxane solution the decomposition of optically active N-(2-butyl)-N-nitrosobenzamide gave 2-butyl benzoate with about 40% retention of configuration. The intramolecular cyclic mechanism proposed by White[9d] to account for this stereochemistry would be expected, if correct, to apply at least as well to primary systems. Since our results show that the decomposition of primary alkyl nitrosoamides is actually intermolecular, the cyclic mechanism seems improbable for secondary systems.

On the other hand, the stereochemical results in secondary systems are readily accommodated by an "ion-pair" mechanism, reaction 5, analogous to that demonstrated in some decompositions of alkyl chlorosulfites.[24]

$$\mathrm{R{-}N{=}N{-}O{-}\overset{\overset{O}{\|}}{C}{-}R' \longrightarrow R^{\oplus} \cdots \ominus O_2CR' + N_2 \longrightarrow R{-}O{-}\overset{\overset{O}{\|}}{C}R' + N_2} \quad (5)$$

Reaction 5 involves a simple decomposition of the diazoester intermediate to nitrogen and a carbonium ion–carboxylate ion "ion-pair" in which the stereochemical configuration is largely preserved. Subsequent collapse of the ion-pair leads to product ester with predominant retention of configuration. Since this paper was first submitted for publication, the paper of Huisgen and Reimlinger[17b] appeared in which a similar mechanism was proposed.[25] These authors discussed the possible role of diazoalkanes without coming to definite conclusions.[26]

(24) D. J. Cram, THIS JOURNAL, **75**, 332 (1953); C. E. Boozer and E. S. Lewis, *ibid.*, **75**, 3182 (1953).

(25) In personal discussions with Professor Huisgen, it developed that both groups had independently arrived at similar mechanisms.

(26) Huisgen and Reimlinger[17b] reported some interesting experiments which demonstrated that the reaction of diazomethane with a mixture of carboxylic acids yields the same product mixture as the decomposition of a methyl nitrosoamide in the same mixture of acids. They pointed out that these results require that either diazomethane is a common intermediate in both reactions or that diazomethane reacts with carboxylic acids to give the same intermediate (a diazonium ion–carboxylate ion ion-pair) produced in the nitrosoamide decomposition. Our present demonstration that diazoalkanes *are intermediates* in the decomposition of primary alkyl nitrosoamides indicates that the former of these alternatives is correct.

Reaction product	(20.4)[e]	(56.2)[e]	(23.4)[e]	.177	.473	.267	.22		

[a] For the pure liquid in a 0.095-mm. cell. The 8.6 μ band is for a 0.025-mm. cell. [b] Calculated from the equations: $\log (I_0/I)_{4.55\mu} = 0.765N_{d_1} + 0.183N_{d_2}$; $\log (I_0/I)_{4.63\mu} = 0.154N_{d_1} + 0.768N_{d_2}$. [c] For 1-butyl-1,1-$d_2$, $\log I_0/I = 1.1$. [d] Shoulder was not resolved. [e] Calculated from the found absorbancies and the equations in (*b*). The undeuterated acetate was found by difference.

However, all of the facts are explicable by the postulate that reactions 2, 3 and 5 are *competing* modes of decomposition of the diazoester. On this basis, the racemization found in secondary systems is due in large measure to the formation of a diazoalkane intermediate. In primary carbinyl systems, carbonium ion stability is so low that reaction 5 is slow compared to the formation of diazoalkane. In the chlorosulfite decomposition the formation of carbonium ion–chloride ion "ion-pairs" also has been demonstrated to be relatively slow for primary systems.[27] As the carbonium ion stability is increased the proportion of reaction *via* reaction 5 is also increased and product with increased *retention* of configuration is expected. Thus, N-(α-phenylethyl)-N-nitrosoamides give ester with greater retention of configuration (48–70% for different amides in various solvents[9d,17b,28]) than do the secondary alkyl systems.

A further corollary of the mechanism proposed here is that in reactions 3 and 5, a carboxylic acid or carboxylate ion is formed in which both oxygens become equivalent. By use of O^{18} tracer techniques, White and Aufdermarsh have recently reported that the two oxygens do, indeed, become completely equivalent.[29]

Experimental

Thermal Decomposition of Optically Active N-(1-Butyl-1-*d*)-N-nitrosoacetamide.[30]—To a 300-ml., three-necked flask equipped with stirrer, condenser and dropping funnel and containing 5.5 g. (0.075 mole) of optically active 1-aminobutane-1-*d*, $\alpha^{25}D$ −0.013 ± 0.004° (*l* 2),[10] was added 8.0 g. (0.133 mole) of acetic acid with cooling. The ice-bath was then removed and 75 ml. of acetic anhydride was added. The mixture was stirred at room temperature for 0.5 hour and was again chilled in an ice-bath. To the cold solution was added 10.0 g. (0.126 mole) of finely divided sodium nitrite in 5.0-g. portions. Additions were made 20 minutes apart. The mixture was cooled in the ice-bath for 3 hours following the addition of the sodium nitrite, and was then allowed to warm to room temperature with stirring during the next 12 hours. The reaction mixture was then poured into 300 ml. of ice and water. After stirring for several hours at room temperature until all of the acetic anhydride had hydrolyzed, the optically active nitrosoamide was extracted into two 50-ml. portions of cyclohexane. The combined cyclohexane extracts were washed with sodium hydroxide and water and were dried with sodium sulfate.

The cyclohexane solution containing the optically active nitrosoamide was transferred to a 250-ml. flask which was arranged for magnetic stirring and which contained 2.0 g. (0.048 mole) of calcium hydride. The reaction flask was fitted with a condenser carrying a drying tube and was immersed in a thermostat at 80 ± 1°. After heating for 24 hours the inorganic salts were filtered and the filtrate was distilled through a small glass spiral column. After removal of the cyclohexane, a 5.9-ml. fraction, b. 121–125°, was collected (59% yield). Redistillation of this fraction through the same column gave 3.5 ml. of deuterobutyl acetate, b. 124–125°, having $\alpha^{25}D$ +0.005 ± 0.004° (*l* 2) and d_4^{25} 0.8836.[31]

Infrared Analyses.—1-Butyl-1-*d* acetate has a single band in the C–D region at 4.55μ. 1-Butyl-1,1-d_2 acetate has a doublet at 4.48 and 4.63μ. The spectra were taken as the pure liquids in a 0.025-mm. cell against a salt plate as reference in a Baird double beam instrument. All of the spectra reported were taken under "routine" conditions; reproducibility was satisfactory. Under the same conditions the product of the nitrosoamide decomposition above had a rather broad band in the C–D region. The spectrum in this region using a 0.095-mm. cell showed a band centered at 4.54 μ with shoulders at 4.48 and 4.63μ. Three known mixtures were made up from *n*-butyl, 1-butyl-1-*d* and 1-butyl-1,1-d_2 acetates and the spectrum of each mixture was taken in both the 0.025-mm. and 0.095-mm. cells. The latter spectra in the C–D region resembled that of the reaction product and were used to analyze for the amounts of -d_1 and -d_2 acetates present. The amount of undeuterated acetate was then obtained by difference since it is blank in this region. The 8.4–9.0μ region of the former spectra provided an independent measure of the amount of -d_2 acetate present.

In Table I are given the compositions of the three mixtures and log I_0/I for the central peaks and the shoulders of the mixtures and the reaction product. For the range of compositions used the contributions of -d_1 and -d_2 to the 4.55 and 4.63μ bands were assumed to be linear. For each band, the absorbancies found and the known compositions were used in a least squares solution of three equations in the two unknowns: $\log I_0/I = aN_{d_1} + nN_{d_2}$, in which N_{d_1} is the mole fraction of 1-butyl-1-*d* acetate; N_{d_2} is the mole fraction of 1-butyl-1,1-d_2 acetate. The resulting equations (Table I) were used to calculate the absorbancies of each band for each mixture. The agreement to the observed values was generally excellent. From the equations and the absorbancies of the nitrosoamide product, the composition was calculated (Table I). The shoulder of the 4.48μ band was not resolved in mixture 1; the other mixtures were too close in -d_2 composition to allow a valid analysis based only on these points.

The spectra reproduced in Fig. 1 show that the three esters exhibit characteristic differences in the 8.4–9.0μ region. The nature of the data does not justify a complete analysis of the entire region, but the similarity of curves D and E demonstrates the essential similarity of the reaction product to a mixture such as mixture 3. The 8.6μ band in the -d_2 acetate does not appear significantly in the others and was used to estimate the amount present. Using the base line drawn from neighboring bands, log I_0/I was determined for each of the mixtures and for the reaction product. These absorbancies are roughly proportional to the mole per cent. of -d_2 ester present and gives an analysis of about 21% for the nitrosamide product.

The analyses are probably good to about ±5%; the average analysis is taken as 22% *n*-butyl acetate, 56%

1-butyl-1-*d* acetate and 22% 1-butyl-1,1-d_2 acetate for the nitrosoamide reaction product.

1-Butyl-1,1-d_2 acetate.—The preparation from 1-butanol-1,1-d_2[32] and acetyl chloride was similar to that described earlier.[32]

Thermal Decomposition of N-Butyl-N-nitrosoacetamide in the Presence of Deuteroacetic Acid.—N-Butyl-N-nitrosoacetamide was prepared from 14.6 g. (0.20 mole) of *n*-butylamine as described above. However, before hydrolyzing the acetic anhydride, the reaction mixture was divided into equal parts and each part was treated separately with ice and water. When hydrolysis was complete one fraction was extracted into cyclohexane and the other fraction was extracted into isopropyl ether.

The cyclohexane solution was dried with sodium sulfate and was transferred to a 250-ml. flask which was arranged for magnetic stirring. To the mixture was added 11.0 g. (0.180 mole) of acetic acid-*d*. The flask was fitted with a condenser and drying tube and was immersed in a thermostat at 75 ± 1°. Not all of the deuteroacetic acid dissolved immediately, but after about 2 hours of heating and stirring a homogeneous solution resulted. After heating for a total of 24 hours the reaction mixture was cooled to room temperature and was washed with sodium hydroxide and water. After drying with anhydrous sodium sulfate the mixture was distilled, collecting 8.0 g. of butyl acetate, b. 124–125°. The infrared spectrum showed the presence of a C–D band at 4.54μ, the intensity of which corresponded to the presence of about 0.26 deuterium atom per molecule.

The isopropyl ether solution prepared above was dried with anhydrous sodium sulfate. Eight grams (0.131 mole) of acetic acid-*d* was added and the mixture was decomposed as above for 30 hours at 67 ± 1°. Isolation of the product as above yielded 4.5 g. of butyl acetate, b. 124–125°, which showed the presence of a C–D band in the infrared spectrum corresponding to the presence of about 0.21 deuterium atom per molecule.

Thermal Decomposition of N-Butyl-N-nitrosoacetamide in Cyclohexane in the Presence of Sodium Benzoate and Calcium Hydride.—A solution of N-butyl-N-nitrosoacetamide in 225 ml. of cyclohexane was prepared from 14.6 g. (0.20 mole) of butylamine as described above. The solution was placed in a 500-ml. flask arranged for magnetic stirring and 4.0 g. (0.029 mole) of sodium benzoate and 2.8 g. (0.067 mole) of calcium hydride was added. The reaction flask was fitted with a condenser and drying tube and was immersed in a thermostat at 80 ± 1° for 24 hours. After cooling to room temperature the solids were removed by filtration. The filtrate was distilled and yielded, after the removal of the cyclohexane, 9.2 g. of butyl acetate (40% yield based on butylamine), b. 124–125°, and 2.0 g. of butyl benzoate (40% yield based on sodium benzoate), b. 238–245°.

Thermal Decomposition of a Mixture of N-Ethyl-N-nitrosopropionamide and N-Butyl-N-nitrosoacetamide.—Five milliliters of 70% ethylamine in water (0.075 mole) was converted to the nitrosoamide as described above with 10 ml. of propionic acid and 75 ml. of propionic anhydride. After the final hydrolysis the mixture was extracted twice with 50-ml. portions of *n*-hexyl ether.

To a solution of 8.6 g. (0.075 mole) of *n*-butylacetamide in 15 ml. of acetic acid and 75 ml. of acetic anhydride in an ice-bath was added 10 g. of sodium nitrite in two portions one-half hour apart. After stirring in the ice-bath for about 10 hours the mixture was allowed to warm slowly to room temperature with stirring. The mixture was poured into 300 ml. of ice and water and was stirred for 4 hours to hydrolyze the anhydride. The mixture was then extracted with two 50-ml. portions of hexyl ether.

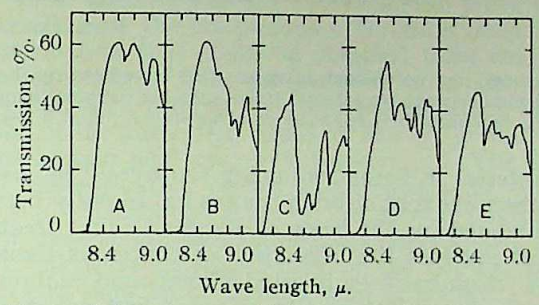

Fig. 1.—Infrared curves of butyl acetate (0.025-mm. cell): A, *n*-butyl acetate; B, 1-butyl-1-*d* acetate; C, 1-butyl-1,1-d_2 acetate; D, mixture 3; E, nitrosoamide reaction product.

The hexyl ether solutions of the two nitrosoamides were combined and were washed with water and with sodium bicarbonate. After drying with anhydrous sodium sulfate the mixture was placed in a constant temperature flask and was maintained at 80° (benzene was used as the refluxing heating bath) for 24 hours. After cooling, the mixture was washed with water and sodium bicarbonate and was dried with anhydrous sodium sulfate. The mixture was distilled until the boiling point rose to 200°. The distillate was redistilled through a spinning band column with intermittant take-off. The following fractions were taken in which the boiling points recorded are the temperatures of the thermometer at the time of take-off; 1, b. 76–81°, 2.3 ml. (ethyl acetate); 2, b. 97–102°, 2.2 ml. (ethyl acetate and ethyl propionate); 3, b. 114°, 0.3 ml.; 4, b. 121–127°, 2.2 ml. (butyl acetate and butyl propionate); 5, b. 132°, 0.3 ml.; 4, b. 142° 1.4 ml. (butyl propionate). The identifications were made by comparing the infrared spectra of the fractions with the infrared spectra of the authentic esters.

Control Stability of Esters in the Presence of Acid.—A mixture of 7.0 g. of butyl acetate (0.06 mole), 6.5 g. of ethyl propionate (0.064 mole), 0.9 g. of acetic acid (0.015 mole) and 1.1 g. of propionic acid (0.015 mole) in 200 ml. of hexyl ether was maintained for 24 hours at 80° using a constant temperature flask with benzene as the heating liquid. After cooling, the mixture was washed with water and with sodium bicarbonate and was dried with sodium sulfate. The mixture was distilled through a glass spiral column and the following fractions were collected, after redistillation of the intermediate cuts: 1, b. <96°, 0.3 ml.; 2, b. 98–103°, 7.2 ml.; 3, b. 106–120°, 1.7 ml.; 4, b. 122–128°, 5.6 ml.; 5, b. 141–170°, 1.4 ml. Fraction 1 contained no ethyl acetate and fraction 5 contained no butyl propionate (infrared). The yield of esters, b. 98–128°, is 95%.

Acknowledgment.—This research was supported in part by a grant from the Petroleum Research Fund of the American Chemical Society.

Azo Dyes Derived from *o*-Hydroxybenzeneboronic Acid Anhydride

BY HENRY GILMAN, LUDOVICO SANTUCCI, D. R. SWAYAMPATI AND R. O. RANCK

RECEIVED DECEMBER 26, 1956

Several new boron-containing azo dyes have been synthesized for testing in brain tumor therapy. Both ethylene chloride and nitrobenzene were found to be valuable recrystallizing solvents for this class of compounds. The infrared spectra of the compounds prepared show an absorption band at 9.1–9.2 μ which may be indicative of the carbon–boron bond.

Interest in boron-containing azo dyes[1,2] for use in the treatment of brain tumors has recently been stimulated by the work of Kruger.[3] This treatment involves the irradiation of cancerous tissue into which has been injected a compound containing the boron isotope 10.[4] Kruger[5] first proposed this type of therapy in 1940 and investigations along this same line have been carried out in the years following by a number of workers.[6–13] Borax was tested by Farr and co-workers,[12] and while this responded favorably to the irradiation treatment, it possessed several disadvantages, the most serious being the low differential uptake of the compound between normal and abnormal tissue,[13] the ratio being 1:2. This led to damage of a large amount of healthy tissue while the abnormal tissue was being destroyed.

Some non-boron containing dyes are absorbed preferentially by the cancerous tissue, and while many azo dyes are carcinogenic to the liver, their activity in this respect can be reduced, even to zero, by the introduction of certain groups such as the bromo, hydroxy, nitro and trifluoromethyl.[14] The azoboronic acids[1,2] which were tested by Kruger were also preferentially absorbed by the cancerous tissue, the differential uptake between the normal and abnormal tissue having a ratio of 1:100, thus indicating their superiority over borax in this respect. These encouraging results have demanded additional azoboron compounds as well as boron compounds in general for testing in the irradiation therapy of brain tumors.

In this most recent work, *o*-hydroxybenzeneboronic acid anhydride[15] was coupled with benzenediazonium chloride, *p*-bromobenzenediazonium chloride and the three nitrobenzenediazonium chloride isomers to give 2-hydroxy-5-(phenylazo)-benzeneboronic acid anhydride, 2-hydroxy-5-(*p*-bromophenylazo)-benzeneboronic acid anhydride and the three 2-hydroxy-5-(nitrophenylazo)-benzeneboronic acid anhydride isomers, respectively. Much lower yields of pure materials were obtained in these preparations than is usually experienced with dyes not containing the boronic acid or anhydride grouping. A 31% yield of pure 2-hydroxy-5-(phenylazo)-benzeneboronic acid anhydride was obtained while a 90% yield of its pure non-boron containing analog was prepared. In the case of the 2-hydroxy-5-(*p*-bromophenylazo)-benzeneboronic acid anhydride, a 20% yield of pure material was obtained while a 99% yield of the non-boron analog has been reported.[16] The three 2-hydroxy-5-(nitrophenylazo)-benzeneboronic acid anhydride isomers were all prepared in yields of less than 25%. Again the non-boron containing analogs can be prepared in much higher yields. For example, Elbs, *et al.*,[17] report a nearly quantitative yield of 4-(*o*-nitrophenylazo)-phenol. This much lower yield is partially explained by the deactivating effect of the boronic acid or anhydride group which certainly must be very pronounced in view of the electron deficiency of the boron atom. Decomposition during processing and purification perhaps also contribute to the lower yield.

Some improvement was noted in the yield and/or quality of the unpurified dye if the length of the coupling time was extended. Coupling times of 8 to 12 hr. were found to be noticeably superior to coupling times of 2 to 3 hr. For example, the melting point of the crude 2-hydroxy-5-(phenylazo)-benzeneboronic acid anhydride was increased 20 to 25° by use of this longer coupling time. There was no increase in the amount of crude material. The longer coupling time increased the amount of crude 2-hydroxy-5-(*p*-bromophenylazo)-benzeneboronic acid anhydride by 22% and raised the melting point by approximately 45°. Although this improvement probably carried through to the purified product, no such data were accumulated because of the difficulty involved in finding suitable purification procedures.

Recrystallization[18] of these dyes from an ethanol-water system, as was used by Snyder[1] for azoboronic acids derived from benzidine, failed to work satisfactorily. In most cases some purifica-

tion resulted as noted by an increase in the melting point over that of the crude. However, the lack of purity was well established by either the neutralization equivalent or quantitative boron analysis, or both, on the dyes in this series.

Dry ethylene chloride[19] was found to be a good recrystallizing solvent for the 2-hydroxy-5-(phenylazo)-benzeneboronic acid anhydride, the 2-hydroxy-5-(*p*-bromophenylazo)-benzeneboronic acid anhydride and the 2-hydroxy-5-(*o*-nitrophenylazo)-benzeneboronic acid anhydride. Even though none of these compounds was exceptionally soluble in the refluxing solvent, 1 g. to 1.5 g./liter, the material recrystallized readily and was far superior with respect to melting point and neutralization equivalent to material which could be obtained from any other solvent or solvent system including benzene, benzene–petroleum ether (b.p. 77–115°), acetone–water and chloroform–carbon tetrachloride.

Both the *m*- and *p*-isomers of 2-hydroxy-5-(nitrophenylazo)-benzeneboronic acid anhydride were purified successfully using nitrobenzene as the recrystallizing solvent. The high boiling point of this solvent makes it difficult to remove from the crystals, this being best accomplished by a washing with petroleum ether (b.p. 28–38°). This particular work was carried out before that done with ethylene chloride, and these particular compounds were never subjected to recrystallization from this solvent, although it is quite possible that the ethylene chloride would be quite adequate.

In studying the purification of these azoboronic acids, the possibility of using chromatographic techniques was investigated, most of the work being carried out on 2-hydroxy-5-(phenylazo)-benzeneboronic acid anhydride and a smaller amount on the 2-hydroxy-5-(*p*-bromophenylazo)-benzeneboronic acid anhydride, the 2-hydroxy-5-(*m*-nitrophenylazo)-benzeneboronic acid anhydride and the 2-hydroxy-5-(*p*-nitrophenylazo)-benzeneboronic acid anhydride. This method looked very promising in the early stages, but it was not possible to get material of a quality equal to that which could be obtained by recrystallization from either ethylene chloride or nitrobenzene. The best results were obtained using chloroform or a chloroform–carbon tetrachloride system as the solvent and eluent and a 1:2 mixture of Celite and silicic acid as the adsorbent.

Melting points have long been regarded as a criterion of purity for most organic compounds. However, this does not seem to hold true for azoboronic acids and in general for organoboronic acids.[15,20] Materials having the same neutralization equivalent may vary considerably in melting point. The rate of heating appears to be very important, much more so for this class of compounds than for the usual organic compound. Also, a wide difference in melting point is experienced depending on whether the sample is immersed initially in an unheated bath or in a previously heated bath. For example, partially purified 2-hydroxy-5-(*p*-bromophenylazo)-benzeneboronic acid anhydride had a melting point of 183–184° when the sample was placed in a previously heated bath and a melting point of 250–251° when the sample was immersed initially in the unheated bath.

In no instance was any effort made to prove the structure of the compounds other than from the information that could be obtained from the infrared spectra. This was believed to be adequate even though little is known about the exact position of the absorption bands for the azo group and the boronic acid anhydride substituent. The first of these possibly occurs at approximately 6.35–6.4 μ,[21,22] although none of the spectra obtained for these compounds showed any sharp absorption at this wave length. Many of the boronic acid spectra show an absorption band at 9.1–9.2 μ[20] as do these azoboronic acids. This may be indicative of the carbon–boron bond, although this has not been established definitely. The greatest use of the infrared was to determine positions of substitution on the aromatic rings as well as to prove the existence of the hydroxy, nitro and bromo groups whose absorption bands are well known. Actually, the method of preparation should establish the structure reasonably well, and the color should give some evidence for the existence of the azo group while the neutralization equivalent should verify the presence of a boronic acid or anhydride group.

Additional attempts were made to produce other boron-azo compounds, but it has not yet been possible to purify these to an acceptable degree. These compounds include those formed by coupling *o*-hydroxybenzeneboronic acid anhydride with diazotized sulfanilic and *p*-aminobenzoic acids and tetrazotized benzidine.

Experimental[23]

2-Hydroxy-5-(phenylazo)-benzeneboronic Acid Anhydride.—The diazotization of 18.6 g. (0.2 mole) of aniline was carried out according to German Dyestuff information.[24] The benzenediazonium chloride solution was then added over a period of 30 minutes to a stirred solution composed of 22 g. (0.55 mole) of sodium hydroxide, 24 g. (0.2 mole) of 2-hydroxybenzeneboronic acid anhydride and 200 ml. of water, cooled to 5° by means of an ice–salt-bath; 200 g. of ice was added to the reaction flask immediately before the addition was started. Agitation was continued for 11 hr. at 0–5° following completion of the addition. The reaction mass was then filtered, the filter cake was suspended in 2000 ml. of water at 40° and was acidified by the addition of 10% hydrochloric acid. After cooling to room temperature, the precipitated solid was removed by filtration and was dried in a vacuum oven at 45°; 45 g. (100%) of crude reddish-brown material having a melting point range of 178–188° was obtained. Acidification of the filtrate from the reaction mass gave less than 1 g. of additional crude material which was combined with the bulk of the crude.

(19) Eastman Kodak white label 1,2-dichloroethane distilled over phosphorus pentoxide was used for this purpose.

(23) All melting points are uncorrected. In taking the melting points, the sample generally was immersed in a previously unheated bath. However, when it was noted that the rate of heating affected the melting point appreciably, a previously heated bath was used. The neutralization equivalents were obtained by complexing the compound with D-mannitol in an ethanol–water system and titrating with standard sodium hydroxide using a Beckman model G *p*H meter to detect the end-point.

The crude material was washed with approximately 500 ml. of dry ethylene chloride. This removed a large portion of the impurities, the washed material now having a melting point range of 210–220°. This material was recrystallized three times from ethylene chloride to give 14 g. (31%) of bright yellow fibrous material melting at 236–238°. After each recrystallization the volume of the filtrate was reduced in order to recover the maximum amount of material. The infrared spectrum supported the expected structure.

Anal. Calcd. for $C_{12}H_9BN_2O_2$: B, 4.84; N, 12.51; neut. equiv., 224. Found: B, 5.08, 4.96; N, 12.63, 12.42; neut. equiv., 226, 227.

In an experiment where a 3-hr. coupling time was employed, the crude yield was 100% and the material had a melting point range of 150–185°. A 9-hr. coupling time gave a 94% yield of material isolated in two portions; the first had a melting point range of 170–180° and represents 21.3% of the yield while the second portion had a melting point range of 188–192° and represents 72.7% of the yield.

Chromatographic purification of this dye was studied to a reasonable extent without any outstanding success being attained. In one experiment, 2.25 g. of crude dye (m.p range 188–197°) was dissolved in 500 ml. of chloroform and was chromatographed on a column composed of 225 g. of a 1:2 mixture of Celite and silicic acid. The column was eluted with additional chloroform. Nine fractions were collected. Fractions 1 through 3 were semi-solids and represented 20% of the original weight. No melting point was obtained on this portion of the material. Fraction 4 which represented 11% of the original weight had a melting point range of 140–150°. Fractions 5 through 8 all had melting points higher than the crude, fraction 6 having the maximum range of 204–209°. This series represents 49% of the original weight. Fraction 9 was again a semi-solid, no melting point being obtained, and represents 4.5% of the original weight. Fraction 6 had a neutralization equivalent of 234 which indicates material of fair purity. The calculated value for the neutralization equivalent for the anhydride is 224.

The use of a 1:1 mixture of chloroform and carbon tetrachloride solution as the solvent and eluent was superior in one respect to chloroform alone in that sharper separations could be made but was inferior in another in that the solubility of the compound was less.

A 1:1 mixture of Celite and silicic acid showed no advantage while activated alumina was of no value whatsoever.

2-Hydroxy-5-(*p*-bromophenylazo)-benzeneboronic Acid Anhydride.—Eight and six-tenths grams (0.05 mole) of *p*-bromoaniline was diazotized according to the method of Gomberg and Bachmann.[25] This *p*-bromobenzenediazonium chloride solution was then added over a 10-minute period to a stirred solution composed of 5.5 g. (0.135 mole) of sodium hydroxide, 6.0 g. (0.05 mole) of 2-hydroxybenzeneboronic acid anhydride, 50 ml. of water and 50 g. of ice; and cooled in addition with an ice–salt-bath. Agitation was continued for 9 hr. following completion of the addition, the temperature being maintained at 0–5°. The reaction mixture was filtered, the filter cake was suspended in 500 ml. of water at 40° and was then acidified by the addition of 10% hydrochloric acid. The precipitated solid was removed by filtration after cooling to 20° and was dried at 45° in the vacuum oven. The dried material weighed 14.3 g., had a melting point range of 170–190° and represents a crude yield of 89%. Acidification of the filtrate from the reaction mass gave a small amount of additional, but worthless, material.

The brown crude material was washed with 200 ml. of dry ethylene chloride, a process which removed a large portion of the impurities, and the washed material was recrystallized three times from ethylene chloride to give 3 g. of bright yellow and rather fibrous material melting at 350–355°. This weight represents a 20% yield of pure material. After each recrystallization, the volume of the solvent was reduced in order to recover the maximum amount of material. The infrared spectrum supported the expected structure.

Anal. Calcd. for $C_{12}H_8BBrN_2O_2$: B, 3.57; Br, 26.38; neut. equiv., 302.9. Found: B, 3.95, 3.70; Br, 25.65, 25.44; neut. equiv., 308.

In an experiment where a 30-minute coupling time was employed, an 86% yield of crude material having a melting point range of 130–141° was obtained.

In the attempted chromatographic purification of this compound, 12 g. of crude (m.p. range 180–200°) was partially dissolved in 500 ml. of benzene and was poured on a column containing 450 g. of a 1:2 mixture of Celite and silicic acid. The purest material which could be obtained on elution with additional benzene had a melting point range of 210–220° which is far below that of the recrystallized material. Poorer separations were obtained when chloroform was substituted for benzene as the solvent and eluent. A mixture of chloroform and carbon tetrachloride (1:1) was superior to chloroform alone.

2-Hydroxy-5-(*o*-nitrophenylazo)-benzeneboronic Acid Anhydride.—Two and eight-tenths grams (0.02 mole) of *o*-nitroaniline was diazotized according to the method employed by Smith and Boyer.[26] The filtered *o*-nitrobenzenediazonium chloride solution was added to a stirred solution composed of 2.76 g. (0.023 mole) of 2-hydroxybenzeneboronic acid anhydride, 2.2 g. (0.055 mole) of sodium hydroxide and 25 ml. of water cooled to 0–5° by means of an ice–salt-bath. Agitation was continued for 2 hr. following completion of the addition, the temperature being maintained below 5°. The reaction mass was filtered after which the filter cake was suspended in 200 ml. of water and acidified by the addition of 10% hydrochloric acid. The product was filtered, washed and air-dried to give 4 g. of a brown product having a melting point range of 137–198°. This weight represents a 75% crude yield. Acidification of the filtrate from the reaction mixture gave a very small amount of even poorer quality material.

The crude material was recrystallized two times from benzene to give 1.3 g. of an orange colored solid melting at 213–214°. This weight represents a 24% yield of reasonably pure material. The infrared spectrum supported the structure.

Anal. Calcd. for $C_{12}H_8BN_3O_4$: N, 15.61; neut. equiv., 269. Found: N, 15.18, 15.24; neut. equiv., 290.[27]

After it was found that ethylene chloride was a good recrystallizing solvent for this type of compound, some of the benzene-recrystallized material, obtained in the experiment above, was also recrystallized from ethylene chloride. This gave orange colored material having a melting point of 236–238° and a neutralization equivalent closer to the anhydride than the material which was recrystallized from benzene.

Anal. Calcd. for $C_{12}H_8BN_3O_4$: B, 4.02; N, 15.61; neut. equiv., 269. Found: B, 4.46, 4.37; N, 15.15, 15.43; neut. equiv., 280.

In another experiment where an 8-hr. coupling time was used, a 78% yield of material having a melting point range of 150–180° was obtained. Recrystallization of this from ethylene chloride gave a 24% yield of material melting over the range of 230–235°. No chromatographic purification was attempted on this compound.

2-Hydroxy-5-(*m*-nitrophenylazo)-benzeneboronic Acid Anhydride.—To a stirred solution of 6.00 g. (0.05 mole) of *o*-hydroxybenzeneboronic acid anhydride and 10.0 g. (0.25 mole) of sodium hydroxide in 50 ml. of water, cooled to 0–5° in an ice–salt-bath, was added slowly a solution containing 6.9 g. (0.05 mole) of *m*-nitroaniline diazotized according to the method of Kaslow and Summers.[28] The alkaline reaction mixture (*p*H approximately 8) was stirred for 10 hr. at 0–5° and was then filtered. The orange filter cake was suspended in 500 ml. of water and was acidified by the addition of 10% hydrochloric acid. A 93% (12.37 g.) yield of material melting over the range of 168–180° was obtained. Acidification of the filtrate from the reaction mixture gave no appreciable amount of additional material.

The crude product was recrystallized twice from nitrobenzene, a Norit-A treatment being employed and care being taken not to heat the solution above 95°. Thorough washing of the recrystallized material with petroleum ether (b.p.

28–38°) was done in order to remove the nitrobenzene completely. A 20.5% (2.74 g.) yield of yellow material melting at 220–222° was obtained. The analytical sample was recrystallized a third time from nitrobenzene to give material melting at 221–222°. The infrared spectrum supported the expected structure.

Anal. Calcd. for $C_{12}H_8BN_3O_4$: C, 53.60; H, 3.00; N, 15.61; B, 4.02; neut. equiv., 269.06. Found: C, 53.73, 53.80; H, 3.27, 3.18; N, 15.39, 15.41; B, 4.00, 3.98; neut. equiv., 285.7.

In another experiment where the reaction mass was stirred at 0–5° for 8 hr., an 82.5% yield of crude material melting over the range of 144–170° was obtained. This gave a 17.5% yield of pure material.

For best results, the optimum *p*H was found to be about 8. Both sodium bicarbonate and sodium acetate were used as buffers in some experiments, but they did not seem to be particularly useful. Chromatographic purification was tried without any great success.

2-Hydroxy-5-(*p*-nitrophenylazo)-benzeneboronic Acid Anhydride.—To a stirred solution of 6.00 g. (0.05 mole) of *o*-hydroxybenzeneboronic acid anhydride and 10 g. (0.25 mole) of sodium hydroxide in 50 ml. of water, cooled in an ice–salt-bath to 0–5°, was added slowly a solution of 6.9 g. (0.05 mole) of *p*-nitroaniline diazotized according to the method of Ropp and Coyner.[29] The alkaline reaction mixture (*p*H approximately 8) was stirred at −10 to 0° for 6 hr. and was then filtered. The brick-red filter cake was suspended in 500 ml. of water, and this was acidified by the addition of 10% hydrochloric acid. A 70% (9.35 g.) yield of material melting over the range of 184–200° was obtained. Acidification of the filtrate from the reaction mixture gave an additional 0.51 g. (3.8%) of material having a melting point range of 205–225°. The combined crude materials could not be recrystallized directly from any solvent with much success. The crude was therefore extracted with a small amount of hot acetone and the residue was dissolved in 250 ml. of hot acetone. The insoluble portion was removed by filtration and the dye was reprecipitated from the filtrate by the addition of 900 ml. of warm water. The material, now having a melting point of 207–208°, was recrystallized from nitrobenzene using the procedure described above for the *m*-isomer; 1.4 g. (10.4%) of orange product melting sharply at 241.8–242° was obtained. The analytical sample was recrystallized one additional time from nitrobenzene to give material melting at 242–242.2°. The infrared spectrum supported the expected structure.

Anal. Calcd. for $C_{12}H_8BN_3O_4$: N, 15.61; B, 4.02; neut. equiv., 269.06. Found: N, 15.39, 15.16; B, 3.92, 4.22; neut. equiv., 290.1.

In another experiment an 84% yield of crude material was obtained when an 8-hr. coupling time at 0–5° was used. When the coupling time was increased to 10.5 hr., the amount of crude material did not change, but the product melted at 187° instead of over the range reported above. In this particular experiment 17% of the original *o*-hydroxybenzeneboronic acid anhydride was recovered. The pure yield was not determined exactly in these last two cases. The use of sodium bicarbonate as a buffer did not show any advantages. All of the couplings were run at a *p*H of 8. Chromatographic purification also was attempted on this compound, but it did not work very satisfactorily.

Acknowledgment.—We wish to thank Mr. Robert McCord and Mr. E. Miller Layton of the Ames Laboratory of the Atomic Energy Commission for the infrared spectra. We also wish to acknowledge the support of the Division of Biology and Medicine of the United States Atomic Energy Commission who have made this work possible. The results of the biological testing of these compounds will be reported by Dr. Otho D. Easterday of the Brookhaven National Laboratory.

Terpenoids. XXVII.[1] The Structure of the Cactus Triterpene Myrtillogenic Acid[2]

BY CARL DJERASSI AND H. G. MONSIMER[3]

RECEIVED JANUARY 9, 1957

Myrtillogenic acid has been shown to be 3β,16β,28-trihydroxy-Δ^{12}-oleanen-29-oic acid (Ia) by various degradation reactions and by conversion to longispinogenin triacetate (XIIb).

During an investigation[4] of the triterpene composition of the genus *Myrtillocactus*, there was isolated from several species in small amounts a new triterpene acid. Since this substance has not been encountered in any other genus of the cactus family, we have named it "myrtillogenic acid" and the present paper is concerned with its structure elucidation.

Myrtillogenic acid was separated from the other triterpenes as the methyl ester ($C_{31}H_{50}O_5$) and then saponified to the free acid ($C_{30}H_{48}O_5$). Mild acetylation with acetic anhydride–pyridine of either the ester or the acid led to the corresponding triacetate, thus accounting for all oxygen functions. The ease of acetylation suggested that the three hydroxyl groups were either equatorially oriented or that one or more were primary. Membership in the β-amyrin class of triterpenes was indicated[5] by the course of the selenium dioxide oxidation of triacetyl methyl myrtillogenate which furnished a $\Delta^{11,13(18)}$-diene (subsequently shown to be II) with the typical[6] triple ultraviolet absorption maxima at 240, 248 and 258 mμ.

All of the triterpene acids which have been encountered[1] so far among the *Cactaceae* contained the carboxyl group at C-17, but two different lines of evidence could be presented that this was not the case with myrtillogenic acid. Oleanolic acid (IIIa)

(5) That this is not an unambiguous criterion, as had been believed earlier, was demonstrated recently in the case of the cactus triterpene dumortierigenin (C. Djerassi, C. H. Robinson and D. B. Thomas, *ibid.*, **78**, 5085 (1956)) which belongs to the β-amyrin series but does not react to any appreciable extent with selenium dioxide. However, a positive reaction, as was observed with myrtillogenic acid, appears to be conclusive.

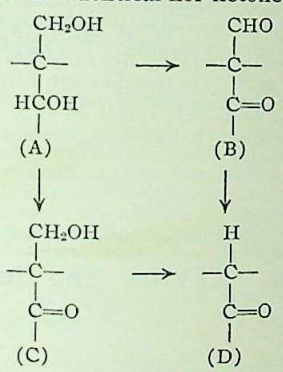
and related triterpenes are known to form bromolactones[7] and a 16β-acetoxy group does not interfere as shown by the facile formation of the bromolactone IV derived from cochalic acid (IIIc)[8] diacetate. Similar treatment of triacetyl myrtillogenic acid (subsequently shown to be Ic) led only to recovered starting material. Bromolactone formation requires the presence of a carboxyl group at C-17 as well as a double bond at 12–13, and since the presence of the latter was established by the course of the above-mentioned selenium dioxide oxidation as well as by allylic oxidation to an α,β-unsaturated 11-ketone (see Experimental), it was concluded that the carboxyl group of myrtillogenic acid was located elsewhere. Strong support for this supposition was provided by comparative saponification studies.

The methyl esters of oleanolic (IIIb), cochalic (IIId), desoxoglycyrrhetic (IIIf) and myrtillogenic (Ib) acids were refluxed for 8 hr. with 5, 7 and 10% methanolic potassium hydroxide and the extent of saponification determined quantitatively (see Table I, Experimental). The order of ease of saponification was found to be methyl myrtillogenate (Ib) > methyl desoxoglycyrrhetate (IIIf) > methyl cochalate (IIId) > methyl oleanolate (IIIb), the latter being recovered completely unchanged even after treatment with 10% alkali. The facility with which methyl myrtillogenate could be saponified—exceeding even the relatively unhindered methyl desoxoglycyrrhetate (IIIf)—definitely excluded any of the angular positions[9] as sites for the carboxyl group[10] thus leaving only C-4 and C-20 as possible points of attachment.[11]

Attention was next directed toward locating the three hydroxyl groups of myrtillogenic acid. Since the fifteen cactus triterpenes for which structures have been established[1] all possess a 3β-hydroxyl function, it was assumed that this also applied to myrtillogenic acid. The methyl ester did not react with lead tetraacetate nor did it form an acetonide, thus excluding a 1,2-glycol moiety as well as hydroxylation at C-23 or 24.[12] More precise information about the disposition of the hydroxyl groups could be adduced by oxidation experiments.

Oxidation of methyl myrtillogenate ($C_{31}H_{50}O_6$) with chromium trioxide in acetic acid–chloroform[13] led to a neutral substance ($C_{31}H_{44}O_5$), lacking hydroxyl absorption in the infrared, and mild treatment with base resulted in the loss of the elements of CO and the formation of a second neutral product ($C_{30}H_{44}O_4$). When the oxidation was carried out with chromium trioxide in pyridine solution,[14] there was isolated a new compound ($C_{31}H_{46}O_6$) which still exhibited infrared hydroxyl absorption. Treatment with base gave the above mentioned neutral product $C_{30}H_{44}O_4$, which did not show any high, selective ultraviolet absorption, did not give a color with ferric chloride but did possess a 3-keto group since its precursor exhibited a positive Zimmermann test comparable with that of β-amyrone.[15] These observations require the presence of a 1,3-glycol system of type A, chromium trioxide–acetic acid oxidation producing a keto-aldehyde B while chromium trioxide–pyridine apparently did not attack the primary hydroxyl function and led to a keto-alcohol C. Base treatment of B (reverse Claisen condensation)[16] or C (retro-aldol condensation)[17] then furnished the identical nor-ketone D.



With this information at hand it is possible by a process of elimination to reduce the structural alternatives for myrtillogenic acid to two (I or VI). The 1–3 glycol system A cannot involve C-3 since acetonide formation[12] should have been feasible. Furthermore, partial saponification of triacetyl methyl myrtillogenate (Id) under conditions where a 3β-acetoxy group is not attacked[18] gave a 3-monoacetate Ie which was oxidized with chromium trioxide–pyridine[14] to a ketone still showing a hydroxyl band in the infrared. This oxidation product is assigned structure VII since it gave a negative Zimmermann reaction[15] (absence of 3-keto function), exhibited a

(7) See E. J. Corey and J. J. Ursprung, THIS JOURNAL, **78**, 183 (1956), and earlier literature.

(8) C. Djerassi, G. H. Thomas and H. Monsimer, *ibid.*, **77**, 3579 (1955).

(9) Position 27 was eliminated at an early stage since myrtillogenic acid does not suffer decarboxylation upon melting as would be expected from a β,γ-unsaturated acid (*e.g.*, quinovic acid—H. Wieland and M. Erlenbach, *Ann.*, **453**, 83 (1927)).

(10) Suitably situated hydroxyl groups can have an activating effect (Table I—methyl oleanolate (IIIb) *vs.* methyl cochalate (IIId)) but only a carbonyl group (known to be absent in myrtillogenic acid) γ to the carboxyl group will produce a striking effect (*cf.* C. Djerassi and A. E. Lippman, THIS JOURNAL, **77**, 1825 (1955)).

(11) Since adjacent hydroxyl groups can have an effect upon the rate of saponification (ref. 10) and since the location of the hydroxyl substituents in myrtillogenic acid has not yet been discussed, both orientations (29 and 30) at C-20 should be considered. On the other hand, it is known that an axial (β) carboxyl group (24) at C-4 is extremely hindered (*e.g.*, β-boswellic acid—P. Bilham, G. A. R. Kon and W. C. J. Ross, *J. Chem. Soc.*, 35 (1942); J. L. Beton, T. G. Halsall and E. R. H. Jones, *ibid.*, 2904 (1956)), so that here only an equatorial substituent would be compatible with the experimental facts.

(12) A 3β,23-diol (W. Jacobs, *J. Biol. Chem.*, **63**, 631 (1925)) or a 3β,24-diol (J. L. Beton, T. G. Halsall and E. R. H. Jones, *J. Chem. Soc.*, 2904 (1956)) is known to form an acetonide, but 1,3-glycols in other locations are not necessarily excluded. For instance, longispinogenin (XIIa) does not condense with acetone under standard conditions (L. E. Geller, M.S. Thesis, Wayne University, 1954; P. R. Leeming, unpublished observation).

(14) G. I. Poos, G. E. Arth, R. E. Beyler and L. H. Sarett, THIS JOURNAL, **75**, 422 (1953).

(15) We are greatly indebted to Drs. W. Klyne and P. M. Jones (Postgraduate Medical School, London) for carrying out the color reactions by the spectrophotometric procedure of I. E. Broadbent and W. Klyne, *Biochem. J.*, **56**, XXX (1954).

(16) Formyl ketones are very sensitive to base and lose formate under mild conditions (for pertinent examples see A. L. Wilds and C. Djerassi THIS JOURNAL, **68**, 1715 (1946)).

(17) A typical example is represented by icterogenin (D. H. R. Barton and P. de Mayo, *J. Chem. Soc.*, 887 (1954)).

rotatory dispersion curve suggestive of a 16-keto triterpene[19] and upon Wolff–Kishner reduction produced an acid VIIIa, further characterized as a methyl ester VIIIb, in which two of the oxygen functions had been lost. These missing oxygen atoms must have been derived almost certainly from a 1,3-glycol A *via* C followed by retro-aldolization and Wolff–Kishner reduction and cannot have involved C-3, which was protected (up to the Wolff–Kishner stage) by acetylation.

The 1,3-glycol system A cannot be located at C-1 and C-25 since the resulting keto-aldehyde B and keto-alcohol C would have to be represented by IXa and IXb. Base treatment would not only have resulted in expulsion of the angular substituent but the nor-ketone D, still possessing a 1,3-diketone moiety (IXc), would itself have been labile to base; furthermore its structure would not have been consistent with the spectroscopic properties of the product. Positions 7 and 26 were not considered seriously as sites for the glycol system A since no naturally occurring triterpenes are known which are oxygenated at those carbon atoms.[20] Finally C-15 and C-27 could be excluded since the oxidation products (B and C) would have to be represented by X (a and b) and base treatment would have led to an α,β-unsaturated nor-ketone XI, while the actual product did not show any infrared or ultraviolet maxima corresponding to such a chromophore.

The above analysis indicated that the primary alcohol of the 1,3-glycol would have to be attached at C-17 or C-20. However, the latter (on the basis

(19) The use of rotatory dispersion curves for locating carbonyl groups in triterpenoids will be reported in a future paper.

(20) It was appreciated that rigorous elimination of this alternative would have to be based on an experimental connection with a known triterpene and this was eventually accomplished by conversion to longispinogenin (XIIa).

Digitized by Arya Samaj Foundation Chennai and eGangotri

of the earlier mentioned saponification studies) was one of the only two possible sites for the carboxyl group of myrtillogenic acid and if the primary hydroxyl function were in fact located in ring E, then the carboxyl group would have to be equatorially attached to C-4. An experimental test was now available in the pyridine–chromium trioxide oxidation product (now known to be Vb) of methyl myrtillogenate. As pointed out above, this substance had to possess a 3-keto function (positive Zimmermann test in contrast to VII), and if the carbomethoxyl group were attached to C-4, the substance would have to be a β-keto ester. Alkaline saponification followed by acidification yielded a crude acid which did not decarboxylate thus eliminating C-4 from further consideration and consequently requiring that the carboxyl group be situated at C-20. This in turn implied that the primary alcohol function of the 1,3-glycol moiety of myrtillogenic acid was at C-28, from which it follows that myrtillogenic acid itself should be expressed by structures Ia or VI.

In order to distinguish between these two structural alternatives, triacetylmyrtillogenic acid was converted to the acid chloride and subjected to Rosenmund reduction. The product was difficult to purify, but Wolff–Kishner reduction followed by acetylation furnished longispinogenin triacetate (XIIb)[21] thus locating unambiguously the three hydroxyl groups of myrtillogenic acid. In view of the fact that methyl myrtillogenate is saponified more readily than methyl desoxoglycyrrhetate (IIIf)[22] and since it is doubtful that the C-28 hydroxyl group could exert an activating effect upon the ester function, the latter is assigned the equatorial (α) orientation. Myrtillogenic acid (Ia) can now be given the systematic name 3β,16β,28-trihydroxy-Δ^{12}-oleanen-29-oic acid and represents the first naturally occurring triterpene which is oxygenated at C-29. It has already been pointed out earlier[1] that except for the usual 3β-hydroxyl function, oxygenation among cactus triterpenes has so far been found only in rings D and E. It is interesting to note that myrtillogenic acid falls into that same pattern which may eventually prove to be of some biogenetic significance.

Experimental[23]

Myrtillogenic Acid and Derivatives.—Crude methyl myrtillogenate (Ib), obtained by chromatography of the methylated acidic fraction of various *Myrtillocactus* species,[4] was recrystallized several times from methanol–acetone to yield an analytical sample, m.p. 249–250°,[24] $[\alpha]_D$ +85° (*c* 2.14), λ_{max}^{KBr} 3.0 and 5.79 μ.

Anal. Calcd. for $C_{31}H_{50}O_5$: C, 74.06; H, 10.03. Found: C, 73.81; H, 10.21.

Triacetyl methyl myrtillogenate (Id) was obtained by acetylation of Ib with acetic anhydride–pyridine at room temperature overnight. The analytical sample was purified by chromatography followed by recrystallization from methanol; m.p. 146.5–148°, $[\alpha]_D$ +77° (*c* 0.75); $\lambda_{max}^{CHCl_3}$ 5.78, 5.81 (inflect.) and 8.0 μ.

Anal. Calcd. for $C_{37}H_{56}O_8$: C, 70.67; H, 8.98; acetyl, 20.27. Found: C, 70.88; H, 9.09; acetyl, 20.57.

Myrtillogenic acid (Ia) was obtained by saponification of its methyl ester with 10% methanolic potassium hydroxide (see Table I) and was recrystallized several times from acetone and then from methanol; m.p. 288–293°, $[\alpha]_D$ +84° (*c* 0.74 in methanol).

Anal. Calcd. for $C_{30}H_{48}O_5$: C, 73.73; H, 9.90. Found: C, 73.69; H, 9.91.

Acetylation of the acid Ia with acetic anhydride–pyridine and recrystallization from methanol furnished an analytical sample of **myrtillogenic acid triacetate** (Ic), m.p. 259–263°, $[\alpha]_D$ +65° (*c* 1.03).

Anal. Calcd. for $C_{36}H_{54}O_8$: C, 70.33; H, 8.85; O, 20.81. Found: C, 70.47; H, 9.20; O, 20.42.

TABLE I

RATES OF SAPONIFICATION OF TRITERPENE METHYL ESTERS[a]

Methyl ester \ Concn. of MeOH–KOH	5%	7%	10%
	Yield of acid %		
Oleanolate (IIIb)	0	0	0
Cochalate (IIId)	0	3	20
Desoxoglycyrrhetate (IIIf)	5	17(13)[b]	47(40)[b]
Myrtillogenate (Ib)	11	31	85(93)[b]

[a] A 100-mg. sample of the methyl ester was heated under reflux for 8 hr. in 5, 7 or 10% methanolic potassium hydroxide solution, much water was added and the unreacted ester was extracted with ether. The aqueous solution was acidified, extracted with ether, washed, dried and evaporated. Both ester and acid fractions were weighed. [b] Duplicate determination.

Selenium Dioxide Oxidation of Triacetyl Methyl Myrtillogenate (Id).—A solution of 125 mg. of triacetyl methyl myrtillogenate and 125 mg. of selenium dioxide in 10 cc. of glacial acetic acid was heated under reflux for 6 hr., diluted with water and extracted with ether. The residue from the washed and dried ether solution was chromatographed on alumina and recrystallized from methanol to furnish 76 mg. of methyl 3β,16β,28-triacetoxy-$\Delta^{11,13(18)}$-oleadien-29-oate (II), m.p. 178–180°; λ_{max}^{EtOH} 240, 248, and 258 mμ; log ϵ 4.38, 4.42 and 4.23.

Anal. Calcd. for $C_{37}H_{54}O_8$: C, 70.90; H, 8.68. Found: C, 71.07; H, 8.71.

Methyl 3β,16β,28-Triacetoxy-Δ^{12}-oleanen-11-one-29-oate.[25]—To a boiling solution of 200 mg. of triacetyl methyl myrtillogenate (Id) in 2 cc. of glacial acetic acid was added 208 mg. of chromium trioxide in 2 cc. of 90% acetic acid over a period of 30 minutes. After heating for an additional hour, the mixture was allowed to stand overnight and then diluted with water. The product was extracted with ether and recrystallized from methanol whereupon it showed a double m.p. at 159–163° and 190–192°. Chromatography and recrystallization gave material which partially melted near 150°, resolidified and melted at 192–195°, λ_{max}^{EtOH} 245 mμ, log ϵ 4.13.

Anal. Calcd. for $C_{37}H_{54}O_9$: C, 69.13; H, 8.47. Found: C, 68.58; H, 8.59.

Chromium Trioxide Oxidation of Methyl Myrtillogenate (Ib). (a) **With Chromium Trioxide–Acetic Acid–Chloroform.**[13]—To an ice-cooled solution of 250 mg. of methyl myrtillogenate (Ib) in 100 cc. of acetic acid and 10 cc. of chloroform was added over a period of 10 min. 565 mg. of chromium trioxide dissolved in 5 cc. of water and 15 cc. of acetic acid. After 75 min. at room temperature, the excess reagent was destroyed with methanol, water was added and the product was extracted with ether. The ether solution was washed with 5% potassium hydroxide, water, dried and evaporated to afford 240 mg. of semi-solid which crystal-

ized upon trituration with methanol (m.p. 150–200°). Chromatography on Merck acid-washed alumina and recrystallization from methanol afforded 69 mg. of methyl Δ^{12}-oleanen-3,16-dione-28-al-29-oate (Va), m.p. 202–204°, $\lambda_{max}^{CHCl_3}$ 5.79 and 5.86 μ but no free hydroxyl band.

Anal. Calcd. for $C_{31}H_{44}O_5$: C, 74.96; H, 8.93. Found: C, 74.86; H, 9.14.

(b) With Chromium Trioxide–Pyridine.[14]—A solution of 150 mg. of methyl myrtillogenate and 180 mg. of chromium trioxide in 18 cc. of pyridine was allowed to stand at room temperature overnight. After adding much water, the material was extracted with ether, washed well with dilute hydrochloric acid, dried, evaporated and triturated with hexane to give 140 mg. of crystals, m.p. 175–190°. Several recrystallizations from methanol led to the analytical sample of methyl Δ^{12}-oleanen-3,16-dione-28-ol-29-oate (Vb), m.p. 189–192°, $[\alpha]_D$ +47° (*c* 0.32); $\lambda_{max}^{CHCl_3}$ 2.95,[26] 5.80 and 5.87 μ. The rotatory dispersion curve[19] was very similar to that of methyl diketoechinocystate and the Zimmermann reaction over the range 300–700 mμ closely resembled that of β-amyrone.[15]

Anal. Calcd. for $C_{31}H_{46}O_5$: C, 74.66; H, 9.30. Found: C, 74.96; H, 8.90.

When 110 mg. of the oxidation product Vb was heated under reflux for 1 hr. with 25 cc. of 1% methanolic potassium hydroxide and extracted with ether, there was obtained 100 mg. of an oil. Chromatography and elution with benzene gave 90 mg. of solid, m.p. 175–190°, raised after several recrystallizations from methanol to m.p. 203–205°, $[\alpha]_D$ −25° (*c* 0.25), $\lambda_{max}^{CHCl_3}$ 5.78 and 5.83 μ, no strong ultraviolet absorption, negative ferric chloride reaction. The identical substance (mixture melting point and infrared comparison) was obtained when the oxidation product of procedure (a) was heated with 5% methanolic potassium hydroxide solution for 4 hr.

Anal. Calcd. for $C_{30}H_{44}O_4$: C, 76.88; H, 9.46; O, 13.66. Found: C, 77.18; H, 9.70; O, 13.13.

When the oxidation product Vb was heated under reflux for 12 hr. with 10% methanolic potassium hydroxide solution, ether extraction did not remove any material. Acidification followed by ether extraction yielded in nearly quantitative yield an acidic oil which resisted all attempts at crystallization. As pointed out in the discussion, the isolation of an acid eliminates a β-keto ester formulation for Vb and *ipso facto* C-4 as the point of attachment of the carboxyl group of myrtillogenic acid.

Partial Saponification of Triacetyl Methyl Myrtillogenate (Id).—The triacetate (100 mg.) in 34 cc. of methanol was heated for 40 minutes with 2.6 cc. of a solution of 6.3 g. of potassium carbonate in 90 cc. of 1:1 dioxane–water,[18] about 15 cc. of methanol being distilled off during that time. The crude, ether-extracted product was chromatographed on 5 g. of Merck acid-washed alumina. Benzene removed 20 mg. of unreacted triacetate while 1:1 ether–chloroform yielded 56 mg. of the desired **methyl myrtillogenate 3-monoacetate (Ie)**, m.p. 274–280°. Further elution with chloroform–methanol (9:1) furnished 10 mg. of methyl myrtillogenate (Ib). The analytical sample of the monoacetate was obtained from methanol, m.p. 300–302°, $[\alpha]_D$ +77° (*c* 0.90); $\lambda_{max}^{CHCl_3}$ 2.90, 5.78 and 8.00 μ.

Anal. Calcd. for $C_{32}H_{52}O_6$: C, 72.75; H, 9.62; O, 17.63. Found: C, 72.76; H, 9.56; O, 18.01.

Chromium Trioxide–Pyridine Oxidation of Methyl Myrtillogenate 3-Monoacetate (Ie).—The oxidation was carried out exactly as described above for methyl myrtillogenate (Ib) and the crude product (m.p. 225–230°) upon recrystallization from chloroform–methanol yielded the analytical sample of **methyl Δ^{12}-oleanen-3β,28-diol-16-one-29-oate 3-acetate (VII)**, m.p. 237–239°, $[\alpha]_D$ +7° (*c* 0.53), negative Zimmermann reaction,[15] no high selective ultraviolet absorption; λ_{max}^{KBr} 2.90, 5.79, 5.84 and 8.00 μ. The rotatory dispersion curve[19] was very similar to that of methyl 16-keto-oleanolate.

Anal. Calcd. for $C_{33}H_{50}O_6$: C, 73.03; H, 9.29; O, 17.69. Found: C, 72.72; H, 9.54; O, 17.74.

Wolff–Kishner reduction of 114 mg. of VII by the Huang-Minlon modification[27] using hydrazine hydrate, ethylene glycol and potassium hydroxide gave 82 mg. of crude acid (m.p. 230–240°) which melted at 280–284° after two recrystallizations from methanol; it is most likely **3β-hydroxy-28-nor-Δ^{12}-oleanen-29-oic acid (VIIIa)**.

Anal. Calcd. for $C_{29}H_{46}O_3$: C, 78.68; H, 10.47. Found: C, 78.76; H, 10.78.

The mother liquors from the above recrystallizations were methylated with diazomethane and the resulting **methyl ester VIIIb** was recrystallized from methanol; m.p. 191–193°, $[\alpha]_D$ +60° (*c* 1.37), $\lambda_{max}^{CHCl_3}$ 2.8 and 5.77 μ. The analysis was not satisfactory, but insufficient material was available for a repetition.

Anal. Calcd. for $C_{30}H_{48}O_3$: C, 78.89; H, 10.59. Found: C, 78.07; H, 11.07.

Conversion of Triacetylmyrtillogenic Acid (Ic) to Longispinogenin Triacetate (XIIb).—Triacetylmyrtillogenic acid (750 mg.) was converted into the acid chloride by heating under reflux for 45 min. with 2 cc. of thionyl chloride. Benzene was added and all volatile material removed *in vacuo* on the steam-bath.

The crude acid chloride, dissolved in 30 cc. of xylene, was stirred at 120° with 0.8 g. of palladium–barium sulfate catalyst and 0.1 cc. of sulfur–quinoline poison, and hydrogen gas was bubbled for 3 hr. through the solution. The crude product, obtained by filtration, washing with dilute sodium hydroxide, water, drying and evaporation was chromatographed on 20 g. of alumina. Benzene elution afforded 500 mg. of solid (m.p. 188–194°), the melting point range of which could not be sharpened even after repeated crystallization from methanol.

A 350-mg. sample of the Rosenmund reduction product was subjected to Wolff–Kishner reduction[27] with 30 cc. of ethylene glycol, 1.5 cc. of hydrazine hydrate and 1.5 g. of potassium hydroxide. The total product was acetylated with acetic anhydride–pyridine and chromatographed on 10 g. of Merck acid-washed alumina. Elution with benzene and recrystallization from methanol yielded 110 mg. of **longispinogenin triacetate**, m.p. 220–222°, $[\alpha]_D$ +68° (*c* 0.64), which was shown to be identical with an authentic sample[21] by mixture melting point determination and infrared spectral comparison (Nujol mull).

Miscellaneous Experiments with Myrtillogenic Acid.—Methyl myrtillogenate was recovered in nearly quantitative yield when subjected to acetonide formation conditions[12] (acetone–hydrochloric acid or acetone–sulfuric acid). Triacetylmyrtillogenic acid was recovered unchanged under conditions where diacetylcochalic acid formed a bromolactone.

Diacetylcochalic Acid Bromolactone (IV).—A methylene chloride solution of 107 mg. of diacetylcochalic acid[8] was treated dropwise with 0.013 cc. of bromine in 1 cc. of methylene chloride, decolorization occurring immediately. Removal of the solvent and crystallization of the solid from methanol–methylene chloride gave 95 mg. of the desired bromolactone IV, m.p. 296–298°, $[\alpha]_D$ +60° (*c* 1.12); $\lambda_{max}^{CHCl_3}$ 5.61, 5.78 and 8.00 μ.

Anal. Calcd. for $C_{34}H_{51}BrO_6$: C, 64.24; H, 8.09; Br, 12.57; O, 15.10. Found: C, 63.70; H, 8.08; Br, 12.95; O, 15.41.

DETROIT, MICHIGAN

(26) The presence of a hydroxyl group was confirmed further by acetylation with acetic anhydride–pyridine. The resulting oil could not be crystallized but its infrared spectrum now lacked absorption in the 3 μ region and showed an intense band at 8.0 μ, not present in the starting material.

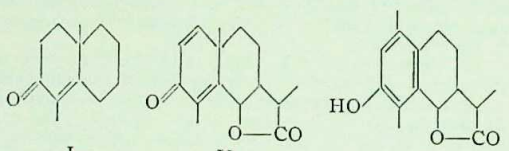
Synthesis of 4-Methylated Steroids[1]

BY FRANZ SONDHEIMER AND YEHUDA MAZUR

RECEIVED DECEMBER 18, 1956

Two methods of synthesis of 4-methyl-Δ^4-cholesten-3-one (Xa) are described. The first involves the reaction of the enol lactone VIa with ethylmagnesium bromide, followed by treatment with base. The second, which proceeds only in poor yield, involves the direct monomethylation of Δ^4-cholesten-3-one (IVa). The first method is applied to the synthesis of 4-methyltestosterone (Xb) and 4-methylprogesterone (Xd). 4-Methyltestosterone acetate (Xc) is dehydrogenated with selenium dioxide to 4-methyl-1-dehydrotestosterone acetate (XIc), which on dienone–phenol rearrangement and saponification produces 1,4-dimethylestradiol (XIIb). This rearrangement is an exact parallel in the steroid series to the santonin–desmotroposantonin rearrangement.

The possibility that a substance isolated in these laboratories from grapefruit oil was a 4-methylated steroid first aroused our interest in this class of compound. Such substituted steroids, in particular the 4-methyl-Δ^4-3-ketones (type X), were unknown, although in the bicyclic series the analogous 3-keto-4,9-dimethyl-Δ^4-octahydronaphthalene (I)[2] and substituted derivatives are well known. Thus, the sesquiterpenes α-cyperone[3a] and carissone[3b] contain the system I, and other derivatives have been



I II III

described in connection with studies related to the synthesis of santonin (II).[4] 4-Methylated steroidal Δ^4-3-ketones have furthermore become of considerable interest recently in view of the announcement that certain steroidal Δ^4-3-ketones methylated at the C-2 position possess higher biological activities than the unmethylated hormones.[5]

The preparation of a 4-methyl-Δ^4-3-ketone was first investigated in the cholesterol series. Two successful routes were found, both proceeding from Δ^4-cholesten-3-one (IVa) itself. The first utilized the enol lactone VIa, readily prepared from IVa through ozonolysis to the keto-acid Va, followed by heating with sodium acetate and acetic anhydride.[6] It is known that the enol lactone on reaction with methylmagnesium iodide, followed by base cyclization of the product, regenerates Δ^4-cholesten-3-one in high yield.[7] The analogous treatment of VIa with ethylmagnesium bromide when carried out with one equivalent at room temperature or below (conditions which have been used with the methyl Grignard reagent[6b,7a,8]) was unsatisfactory. However, when an excess of ethylmagnesium bromide was used in refluxing ether–benzene, the required 4-methyl-Δ^4-cholesten-3-one (Xa) was obtained in 65% yield after base cyclization.[9] The structure of Xa was confirmed by the infrared spectrum which indicated the presence of an α,β-unsaturated ketone and especially by the ultraviolet spectrum. The latter (λ_{max} 251 mμ, log ϵ 4.18) is in good agreement with the value (λ_{max} 252 mμ) to be expected of an α,β,β-trisubstituted α,β-unsaturated ketone with one exocyclic double bond.[10] Other substances containing the same chromophoric system as Xa have been shown to exhibit similar absorption (λ_{max} 248–251 mμ, log ϵ 4.13–4.21).[2,3,4,6b]

The substance produced by the reaction of Δ^4-cholesten-3-one with the ethyl Grignard reagent, which on base treatment furnishes the 4-methyl-Δ^4-3-ketone Xa, is presumably the unsaturated hemiketal VIIa or the corresponding diketone (*cf.* ref. 7b). No attempt at isolation of this intermediate was made in view of the known lability of the corresponding methyl compound.[7b] However, two further substances were produced by the Grignard reaction and could be isolated after the base treatment. The more polar of the two was a comparatively high melting substance, saturated to tetranitromethane, exhibiting an associated hydroxyl band at 3.08 μ, but no carbonyl bands in the infrared. The empirical formula appeared to be $C_{59}H_{54}O_2$, and we believe this compound to be the hemiketal VIIIa derived from VIa by reaction with two equivalents of the Grignard reagent. It has previously been reported[6b] that enol lactones of type VI on reaction with methylmagnesium iodide may yield a polar high-melting "over-reacted" product which very probably has a structure analogous to VIII. The other substance obtained from VIa and ethylmagnesium bromide was less polar than the 4-methyl-Δ^4-3-ketone Xa, was unsaturated to tetranitromethane and in the infrared showed no hydroxyl band but a medium intensity band at 5.98 μ. The empirical formula was $C_{30}H_{52}O$ and all these observations are consistent with the enol

ether structure IX, the dehydration product of VIII.[11]

The other route to 4-methyl-Δ^4-cholesten-3-one involves the direct methylation of Δ^4-cholesten-3-one by means of methyl iodide and *t*-potassium butoxide in *t*-butyl alcohol. This reaction, when carried out with 3 molar equivalents of the potassium alkoxide, is known to produce 4,4-dimethyl-Δ^5-cholesten-3-one in over 60% yield.[12] The process presumably proceeds *via* the desired monomethylation product Xa, but the latter can only be formed in high yield by the monomethylation of IVa if this reaction takes place appreciably faster than the further methylation of Xa to the 4,4-dimethyl-Δ^5-compound. Unfortunately no indication of the first step occurring faster than the second could be found, as evidenced by the fact that the dimethylation of Δ^4-3-ketones can be brought about by means of methyl iodide and potassium *t*-butoxide in *t*-butyl alcohol even at room temperature[13] and that the further methylation of the 4-methyl-Δ^4-3-ketone Xa (obtained by the route described above) to the corresponding 4,4-dimethyl-Δ^5-3-ketone occurs very readily (see Experimental). Nevertheless the monomethylation of Δ^4-cholesten-3-one was studied under different conditions. It was found that when conditions were used so that unchanged ketone remained, already much of the dimethyl ketone was formed. However, the presence of the monomethyl ketone Xa could be detected by ultraviolet spectroscopy, and under suitable conditions this compound could be isolated in about 5% yield. Although this constitutes a one-step synthesis of Xa, the first-mentioned route is to be preferred in view of the much higher yield and ease of isolation of the product.

Methods for producing 4-methyl-Δ^4-3-ketones having been worked out in the cholesterol series, we applied the preferred one for making available the 4-methylated hormones in the testosterone, esterone and progesterone series. The enol lactone VIc readily obtained by ozonolysis of testosterone or of its acetate and treatment of the resulting keto acid with acetic anhydride and sodium acetate,[7a,14] was allowed to react with excesss ethylmagnesium bromide. Base treatment of the product then furnished 4-methyltestosterone (Xb) in *ca.* 25% yield,[15] and 40% of the keto-acid Vb could be recovered. 4-Methyltestosterone (Xb), as well as the corresponding 17-acetate (Xc), showed the expected maximum in the ultraviolet at 251 mμ.

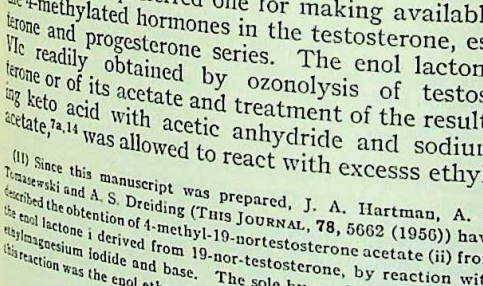
It has been shown that steroidal Δ^4-3-ketones may be dehydrogenated to the corresponding $\Delta^{1,4}$-dien-3-ones by means of selenium dioxide,[16] preferably in a tertiary alcohol containing some acetic acid.[17] We have found that 4-methyl-Δ^4-3-ketones may similarly be dehydrogenated, for 4-methyltestosterone (Xb) under these conditions produced 4-methyl-1-dehydrotestosterone (4-methyl-$\Delta^{1,4}$-androstadien-17β-ol-3-one) (XIb). Similarly, 4-methyltestosterone acetate (Xc) gave the acetate XIc.[18] Both XIb and XIc showed ultraviolet maxima at 244 mμ (log ϵ 4.16), in good agreement with the spectra of the various stereoisomers of santonin (II) (λ_{max} 242–246 mμ, log ϵ 4.01–4.27),[4] which contain the identical chromophoric system. The infrared spectra showed the doublets at 6.17 and 6.23 μ in the double bond region, typical of $\Delta^{1,4}$-dien-3-ones.[19]

In addition to the expected dienones, the selenium dioxide dehydrogenation of Xb and Xc produced selenium-containing substances (*cf.* ref. 17a), which are now being investigated.

The various stereoisomers of santonin (II) on treatment with acids[4,20] (most conveniently with acetic anhydride–sulfuric acid and subsequent saponification[21]) yield the desmotroposantonins (III), this reaction being the classical example of the so-called dienone–phenol rearrangement. The exact parallel in the steroid series was realized when 4-methyl-1-dehydrotestosterone acetate (XIc) was treated with *p*-toluenesulfonic acid in acetic anhydride and the product was saponified, thereby producing 1,4-dimethylestradiol (XIIb). The structure of this substance was confirmed by its ultraviolet spectrum (λ_{max} 288 mμ, log ϵ 3.23), very similar to that of the desmotroposantonins (λ_{max} 290 mμ, log ϵ 3.33–3.46)[4] and exhibiting the expected bathochromic shift compared to estradiol (λ_{max} 280 mμ, log ϵ 3.30)[22] and 1-methylestradiol (λ_{max} 284 mμ, log ϵ 3.28).[22]

In the progesterone series, the keto-acid Vd obtained by the ozonolysis of progesterone was converted to the enol lactone enol acetate VIe (stereo-

(11) Since this manuscript was prepared, J. A. Hartman, A. J. Tomaszewski and A. S. Dreiding (THIS JOURNAL, **78**, 5662 (1956)) have described the obtention of 4-methyl-19-nortestosterone acetate (ii) from the enol lactone i derived from 19-nor-testosterone, by reaction with ethylmagnesium iodide and base. The sole by-product isolated from this reaction was the enol ether iii, analogous to our by-product IX. It



i ii iii

was considered that the "over-reacted" material[6b] derived from enol lactones of type VI with methylmagnesium iodide therefore had a structure analogous to iii (and IX). However, this "over-reacted" material is polar and high-melting, like VIII, whereas the enol ethers iii and IX are non-polar (less polar than the corresponding 4-methyl-Δ^4-3-ketones) and comparatively low-melting.

isomeric mixture at C-20).[23] Reaction with ethylmagnesium bromide and base treatment, as previously, then produced 4-methylprogesterone (Xd) with the typical ultraviolet maximum at 251 mμ. In addition, a polar comparatively high-melting saturated by-product could again be isolated, to which the hemi-ketal structure VIIId is assigned.

In Table I, the molecular rotations ($[M]_D$) of the various 4-methyl-Δ^4-3-ketones are compared with those of the parent Δ^4-3-ketones. It can be seen that in all cases the introduction of the 4-methyl group results in an appreciable increase in the $[M]_D$, ranging from +91 in the cholestenone to +130 in the progesterone series. A similar increase is observed in passing from $\Delta^{1,4}$-dien-3-ones to the corresponding 4-methyl compounds. It is of interest to note that whereas testosterone and its acetate have almost the identical $[M]_D$, the increase in the $[M]_D$ which occurs in acetylating 1-dehydrotestosterone is also observed in the 4-methyl-1-dehydro series.

In preliminary assays carried out by the Endocrine Laboratories (Madison, Wis.), 4-methyltestosterone was found to possess *ca.* 40% of the androgenic and 120% of the myothrophic activity of testosterone, when tested by injection in castrated immature mice. 4-Methylprogesterone had *ca.* 50% of the progestational activity of progesterone, when tested by subcutaneous injection in estrogen-primed rabbits.

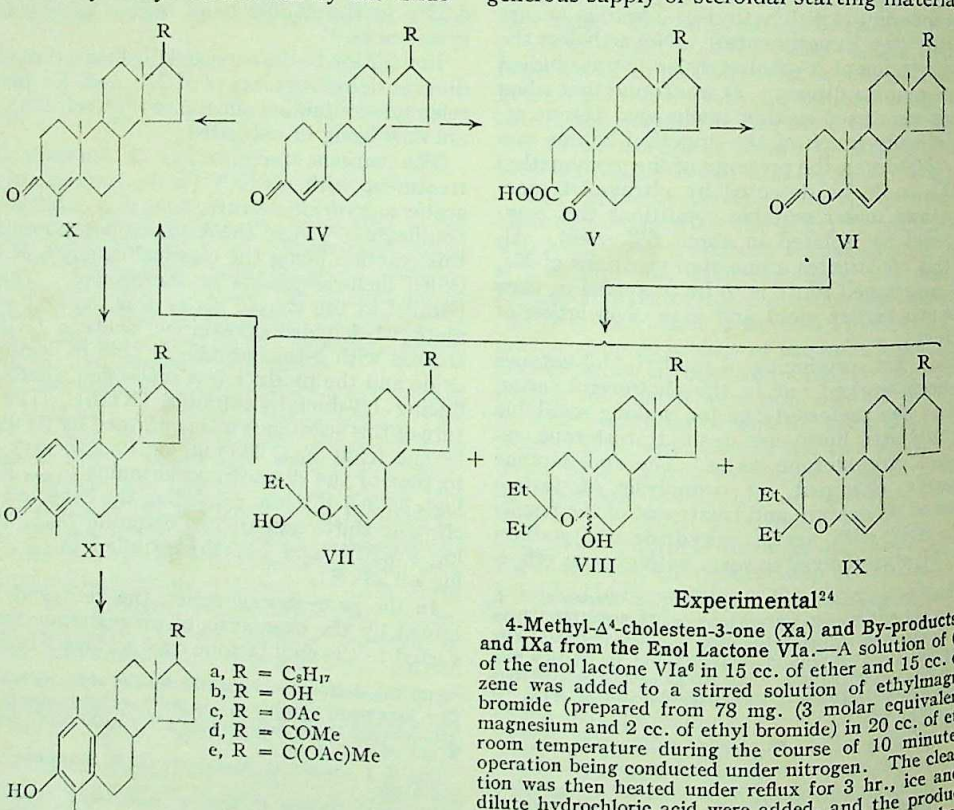
Various reactions of the 4-methylated steroids described in this paper are now being investigated and will be reported in a subsequent publication.

Acknowledgment.—We are indebted to Dr. G. Rosenkranz of Syntex S.A., Mexico City, for the generous supply of steroidal starting materials.



Experimental[24]

4-Methyl-Δ^4-cholesten-3-one (Xa) and By-products VIIIa and IXa from the Enol Lactone VIa.—A solution of 0.42 g. of the enol lactone VIa[6] in 15 cc. of ether and 15 cc. of benzene was added to a stirred solution of ethylmagnesium bromide (prepared from 78 mg. (3 molar equivalents) of magnesium and 2 cc. of ethyl bromide) in 20 cc. of ether at room temperature during the course of 10 minutes, the operation being conducted under nitrogen. The clear solution was then heated under reflux for 3 hr., ice and then dilute hydrochloric acid were added, and the product was isolated with ether. The residue remaining after the evaporation of solvents was dissolved in 200 cc. of methanol and heated under reflux with 4 g. of sodium hydroxide in 40 cc. of water for 2 hr. Water and ether were then added, and the product, obtained by the evaporation of the dried ether extract, was chromatographed on 15 g. of alumina.

(24) Melting points are uncorrected. Rotations were determined (at 20°) in chloroform solution unless specified otherwise. Ultraviolet spectra were measured in 95% ethanol solution on a Uniecam Model S.P. 500 spectrophotometer and infrared spectra in chloroform solution on a Baird double beam recording spectrophotometer (for brevity only bands in the hydroxyl region (2.8–3.2 μ) and carbonyl region (5.5–6.0 μ) are mentioned). Analyses were carried out in our microanalytical department under the direction of Mr. Erich Meier.

The solid fractions (56 mg., 12%) eluted with pentane yielded the enol ether IXa (see below). The next solid fractions, eluted with pentane–benzene (9:1) on crystallization from ether–methanol furnished 285 mg. (66%) of 4-methyl-Δ^4-cholesten-3-one, m.p. 102–103°, $[\alpha]_D$ +110°, λ_{max} 251 mμ (log ε 4.18), λ_{max} 6.02 and 6.18 μ.

Anal. Calcd. for $C_{28}H_{46}O$: C, 84.35; H, 11.63. Found: C, 84.39; H, 11.65.

The fractions eluted with ether on crystallization from ether-pentane gave 66 mg. (14%) of the hemi-ketal VIIIa, m.p. 175–176°, $[\alpha]_D$ +31°, λ_{max} 2.91 and 3.08 μ.

Anal. Calcd. for $C_{30}H_{54}O_2$: C, 80.65; H, 12.18. Found: C, 80.29; H, 12.07.

The enol ether IXa, eluted first from the column, on crystallization from ether–methanol showed m.p. 103–104°, $[\alpha]_D$ +1°, λ_{max} 5.98 μ.

Anal. Calcd. for $C_{30}H_{52}O$: C, 84.04; H, 12.23. Found: C, 83.93; H, 12.28.

4-Methyl-Δ^4-cholesten-3-one (Xa) by Direct Methylation of Δ^4-Cholesten-3-one (IVa).—A solution of 300 mg. of potassium (3 molar equivalents) in 10 cc. of *t*-butyl alcohol was added to a boiling solution of 1 g. of Δ^4-cholesten-3-one in 30 cc. of benzene. Methyl iodide (3 cc.) in 30 cc. of benzene was then added and refluxing was continued for 5 minutes. The solution was cooled, 0.5 cc. of water was added and the solvents were evaporated to dryness under reduced pressure. Ether was added, the insoluble potassium iodide was collected and the filtrate was evaporated. Crystallization of the residue from methanol yielded 450 mg. of 4,4-dimethyl-Δ^4-cholesten-3-one,[12] m.p. 172–174°, no high-intensity absorption in the ultraviolet. The mother liquors (λ_{max} 243 mμ, log ε 4.01 and 250 mμ, log ε 3.95) were chromatographed on 20 g. of alumina. The fractions eluted with pentane furnished another 35 mg. of the 4,4-dimethyl-Δ^5-3-ketone (total yield 45%). The next solid fractions, eluted with pentane–benzene (9:1), on crystallization from ether–methanol produced 54 mg. (5%) of 4-methyl-Δ^4-cholesten-3-one, m.p. 101–103°, λ_{max} 251 mμ (log ε 4.16). The m.p. was undepressed on admixture with the sample prepared from VIa and the infrared spectra were identical. Further elution with pentane–benzene (8:2) gave an oil (102 mg.) which was not further investigated. Finally, pentane–benzene (6:4) eluted 150 mg. (15%) of unchanged Δ^4-cholesten-3-one, m.p. 79–81°.

When the methylation of cholestenone was carried out with 1 mol. of potassium *t*-butoxide and 1 mol. of methyl iodide (boiling for 15 minutes), 7.5% of the 4,4-dimethyl ketone, 3% of the 4-methylcholestenone (Xa) and 70% of unchanged starting material were obtained.

Methylation of 4-Methyl-Δ^4-cholesten-3-one (Xa) to 4,4-Dimethyl-Δ^5-cholesten-3-one.—Potassium (15 mg., 3 molar equivalents) dissolved in 0.5 cc. of *t*-butyl alcohol was added to a boiling solution of 50 mg. of 4-methyl-Δ^4-cholesten-3-one in 1.5 cc. of benzene. A solution of 0.5 cc. of methyl iodide in 5 cc. of benzene was added and boiling was continued for 5 minutes. The reaction mixture was worked up as described above for the methylation of Δ^4-cholesten-3-one. Crystallization of the residue (after removal of potassium iodide) from ether–methanol produced 32 mg. of 4,4-dimethyl-Δ^4-cholesten-3-one, m.p. 170–172°, undepressed on admixture with a sample prepared by the above-described method.

4-Methyltestosterone (Xb).—A solution of ethylmagnesium bromide (prepared from 0.41 g., 2 molar equivalents, of magnesium) in 40 cc. of ether was added dropwise to a stirred solution of 2.8 g. of the enol lactone acetate VIc[7a] in 50 cc. of ether and 50 cc. of benzene during 15 minutes, under nitrogen. The reaction mixture in which a heavy precipitate had formed was heated under reflux for 2 hr. and was then cooled and decomposed with dilute hydrochloric acid. Isolation with ether yielded a product which was triturated with 250 cc. of ether and the insoluble over-reacted material (0.76 g.), m.p. 273–276°, $[\alpha]_D$ +8° (pyridine) was collected. The filtrate was evaporated, and the residue was heated under reflux for 2 hr. with 1 g. of potassium hydroxide in 30 cc. of methanol. The neutral product was isolated with ether and chromatographed on 30 g. of alumina. The fractions eluted with benzene and benzene–ether (9:1) on crystallization from ether–pentane yielded 0.64 g. (25%) of 4-methyltestosterone, m.p. 172–173°, $[\alpha]_D$ +134°, λ_{max} 251 mμ (log ε 4.16); λ_{max} 2.82, 6.01 and 6.20 μ.

Anal. Calcd. for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00. Found: C, 79.52; H, 10.06.

The acetate Xc crystallized from methanol as needles, m.p. 158–160°, $[\alpha]_D$ +122°, λ_{max} 251 mμ (log ε 4.17); λ_{max} 5.78, 6.00 and 6.20 μ.

Anal. Calcd. for $C_{22}H_{32}O_3$: C, 76.70; H, 9.36. Found: C, 76.89; H, 9.13.

The acidic material obtained after the base treatment on crystallization from acetone furnished 1.05 g. (40%) of recovered keto-acid Vb,[14] m.p. 202–203°.

4-Methyl-1-dehydrotestosterone (XIb).—4-Methyltestosterone (250 mg.) and selenium dioxide (125 mg.) were heated under reflux with 5 cc. of *t*-butyl alcohol and 0.05 cc. of glacial acetic acid under nitrogen for 8 hr., another 125 mg. of selenium dioxide was then added and refluxing was continued for another 16 hr. Ether and water were added, the organic layer was washed with sodium carbonate solution and water, dried and evaporated. The residue was chromatographed on 10 g. of alumina and the fractions eluted with benzene and benzene–ether (9:1) were crystallized from ether–hexane and sublimed in high vacuum. This procedure yielded 72 mg. (29%) of 4-methyl-1-dehydrotestosterone, m.p. 188–190°, $[\alpha]_D$ +46°, λ_{max} 244 mμ (log ε 4.16); λ_{max} 2.90, 6.01, 6.17 and 6.23 μ.

Anal. Calcd. for $C_{20}H_{28}O_2$: C, 79.95; H, 9.39. Found: C, 79.76; H, 9.30.

Further elution of the chromatogram with ether yielded 75 mg. of a selenium-containing substance, m.p. *ca.* 290° (dec. with separation of red selenium).

4-Methyl-1-dehydrotestosterone Acetate (XIc).—4-Methyltestosterone acetate (400 mg.) in 8 cc. of *t*-butyl alcohol and 0.08 cc. of glacial acetic acid was dehydrogenated with two lots of selenium dioxide (2 × 200 mg.) as described above for the corresponding alcohol. Chromatography on 16 g. of alumina and crystallization of the fractions eluted with pentane–benzene (9:1 and 8:2) from pentane–ether yielded 84 mg. (21%) of 4-methyl-1-dehydrotestosterone acetate, m.p. 175–176°, $[\alpha]_D$ +60°, λ_{max} 245 mμ (log ε 4.17); λ_{max} 5.78, 6.02, 6.17 and 6.22 μ.

Anal. Calcd. for $C_{22}H_{30}O_3$: C, 77.15; H, 8.83. Found: C, 77.02; H, 8.71.

The fractions eluted with pentane–benzene (2:1) on crystallization from acetone yielded 64 mg. of a selenium-containing substance, m.p. 240–245° dec.

4-Methyl-1-dehydrotestosterone acetate could alternatively be prepared by acetylating the free alcohol XIb (described above) with acetic anhydride and pyridine at room temperature.

1,4-Dimethylestradiol (XIIb).—A solution of 55 mg. of 4-methyl-1-dehydrotestosterone acetate and 15 mg. of *p*-toluenesulfonic acid in 5 cc. of acetic anhydride was heated on the steam-bath for 3 hr. The residue obtained by isolation with ether was heated under reflux with 0.5 g. of potassium hydroxide in 15 cc. of methanol for 1 hr., under nitrogen. Addition of water, isolation with ethyl acetate and crystallization from methylene chloride–methanol produced 35 mg. (73%) of 1,4-dimethylestradiol as long needles, m.p. 125–129°, $[\alpha]_D$ +155°, λ_{max} 288 mμ (log ε 3.23); λ_{max} 2.88 and 3.08 μ. This substance contained solvent of crystallization as evidenced by the bubbling observed at the m.p. and by the low carbon content. The solvent-free diol could only be obtained by sublimation at 140–160° in high vacuum.

Anal. Calcd. for $C_{20}H_{28}O_2$: C, 79.95; H, 9.39. Found: C, 79.62; H, 9.65.

4-Methylprogesterone (Xd).—A solution of ethylmagnesium bromide (prepared from 0.67 g., 2.5 molar equivalents, of magnesium) in 50 cc. of ether was added to a stirred solution of 4 g. of the enol lactone enol acetate VIe[23] in 75 cc. of ether and 75 cc. of benzene during 15 minutes under nitrogen. The mixture was heated under reflux for 2.5 hr., cooled and decomposed with dilute hydrochloric acid. The residue remaining after evaporation of the dried organic extract was heated under reflux with 1.5 g. of potassium hydroxide in 50 cc. of methanol for 2 hr. under nitrogen. Ice was added and the non-acidic material was isolated with ether in the usual way. The resulting oil (2.8 g.) was chromatographed on 100 g. of alumina. The fractions eluted with pentane–benzene (9:1, 8:2 and 7:3) on crystallization from

The Acid-catalyzed Rearrangement of Cinenic Acid. III.[1] Structure and Synthesis of the Lactonic Product

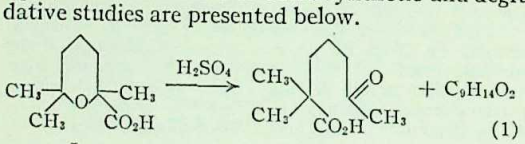
BY JERROLD MEINWALD AND HO CHIEN HWANG

RECEIVED DECEMBER 29, 1956

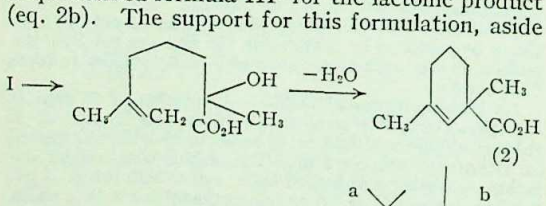
A crystalline lactone, isolated in 15% yield after treatment of α-cinenic acid (I) with concentrated sulfuric acid, has been shown to possess structure III. This lactone has been synthesized using a two-step procedure involving the Diels–Alder addition of isoprene to ethyl methacrylate and lactonization of the resultant adduct. The formation of III from I involves a reaction sequence which is unrelated to the carboxyl transfer process which produces geronic acid (II).

Introduction

As a continuation of our study of the acid-catalyzed rearrangements of α-cinenic acid (I), we have investigated the structure of the crystalline lactone, $C_9H_{14}O_2$, which is formed in about 15% yield when α-cinenic acid is isomerized to geronic acid (II) (see eq. 1).[2,3] The results of these synthetic and degradative studies are presented below.



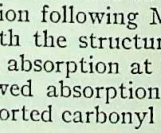
On the basis of a mechanism for the formation of II which is now known to be erroneous (eq. 2a), Rupe derived formula III[2] for the lactonic product (eq. 2b). The support for this formulation, aside

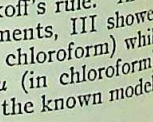


from these "theoretical" considerations, came only from the observations that the lactone was saturated (therefore bicyclic) and that it could be hydrolyzed to a hydroxy-acid which dehydrated to regenerate the original lactone. Since this rather incomplete evidence in favor of III is weakened by the discovery that the formation of II involves a carboxyl transfer process rather than the path shown in equation 2,[4] we have sought a rigorous proof of the lactone structure.

Structure Proof

The rearrangement of I was carried out as previously described, and a crystalline lactone, m.p. 50–51°, was obtained from the neutral portion of the product. A Kuhn–Roth determination indicated the presence of two C-methyl groups. The infrared spectrum of the crystalline lactone (in Nujol) showed a maximum at 5.60 μ. More significantly, in chloroform solution the lactone showed maximal absorption at 5.67 μ. Since these findings were in accord with the proposed structure, an independent synthesis of this structure was undertaken as the simplest method of unambiguous identification. The method chosen for the synthesis is outlined in Chart 1. Diels–Alder addition of isoprene to ethyl methacrylate gave a *mixture* of adducts, not easily separable into its individual components by fractional distillation. The formation of both of the theoretically possible products was anticipated, and ensured the success of the synthesis. Treatment of the mixture with sulfuric acid in acetic acid gave a mixture of lactones, from which III, m.p. 50–51°, and IV, m.p. 48–49°, were isolated by distillation and purified by crystallization. These were the lactones to be expected from acid-catalyzed cyclization following Markownikoff's rule. In accord with the structural assignments, III showed lactonic absorption at 5.67 μ (in chloroform) while IV showed absorption at 5.80 μ (in chloroform). The reported carbonyl bands for the known models





VI and VII are at 5.67 and 5.76 μ, respectively.[5] Finally, III was degraded in good yield to *m*-xylene (identified by conversion to its trinitro derivative, as well as by its infrared and ultraviolet spectra) by

heating with a barium oxide–palladium-on-charcoal mixture. Similarly, degradation of IV gave rise to a good yield of *p*-xylene.

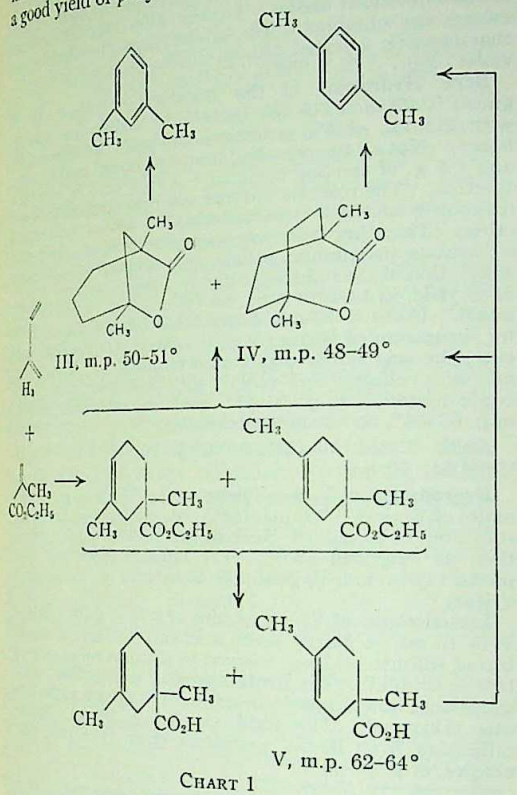

CHART I

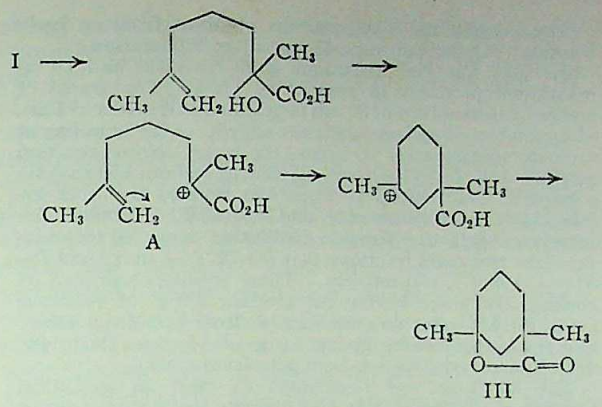
In an effort to separate the hydrolysis and lactonization steps, and to characterize the acid intermediates, a base hydrolysis of the original adduct mixture was carried out. A liquid mixture of acids was obtained, which gave rise to a mixture of lactones on acid treatment. (Chromatography of this mixture produced III and IV, but this procedure for preparing the lactones was much more tedious than that described previously.) The acid V, m.p. 62–64°, was isolated from the crude adduct hydrolyzate by virtue of the fact that it slowly crystallized from the mixture of acids. Its structure was proven by degradation to *p*-xylene and cyclization to the δ-lactone, IV. Unfortunately, it was impossible to characterize the acid precursor to the γ-lactone, III.

An authentic sample of lactone III was now available from these synthetic experiments, and a direct comparison with the neutral α-cinenic acid product was possible. Indistinguishable infrared spectra and an undepressed mixture melting point proved these two samples to be identical. The melting point of the γ-lactone III was depressed strongly upon admixture with the δ-lactone IV.

Concluding Remarks

The transformation of I to III would seem to proceed by the series of steps outlined in equation 3, the essential features of which were present in Rupe's suggestion. It should be pointed out, however, that this sequence is not entirely satisfactory. It would be possible to circumvent the rather un-



attractive intermediate (A) by postulating a cyclization *concerted* with loss of the hydroxyl group. In any event, it is apparent that this reaction is quite unrelated to the carboxyl transfer reaction responsible for the production of geronic acid (II), and that II and III do not have a common carbocyclic precursor as previously postulated.[2] Nevertheless, insofar as the structure and genesis of III is concerned, these results pay tribute to Rupe's organic chemical intuition.

Experimental

Rearrangement of α-Cinenic Acid.—The rearrangement of 30 g. of I was carried out as described previously.[2-4] A neutral fraction weighing 12.1 g. was obtained from the reaction product by the usual extraction procedures. This material yielded a crystalline solid on chilling. Recrystallization from 30–60° petroleum ether gave 4.6 g. (15%) of white plates, m.p. 50–51°. The infrared spectrum of this material showed maxima at 5.60 μ in Nujol and 5.67 μ in $CHCl_3$ solution.

Anal. Calcd. for $C_9H_{14}O_2$: C, 70.10; H, 9.15; $-CH_3$, 19.4. Found: C, 69.86; H, 9.03; $-CH_3$, 10.83.

Addition of Isoprene to Ethyl Methacrylate.—Two hundred grams (1.76 moles) of ethyl methacrylate, 120 g. (1.76 moles) of freshly distilled isoprene and 2 g. of hydroquinone were placed in a steel bomb, heated at 200° overnight, and cooled to room temperature. The crude reaction product (316 g.) was subjected to distillation at diminished pressure. A small amount of unreacted ethyl methacrylate (27 g.) was recovered. A mixture (24 g.) of ethyl methacrylate and adduct was collected below 65° (3 mm.) and the main portion of adduct (263 g.) was collected over the range 66–72° (2.3–2.5 mm.). The infrared spectrum of this adduct was free of the sharp maximum at 6.10 μ characteristic of ethyl methacrylate. The yield, based on unrecovered dienophile, corresponded to 95%. Slow redistillation of the main fraction failed to separate the two isomeric esters, but gave an analytical sample, b.p. 71–72° (2.5 mm.).

Anal. Calcd. for $C_{11}H_{18}O_2$: C, 72.53; H, 9.84. Found: C, 72.73; H, 9.94.

Lactonization of the Diels–Alder Adduct to III and IV. A.—Several techniques were used to prepare the desired lactones. In one experiment, the adduct (1 g.) was boiled with 50% sulfuric acid for about two days. The neutral product (85%) from this experiment was chromatographed on a Magnesol–Celite (1:1) column, using 30–60° petroleum ether as solvent. The early fractions showed carbonyl absorption at 5.80 μ, while later fractions showed a 5.65 μ maximum. Fractions showing chiefly γ-lactone absorption were combined and recrystallized to give about 7% of fine, colorless, platelike crystals, m.p. 50–51°, mixture m.p. with cinenic acid product 50–51°. The infrared spectra of the rearrangement product and the synthetic lactone were in-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Some crystalline δ-lactone was obtained from an early fraction. It showed m.p. 48–49° after sublimation.

B.—The following technique gave both III and IV as crystalline products in reasonable yield. Ten grams of adduct was dissolved in 30 ml. of glacial acetic acid and 1 ml. of concentrated sulfuric acid was added. After standing at room temperature for 96 hours, the honey-colored reaction mixture was neutralized with saturated sodium bicarbonate solution. The neutral product was isolated by ether extraction in the usual manner, and 7 g. (83%) of lactone mixture was obtained. Vacuum distillation separated this mixture into two main fractions, b.p. 70–72° (1.5 mm.) and 79–81° (1.0 mm.), respectively. These products solidified on cooling, the lower boiling cut yielding 2.9 g. of γ-lactone (m.p. 50–51° after recrystallization from petroleum ether) and the higher boiling giving 4.0 g. of δ-lactone (m.p. 48–49° after recrystallization from petroleum ether).

The δ-lactone was resublimed to yield an analytical sample, m.p. 48–49°. It had a single sharp maximum in chloroform at 5.80 μ.

Anal. Calcd. for $C_9H_{14}O_2$: C, 70.10; H, 9.15. Found: C, 69.91; H, 9.00.

Degradation of III to *m*-Xylene.—One gram (0.006 mole) of III (m.p. 50–51°) was ground to a fine powder and mixed thoroughly with 300 mg. of 10% palladium–charcoal and 3.0 g. of barium oxide. The mixture was placed in a 25-ml. distilling flask and heated gently over a micro-flame. The product, *m*-xylene, came over readily as a colorless liquid. The yield was 0.55 g. (80%). For complete identification of this product, infrared and ultraviolet spectra were taken and a nitro derivative was prepared. Maxima at 13.00, 13.75 and 14.50 μ in the infrared[6] and at 259, 265.4, 268.8 and 272.5 mμ in the ultraviolet,[7] all characteristic of *m*-xylene, were observed. Nitration of 500 mg. of the degradation product using 2 ml. of concentrated sulfuric acid and 2 ml. of fuming nitric acid, and keeping the mixture at 100° for 20 minutes, gave a white precipitate when the reaction mixture was poured onto ice. After recrystallization from 95% ethanol, fine, pale yellow, needles, m.p. 177–180° (lit.[8] 182°), were obtained. A melting point of 177–181° was observed on admixture with an authentic sample of 2,4,6-trinitro-*m*-xylene.

Degradation of IV to *p*-Xylene.—Five hundred mg. (0.003 mole) of IV (m.p. 48–49°) was degraded in a fashion parallel to that described above. A yield of 300 mg. (88%) of *p*-xylene was obtained. The product was identified by its characteristic infrared (12.58, 13.72, 14.41 μ)[9] and ultraviolet (260.7, 266.1, 269.0, 275.0 mμ)[10] spectra.

Base Hydrolysis of the Diels–Alder Adduct.—Forty grams (0.22 mole) of the Diels–Alder adduct was refluxed with 210 ml. of 5% potassium hydroxide solution for 70 hours. Not all the ester had been hydrolyzed at this point, and 8.5 g. of starting material was recovered by ether extraction. The reaction mixture was then acidified with hydrochloric acid and extracted with five 100-ml. portions of ether. The ether layer was washed with water, dried over anhydrous magnesium sulfate and evaporated. Vacuum distillation of the residual acid gave a main fraction (21.9 g., 82% yield on basis of ester converted), b.p. 104–105° (1.0 mm.). Using a 70-cm. Podbielniak column, no evidence for separation of isomers was obtained. On cooling, however, the acid slowly deposited crystals of V. These crystals were collected and washed with petroleum ether. The crude material, m.p. 60–64°, gave an analytical sample, m.p. 62–64°, on vacuum sublimation.

Anal. Calcd. for $C_9H_{14}O_2$: C, 70.10; H, 9.15. Found: C, 69.84; H, 8.91.

Degradation of V to *p*-Xylene.—Five hundred mg. (0.003 mole) of V yielded 200 mg. (58%) of colorless distillate when subjected to palladium–charcoal and barium oxide degradation, as described above. The infrared spectrum of the product was indistinguishable from that of authentic *p*-xylene.

Lactonization of V.—A solution of 2.76 g. (0.018 mole) of V in 10 ml. of glacial acetic acid and 0.25 ml. of concentrated sulfuric acid was allowed to stand at room temperature overnight. The neutral product was isolated in the usual way, and appeared as long needles as soon as the ether was taken off. The yield was 1.9 g. (69%). Recrystallization from 30–60° petroleum ether gave pure white needles, m.p. 48–49°.

The Synthesis of β-(3-Methoxy-2,6-dinitrophenyl)-D,L-alanine and β-(3-Methoxy-4,6-dinitrophenyl)-D,L-alanine. Proof of the Structures of Two Isomeric Dinitro-*m*-tyrosines

BY ERNEST L. JACKSON

RECEIVED DECEMBER 29, 1956

β-(3-Methoxy-2,6-dinitrophenyl)-D,L-alanine and β-(3-methoxy-4,6-dinitrophenyl)-D,L-alanine have been synthesized from 3-methoxy-2,6-dinitrobenzaldehyde and 3-methoxy-4,6-dinitrobenzaldehyde. These two amino acids have been correlated with two of the β-(3-methoxydinitrophenyl)-D,L-alanines that were obtained by way of the nitration of *m*-tyrosine, thus proving two of the nitration products to be β-(3-hydroxy-2,6-dinitrophenyl)-D,L-alanine and β-(3-hydroxy-4,6-dinitrophenyl)-D,L-alanine.

The nitration of *m*-tyrosine has been shown[1] to produce three crystalline isomers of β-(3-hydroxydinitrophenyl)-D,L-alanine which upon acetylation yielded three isomers of N-acetyl-β-(3-hydroxydinitrophenyl)-D,L-alanine; methylation of two of these compounds afforded two isomers of N-acetyl-β-(3-methoxydinitrophenyl)-D,L-alanine methyl ester. Hydrolysis and deacetylation of these two methyl esters gave the two isomeric β-(3-methoxydinitrophenyl)-D,L-alanines. The present paper describes the third isomer of β-(3-methoxydinitrophenyl)-D,L-alanine and its N-acetyl methyl ester; it also establishes the orientation of the nitro groups for two of the isomers by their comparison with the authentic compounds which have been synthesized from 3-methoxy-2,6-dinitrobenzaldehyde and 3-methoxy-4,6-dinitrobenzaldehyde, the structures of which were proved by Hodgson and Beard[2] and by Tröger and Eicker.[3]

3-Methoxy-2,6-dinitrobenzaldehyde in toluene solution yielded, by reduction of the aldehyde group with aluminum isopropoxide, 3-methoxy-2,6-dinitrobenzyl alcohol (m.p. 139.5–140.5°) which reacted with phosphorus pentachloride to produce 3-methoxy-2,6-dinitrobenzyl chloride (m.p. 103.5–104.5°). Ethyl α-acetamido-α-carbethoxy-β-(3-methoxy-2,6-dinitrophenyl)-propionate (m.p. 143°) resulted in 62% yield from the reaction of sodium ethyl acetamidomalonate with 3-methoxy-2,6-dinitrobenzyl chloride in ethanol solution at room temperature. This reaction was unsuccessful in boiling ethanol solution presumably due to the oxidizing[4] action of the nitro groups in the molecule of 3-methoxy-2,6-dinitrobenzyl chloride. β-(3-Methoxy-2,6-dinitrophenyl)-D,L-alanine (m.p. 209° dec.) was produced in 57% yield through reaction of a hot mixture of sulfuric and acetic acids with ethyl α-acetamido-α-carbethoxy-β-(3-methoxy-2,6-dinitrophenyl)-propionate. Acetylation of β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine in aqueous sodium hydroxide solution by acetic anhydride gave N-acetyl-β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine (m.p. 252° dec.), methylation of which by either diazomethane or by the methanol–acetyl chloride method of Hanby, Waley and Watson[5] afforded N-acetyl-β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine methyl ester (m.p. 158–159°).

The isomer of N-acetyl-β-(3-hydroxydinitrophenyl)-D,L-alanine[1] melting at 194–195°, the one previously designated N-acetyl-C, now has been found to react with diazomethane to produce N-acetyl-β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine methyl ester (m.p. 157–158°). This product was shown by a mixed melting point determination and by comparison of the infrared spectra to be identical with the N-acetyl-β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine methyl ester that was synthesized from 3-methoxy-2,6-dinitrobenzaldehyde. Hydrolysis and deacetylation of N-acetyl-β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine methyl ester, derived from N-acetyl-C, by a hot mixture of sulfuric and acetic acids yielded β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine melting at 208° dec. alone or mixed with the compound which was synthesized from 3-methoxy-2,6-dinitrobenzaldehyde. Isomer C[1] of β-(3-hydroxy-dinitrophenyl)-D,L-alanine (m.p. 197°, explosively) consequently must be β-(3-hydroxy-2,6-dinitrophenyl)-D,L-alanine.

The synthesis of β-(3-methoxy-4,6-dinitrophenyl)-D,L-alanine from 3-methoxy-4,6-dinitrobenzaldehyde was accomplished by the preparation in successive steps of 3-methoxy-4,6-dinitrobenzyl alcohol (m.p. 135–136°), 3-methoxy-4,6-dinitrobenzyl chloride (m.p. 110–111°) and ethyl α-acetamido-α-carbethoxy-β-(3-methoxy-4,6-dinitrophenyl)-propionate (m.p. 167°) which was converted to β-(3-methoxy-4,6-dinitrophenyl)-D,L-alanine (m.p. 230° dec.) in 68% yield. The purification of the amino acid was facilitated greatly by the use of a Dowex-1 anion exchange resin. A mixed melting point determination and paper chromatography tests, employing both 60% ethanol and *t*-amyl alcohol as solvents, established the identity of this authentic β-(3-methoxy-4,6-dinitrophenyl)-D,L-alanine with the β-(3-methoxydinitrophenyl)-D,L-alanine (m.p. 231–232° dec.) which was prepared[1] from the isomer of N-acetyl-β-(3-methoxydinitrophenyl)-D,L-alanine methyl ester melting at 172–173°. Moreover, this methyl ester was prepared from the authentic β-(3-methoxy-4,6-dinitrophenyl)-D,L-alanine by acetylation to N-acetyl-β-(3-methoxy-4,6-dinitrophenyl)-D,L-alanine (m.p. 212–213°) which reacted with diazomethane to yield N-acetyl-β-(3-methoxy-4,6-dinitrophenyl)-D,L-alanine methyl ester melting at 172–173° alone or mixed with the compound derived from *m*-tyrosine. This proves isomer B[1] of β-(3-hydroxydinitrophenyl)-D,L-alanine (m.p. 235–236° dec.) to be β-(3-hydroxy-4,6-dinitrophenyl)-D,L-alanine.

Isomer A[1] of β-(3-hydroxydinitrophenyl)-D,L-alanine (m.p. 234° dec.) would be expected from orientation rules to be β-(3-hydroxy-2,4-dinitrophenyl)-D,L-alanine.

Experimental

Except where otherwise stated, melting points are corrected and, in the case of the amino acids, their N-acetyl derivatives and N-acetyl methyl esters the melting points were determined with the bath of the Hershberg apparatus preheated to 15–30° below the melting point.

3-Methoxy-2,6-dinitrobenzyl Alcohol and 3-Methoxy-4,6-dinitrobenzyl Alcohol.—To a solution of 2.5 g. of pure 3-methoxy-2,6-dinitrobenzaldehyde[2,3] in 40 ml. of anhydrous toluene was added 3.7 ml. of approximately 1.4 *M* solution of aluminum isopropoxide in anhydrous 2-propanol. After the solution had been refluxed for 3 hr., 10 ml. of anhydrous 2-propanol was added. The mixture was heated for 2 hr. on the steam-bath in an apparatus[6] that allowed slow distillation of the solvent and the acetone formed, 2-propanol being replenished as needed. The solvent was evaporated *in vacuo* and the solid residue was mixed thoroughly with 60 ml. of 5% hydrochloric acid. The crude 3-methoxy-2,6-dinitrobenzyl alcohol was collected, washed with water and recrystallized from ethanol as light-brown prismatic needles, yield 2 g. or 80%, m.p. 139.5–140.5°.

Anal. Calcd. for $C_8H_8N_2O_6$: C, 42.11; H, 3.53; N, 12.28. Found: C, 42.39; H, 3.46; N, 12.06.

Pure 3-methoxy-4,6-dinitrobenzaldehyde[2,3] (2.42 g.) in 38 ml. of anhydrous toluene was reduced by aluminum isopropoxide (3.6 ml. of 1.4 *M* solution in anhydrous 2-propanol) as described for the reduction of 3-methoxy-2,6-dinitrobenzaldehyde. Purified from ethanol and dried in an evacuated desiccator over calcium chloride, the light-brown crystals of 3-methoxy-4,6-dinitrobenzyl alcohol melted at 135–136°, yield 1.7 g. or 70%. Found: C, 42.27; H, 3.72; N, 12.20.

3-Methoxy-2,6-dinitrobenzyl Chloride and 3-Methoxy-4,6-dinitrobenzyl Chloride.—A mixture of 1.74 g. of 3-methoxy-2,6-dinitrobenzyl alcohol and 26 ml. of chloroform, which had been washed with water and dried over calcium chloride, was boiled for a few minutes, then cooled to 0–5° and treated with 1.91 g. of phosphorus pentachloride. The cold mixture was shaken until all solid dissolved. The solution was kept at room temperature for 2 hr., 16 ml. of *n*-hexane was added and a little amorphous solid was removed by filtration. The solution was washed once with water, four times with 5% sodium bicarbonate solution and finally with water. After the solution had been dried over calcium chloride and filtered, the solvent was evaporated *in vacuo* and the residue was recrystallized from a mixture of benzene and *n*-hexane; yield 1.6 g. or 84%, m.p. 103.5–104.5°.

Anal. Calcd. for $C_8H_7ClN_2O_8$: C, 38.96; H, 2.86; Cl, 14.38; N, 11.36. Found: C, 39.31; H, 2.77; Cl, 14.89; N, 11.29.

3-Methoxy-4,6-dinitrobenzyl alcohol (1.25 g.) in 25 ml. of absolute chloroform was treated with phosphorus pentachloride (1.37 g.) as described for the similar reaction with 3-methoxy-2,6-dinitrobenzyl alcohol. The crude product was recrystallized as yellow prisms from absolute ethanol and dried in an evacuated desiccator over calcium chloride; yield 1.1 g. or 81%, m.p. 110–111°. Found: C, 39.30; H, 2.91; Cl, 14.17; N, 11.27.

Ethyl α-Acetamido-α-carbethoxy-β-(3-methoxy-2,6-dinitrophenyl)-propionate and Ethyl α-Acetamido-α-carbethoxy-β-(3-methoxy-4,6-dinitrophenyl)-propionate.—Ethyl acetamidomalonate (1.54 g.) was dissolved in a solution of 0.187 g. of sodium in 60 ml. of absolute ethanol. 3-Methoxy-2,6-dinitrobenzyl chloride (1.59 g.) was shaken with this solution at room temperature and nearly all of the crystals soon dissolved. It was kept at room temperature for 43 hr., some crystals of sodium chloride were removed and, after the solution had been made slightly acid with acetic acid, the solvent was evaporated at 25° *in vacuo*. The crystalline residue was taken up in hot absolute ethanol, some insoluble solid was filtered off and the filtrate was concentrated to deposit at 25° a dense mass of crystals of ethyl α-acetamido-α-carbethoxy-β-(3-methoxy-2,6-dinitrophenyl)-propionate, which was dried in an evacuated desiccator over calcium chloride; yield 1.7 g. or 62%, m.p. 143°.

Anal. Calcd. for $C_{17}N_{21}N_3O_{10}$: C, 47,77; H, 4.95; N, 9.83. Found: C, 47.63; H, 4.89; N, 9.86.

Ethyl acetamidomalonate (1.0 g.) was dissolved in a solution of 0.12 g. of sodium in 40 ml. of absolute ethanol. 3-Methoxy-4,6-dinitrobenzyl chloride (1.03 g.) was shaken mechanically with this solution at room temperature for 47 hr. The suspended crystals were collected, washed with absolute ethanol, dried and then stirred with 15 ml. of cold water. The undissolved crystals (1.0 g. melting at 159–163°) were purified by recrystallization first from absolute ethanol and then from ethyl acetate to give 0.75 g. of pure ethyl α-acetamido-α-carbethoxy-β-(3-methoxy-4,6-dinitrophenyl)-propionate melting at 167°. Found: C, 47.99; H, 4.81; N, 9.60.

β-(3-Methoxy-2,6-dinitrophenyl)-D,L-alanine and β-(3-Methoxy-4,6-dinitrophenyl)-D,L-alanine.—To a solution of 1.58 g. of ethyl α-acetamido-α-carbethoxy-β-(3-methoxy-2,6-dinitrophenyl)-propionate in 47 ml. of glacial acetic acid was added 63 ml. of 6.258 *N* sulfuric acid. After the solution had been refluxed for 8 hr., it was diluted with 60 ml. of water and concentrated *in vacuo* (bath 65°) to 20 ml., some sirup having separated. It was diluted with 50 ml. of water, the mixture was concentrated *in vacuo* to *ca.* 30 ml., then diluted with 70 ml. of water and heated on the steam-bath for a few minutes. After being cooled to room temperature, the mixture of solution and sirup was extracted six times with ethyl acetate. The hot aqueous solution was treated with sufficient barium hydroxide solution to remove sulfate ions exactly. The solution upon concentration *in vacuo* yielded in two crops 0.5 g. of crystalline β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine, most of which melted at 208°. The ethyl acetate extract was concentrated *in vacuo* to deposit a thick, brown sirup which was dissolved in 250 ml. of hot water. The filtered aqueous solution was extracted with benzene and then evaporated *in vacuo* to deposit solid material which, after further purification from water, increased the yield of β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine to 0.6 g. or 57%. The analytical sample was recrystallized from water as almost colorless needles and dried for 24 hr. in the air at room temperature. These crystals, which melted at 209° (uncor., dec.), lost 5.3% in weight at 100° *in vacuo*.

Anal. Calcd. for $C_{10}H_{11}N_3O_7$: C, 42.11; H, 3.89; N, 14.74; OCH_3, 10.88. Found (dried at 100° *in vacuo*): C, 41.91; H, 3.83; N, 14.51; OCH_3, 10.77.

β-(3-Methoxy-2,6-dinitrophenyl)-D,L-alanine was prepared also from N-acetyl-β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine methyl ester, which was obtained as described below by the reaction of diazomethane with one of the isomers of N-acetyl-β-(3-hydroxydinitrophenyl)-D,L-alanine[1] (N-acetyl-C, m.p. 194–195°). A solution of 75 mg. of this N-acetyl-β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine methyl ester (somewhat impure; m.p. 145–147°) in a mixture of 2 ml. of acetic acid and 2.3 ml. of 5.76 *N* sulfuric acid was kept at 100° under reflux for 5 hr. The product (47 mg.) was isolated as previously described[1] and purified by several recrystallizations from water as almost colorless needles. The air-dried crystals melted at 208° (uncor., dec.) and lost 5.8% in weight at 100° *in vacuo*. A mixed melting point determination with crystals of β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine prepared from ethyl α-acetamido-α-carbethoxy-β-(3-methoxy-2,6-dinitrophenyl)-propionate showed no depression. Found (dried at 100° *in vacuo*): C, 42.52; H, 4.09.

For the preparation of β-(3-methoxy-4,6-dinitrophenyl)-D,L-alanine, a solution of 0.542 g. of ethyl α-acetamido-α-carbethoxy-β-(3-methoxy-4,6-dinitrophenyl)-propionate in a mixture of 16 ml. of glacial acetic acid and 21.7 ml. of 6.258 *N* sulfuric acid was refluxed for 6 hr. The solution was diluted with 150 ml. of water and left overnight at 25° to deposit 26 mg. of crystalline ethyl α-acetamido-α-carbethoxy-β-(3-methoxy-4,6-dinitrophenyl)-propionate melting at 163–164°. The solution was concentrated *in vacuo* to a small volume, then diluted with water, and the concentration *in vacuo* was repeated. The solution was diluted with water and extracted twice with ethyl acetate. After treatment with barium hydroxide for exact removal of sulfate ions, the aqueous solution was evaporated *in vacuo* to dryness. The crystalline residue was taken up in water and the solution was evaporated again *in vacuo;* this operation was repeated until the distillate was free of acetic acid. The crystals were dissolved in 75 ml. of hot water, the yellow solution was filtered, cooled and passed through a column (13 × 1.7 cm.) of Dowex 1–X2, 200–400 mesh in the acetate form; the column was then washed with some water. The small residue left by evaporation of the solution, which had passed through the column, was found by paper chromatography to be free of β-(3-methoxy-4,6-dinitrophenyl)-D,L-alanine. The column was eluted with 200 ml. of *N* acetic acid, and the eluate was evaporated *in vacuo* to dryness. The crystalline residue was dissolved in hot water and the solution was evaporated *in vacuo;* this operation was repeated until the distillate was free of acetic acid. Recrystallization of the compound from water as slightly yellow needles gave in two crops 246 mg. (68%) of β-(3-methoxy-4,6-dinitrophenyl)-D,L-alanine, most of it melting at 228° dec. After another recrystallization from water and drying in the air at room temperature, the crystals melted at 230° (uncor., dec.) and lost 3.0% in weight at 100° *in vacuo*. Found (dried at 100° *in vacuo*): C, 42.45; H, 4.10; N, 14.96.

The melting point of a mixture of the above described crystals of authentic β-(3-methoxy-4,6-dinitrophenyl)-D,L-alanine with crystals of the previously reported[1] β-(3-methoxydinitrophenyl)-D,L-alanine (m.p. 231–232° dec.), which was prepared from the isomer of N-acetyl-β-(3-methoxydinitrophenyl)-D,L-alanine methyl ester melting at 172–173°, showed no depression. The melting point was depressed when crystals of the authentic compound were mixed with crystals of β-(3-methoxydinitrophenyl)-D,L-alanine[1] of m.p. 234–235° dec. which was prepared from the isomer of N-acetyl-β-(3-methoxydinitrophenyl)-D,L-alanine methyl ester melting at 128–129°. In paper chromatography tests, with the use of both water–ethanol (2:3) and *t*-amyl alcohol saturated with water, the authentic β-(3-methoxy-4,6-dinitrophenyl)-D,L-alanine showed R_f values in agreement with the values for the compound that was derived from N-acetyl-β-(3-methoxydinitrophenyl)-D,L-alanine methyl ester melting at 172–173°. The R_f value for the compound in water–ethanol (2:3) was 0.66, and in *t*-amyl alcohol the R_f was 0.32. For the isomer melting at 234–235° dec. the R_f value in water–ethanol (2:3) was 0.70, and *t*-amyl alcohol the R_f was 0.47.

N-Acetyl-β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine and N-Acetyl-β-(3-methoxy-4,6-dinitrophenyl)-D,L-alanine.—A solution of 0.15 g. of β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine, derived from 3-methoxy-2,6-dinitrobenzaldehyde, in 0.4 ml. of water and 0.42 ml. of 1.92 *N* sodium hydroxide was kept in ice-water during the alternate addition of six 0.36-ml. portions of 1.92 *N* sodium hydroxide and six 0.06-ml. portions of acetic anhydride. After 4 hr. at room temperature the mixture of solution and solid was treated with 0.9 ml. of 6.258 *N* sulfuric acid. The somewhat impure crystals of N-acetyl-β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine (0.15 g.) were collected, washed with water and purified by recrystallization from aqueous ethanol (1:1) or from ethyl acetate, being dried in an evacuated

desiccator over calcium chloride, the pure light-yellow crystals melted at 252° dec.

Anal. Calcd. for $C_{12}H_{13}N_3O_8$: C, 44.04; H, 4.00; N, 12.84. Found (dried at 100° *in vacuo*): C, 44.25; H, 4.14; N, 12.65.

β-(3-Methoxy-4,6-dinitrophenyl)-D,L-alanine (50 mg.), derived from 3-methoxy-4,6-dinitrobenzaldehyde, was acetylated as described for β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine using one-third the quantities of sodium hydroxide, acetic anhydride and sulfuric acid. The crude product (50 mg., m.p. 205°) was purified from absolute ethanol; m.p. 212–213°. Found (dried at 79° *in vacuo*): C, 43.83; H, 3.98; N, 12.70.

N-Acetyl-β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine Methyl Ester and N-Acetyl-β-(3-methoxy-4,6-dinitrophenyl)-D,L-alanine Methyl Ester.—A solution of 50 mg. of N-acetyl-β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine in 2.5 ml. of pure dioxane was mixed with a dry ether solution of diazomethane, prepared[7] from 0.4 g. of N-nitrosomethylurea and 4 ml. of ether. After the solution had been kept at 26–27° for 16 hr., the solvent was evaporated to deposit a sirup which crystallized upon being stirred with ether. Purified by recrystallization as slightly yellow needles from aqueous methanol and dried in an evacuated desiccator over calcium chloride, the compound melted at 158–159°, yield 35 mg.

Anal. Calcd. for $C_{13}H_{15}N_3O_8$: C, 45.75; H, 4.43; N, 12.32. Found: C, 45.55; H, 4.54; N, 12.31.

The compound was prepared also by esterification of N-acetyl-β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine with the use of methanol and acetyl chloride.[5] To a solution prepared by adding 0.5 ml. of acetyl chloride to 5 ml. of methanol was added at 0° 43 mg. of N-acetyl-β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine. The solution was kept at 25° for 23 hr., and the solvent then was evaporated at 30° *in vacuo*; the sirup was taken up in methanol, the solvent was evaporated and the operation was repeated. The sirup was crystallized as needles from methanol and purification was completed by recrystallization from benzene; m.p. 157–158°, not depressed when the substance was mixed with crystals of the methyl ester prepared with the use of diazomethane.

The reaction of diazomethane with the isomer of N-acetyl-β-(3-hydroxydinitrophenyl)-D,L-alanine melting at 194–195° (N-acetyl-C)[1] gave N-acetyl-β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine methyl ester identical with the authentic compound obtained by the esterification of N-acetyl-β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine. A solution of 40 mg. of pure N-acetyl-β-(3-hydroxydinitrophenyl)-D,L-alanine (m.p. 194–195°) in 2 ml. of pure dioxane was treated with diazomethane as described for N-acetyl-β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine; yield 28 mg., m.p. 157–158°. A mixed melting point with crystals of the methyl ester prepared from N-acetyl-β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine showed no depression and the infrared spectra (solid potassium bromide disk method) of the compound from the two sources were identical. Found: C, 46.23; H, 4.43.

The reaction of diazomethane with N-acetyl-β-(3-methoxy-4,6-dinitrophenyl)-D,L-alanine (38 mg.) was carried out as described for the similar reaction with N-acetyl-β-(3-methoxy-2,6-dinitrophenyl)-D,L-alanine, using 0.3 g. of N-nitrosomethylurea, 3 ml. of ether and 2 ml. of dioxane. The product, after purification from methanol and drying in an evacuated desiccator over calcium chloride, melted at 172–173°, not depressed when mixed with crystals of the previously reported[1] isomer of N-acetyl-β-(3-methoxydinitrophenyl)-D,L-alanine methyl ester melting at 172–173°. Found: C, 45.78; H, 4.39.

Acknowledgments.—Indebtedness is expressed to Dr. William C. Alford and his associates of the Analytical Laboratory of this Institute for the microanalyses, to Mr. William Jones for the infrared spectra, to Dr. E. L. May for the gift of purified aluminum isopropoxide and to Dr. S. Black and Dr. R. C. Greene for advice on the paper chromatography of one of the compounds.

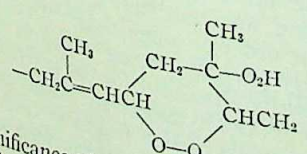
Chain Scission in the Oxidation of Hevea. IV. Low Molecular Weight Products from Dry Rubber

BY E. M. BEVILACQUA

RECEIVED DECEMBER 3, 1956

Estimates of yields of volatile products from the scission by oxygen of hevea rubber in latex[2] have been supplemented with measurements on dry rubber at 140°. The results make it possible to outline a mechanism for the scission reaction which accounts quantitatively for known products.

Some time ago Bolland and Hughes[1] deduced a structure (I) for the primary oxidation product of 1,5-dimethyl-1,5-dienes from the results of functional group analyses of partially oxidized squalene, oxidized under conditions of high chain length so that the primary product was obtained in high yield.



I

The significance of this result to the oxidation of hevea rubber was not known until quantitative estimates of the low molecular weight products of the oxidation of hevea in latex gave indirect evidence that a closely related structure must be formed in order to account for the observed products of the scission reaction.[2]

In latex the observed end-products, acetic acid, formic acid and carbon dioxide, are produced in stoichiometric ratios of 1:1:3. The yields relative to the production of new molecules by breaking the hydrocarbon chain show that six chain atoms appear as low molecular weight products at each scission.[3] A reasonable process involving six chain atoms in the scission reaction can be visualized readily by making use of a simple modification of the reaction mechanism postulated by Bolland and Hughes to account for I as a primary product. The important features of this mechanism are the ready addition of a peroxide radical to a double

bond when a six-membered ring can be formed and the mobility of allylic radicals.[3]

The volatile compound of highest molecular weight previously identified with the oxidation of natural rubber is levulinaldehyde.[4] Although no clearcut evidence has been published for the direct formation of this material during oxidation with molecular oxygen, it generally has been assumed to be the product formed during aging of rubber which reacts with ammonia to give a compound which exhibits a positive "pyrrole" test. The present paper offers evidence supporting this belief and leading further to the conclusion that it is a direct intermediate in the scission reaction, which arises from the decomposition of a peroxide formed by the general process outlined by Bolland and Hughes.

Experimental

The molar ratio of volatile products from the oxidation of rubber to oxygen consumed is a function of temperature[2,3] approaching equivalence above 130°. In order to take advantage of this effect to obtain maximum yields of low molecular weight compounds, an apparatus was set up to permit experiments at elevated temperatures and to remove the volatile products from the reaction site as rapidly as possible.

In this apparatus the cell which contained the sample was mounted in a circulating air oven. The temperature was held constant to ±0.3°. In series with it were a trap immersed in a constant temperature bath and a gas circulating pump. The trap, outside the oven, was held at 0 or −80°, depending on what it was desired to collect. The pump, in the oven, was constructed according to the design of Cockett[5] modified only in that all moving parts in contact with the hot oxygen were of Teflon. A group of gas burets connected in parallel external to the cell were used to measure volume changes. They were surrounded by jackets in which water at 38° was circulated continuously during an experiment. All connections between parts not inside the oven or constant temperature baths were of capillary tubing to keep the volume subjected to uncontrolled temperature fluctuations as small as possible.

Pressure in the system was maintained constant during an experiment by periodic manual adjustment in which oil ("Hyvac" oil-93050) was added to the buret until a reference manometer containing a silicone oil (DC350) showed no head. The reference pressure was established in a sealed cell having nearly the same volume as the sample cell and mounted beside it in the oven. The volume of oil added was taken to be a direct measure of the volume of oxygen disappearing from the system by absorption in the sample. The oil, at 38°, absorbed oxygen at a negligible rate compared with the sample at 140°.

Low molecular weight products were recovered in the traps. The problem of quantitative recovery of very small amounts of products from large volumes of fast moving gas in one pass so that no product re-enters the oven, without raising the pressure drop in the apparatus, still has not been solved in a completely satisfactory way. However, the results indicate that nearly quantitative recovery of important products has been achieved. To trap acid gases two absorbers in series were used designed to give a high gas–liquid interface with a low resistance to flow. They were partially filled with standard alkali and held at 0° during a run. They were followed by a simple U-tube immersed in a Dry Ice–acetone-bath to remove water from the gas stream. In experiments in which it was attempted to estimate levulinaldehyde, this sequence of traps was replaced by a single small H-shaped trap cooled in a Dry Ice–acetone mixture.

Oxidized rubber samples were removed from the oven as soon as the desired amount of oxygen had been absorbed. They were cooled rapidly to room temperature in a stream of air or nitrogen, depending on how fast they absorbed oxygen. Intrinsic viscosities were determined in chloroform solution and molecular weights calculated on the basis of the relation determined by Carter, Scott and Magat,[6] as described previously.[2]

Results and Discussion

The first result using this apparatus was the observation that the condensate obtained in a trap held at −80° (from the gas stream passed over a sample in the oven at 140°) gave a strong positive test when heated with ammonium acetate, and the vapors were tested for pyrrole according to the procedure of Bruni.[4] The first few experiments were erratic and results depended on sample source and preparation. When a method for sample preparation was devised which gave consistently high yields of this product, as judged qualitatively, an effort was made to obtain quantitative determination.

It was assumed that the material is levulinaldehyde; no good quantitative test for this aldehyde is known. Although optical methods for carbonyl compounds based on the formation of the dinitrophenylhydrazone have been reported in the literature to give good results in the concentration range encountered here, they will not differentiate between aldehydes, and in our hands the results for other carbonyl compounds have not been nearly as satisfactory as could be desired at low concentrations. Since no other low molecular weight methyl ketone is suspected to be a probable product from the oxidation of rubber under our conditions, it was attempted to apply the iodoform reaction[7] for the quantitative estimation of levulinaldehyde in the volatile material collected in the trap. When this was done the results shown in Table I were obtained. In this and the other tables and figures in this report where units are not specified they are moles per 10^5 grams of rubber. Plotting the values of methyl ketone against "cuts" from this table we obtain Fig. 1. It is evident that a linear correlation exists between volatile methyl ketone, presumably levulinaldehyde, and cuts of the hydrocarbon chain, and that they are formed in amounts of the same order of magnitude. This observation immediately permits closing a gap in the mechanism originally advanced for the reaction by which oxygen severs the hydrocarbon chain,[2] in which the nature of the five carbon fragment from which low molecular weight products are formed was entirely

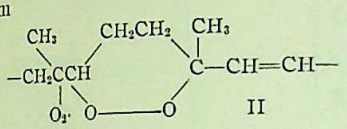
hypothetical. Levulinaldehyde clearly can be the source of both the acetic acid and the carbon dioxide found in the experiments in which rubber was oxidized in latex. The complete mechanism has been outlined elsewhere[3]; it gives a satisfactory explanation for all the known low molecular weight products of the oxidation of rubber, although details of certain steps still need to be worked out. It requires that each scission be accompanied by the loss of six carbon atoms from the hydrocarbon chain, the key intermediate having a structure of the form



II

Upon scission the entire material in the six-membered ring of the peroxide dissociates from the chain, giving as the first stable product levulinaldehyde. When the rubber is oxidized as latex, the aldehyde is trapped in the aqueous phase and rapidly oxidized to CO_2 and acetic acid.[2] Although this step has not been demonstrated experimentally, the readily available levulinic acid does undergo rapid oxidation in dilute aqueous ammonia solution under the same conditions as were used in the latex experiments, giving the theoretical yields of carbon dioxide and acetic acid.

Results of typical experiments are given in Table II. In these the acid[8] (98.1% levulinic acid

TABLE II

PRODUCTS OF LEVULINIC ACID OXIDATION

Oxygen consumed (mmoles)	Produced CO_2 (mmoles)	acid (meq.)	$\frac{CO_2}{acid}$
..	6.59	2.41	2.75

by titration) was oxidized at 90° as a 0.227 *N* solution in 2% ammonia containing a small amount of added copper. The apparatus and procedure have been described.[2] Acetic acid was identified by its volatility and characteristic odor and confirmed by partition chromatography on silica and by X-ray comparison of its silver salt with an authentic specimen.[9] These results correspond to substantially quantitative oxidation of the acid

$$CH_3CCH_2CH_2CO_2H \longrightarrow CH_3CO_2H + 3CO_2\ (+H_2O)$$

No other acids were identified among the products of these experiments, although the oxidation presumably must involve others as intermediates.

In the experiment described here the yield from the oxidation of dry rubber of approximately one-third mole of methyl ketone per mole of scissions is presumably a measure of the efficiency with which levulinaldehyde was removed from the reaction zone before it could undergo further oxidation. If this is so, the low molecular weight acids found as products of latex oxidation should also appear in this experiment, and if quantitative recovery can be obtained it should be possible to calculate roughly the amounts which will be found: One scission is

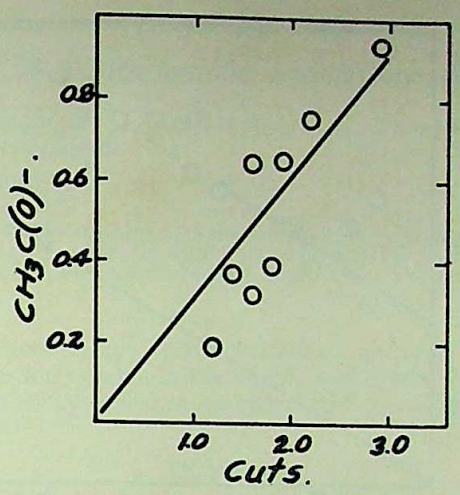

Fig. 1.—Volatile methyl ketone (levulinaldehyde) formed during oxidation of rubber at 140°.

equivalent to one levulinaldehyde plus one formaldehyde which yield as the completely oxidized end products three CO_2 plus one acetic acid from the first aldehyde and one formic acid from the second. Since one-third of the levulinaldehyde is removed as such, the final yields of CO_2 and volatile acids should be

$$CO_2 \approx 2/3 \times 3 = 2 \text{ moles/mole scissions}$$

$$\text{Volatile acid} \approx 2/3 \times 1 + 1 = 1.7 \text{ moles/mole scissions}$$

Experimental results of such determinations are assembled in Table III for the same type of rubber

sample which was used to obtain the results of Table I. When the data of Table III are plotted for comparison with predicted values based on the calculations in the preceding paragraph, the yields of CO_2 and volatile acid are of the expected order of magnitude, although the scatter of the points for CO_2 is undesirably high and the acid yields are somewhat low. Although we can attribute part of the scatter to simple experimental error in separating and measuring the very small quantities of acids obtained from the necessarily small samples of rubber, the results shown in the next Fig. 2 and 3 indicate that fairly good precision can be obtained and some of the differences between prediction and experimental results are real and must be accounted for. The data presented in Fig. 1 and in Table III were obtained by the oxidation of rubber which was coagulated on a form from whole latex and then leached with boiling water for 2 hr. Data

solid lines have theoretical slopes. It is apparent that spuriously high yields of carbon dioxide are formed, probably resulting from [illegible]

bility of serum acids present in the unleached rubber. Presumably the scatter of the CO_2 results in Table III is attributable to incomplete removal of acids in the leaching process. On the other hand, the yields of volatile acids in this experiment are reasonably self consistent and about the same as in the previous one.

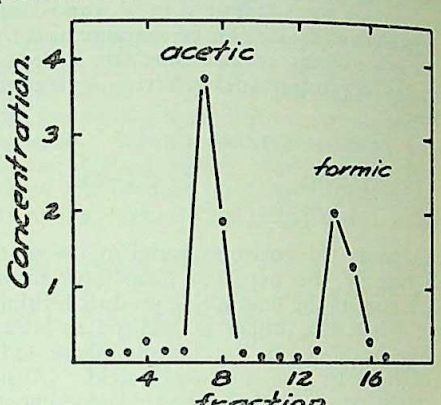

Fig. 4.—Separation of volatile acids on silica column; areas under peaks are proportional to concentrations.

Our calculations are based on the assumption that all the formic acid normally produced when latex is oxidized is formed in the present experiment also and that only the acetic acid yield is lowered by sweeping out the cell with gas. When the mixture of volatile acids actually obtained was analyzed by separation on a silica column, it was found that acetic acid is present in concentrations which are equal to or greater than that of formic acid (Fig. 4). The material which still remains to be accounted for, therefore, is formic acid or a precursor thereof.

Several explanations have been considered for the low apparent yield of formic acid, which has not been resolved experimentally. If formic acid were rapidly oxidized, CO_2 yields should be consistently high. This is not definitely excluded by our data but appears unlikely. If a non-acid intermediate (presumably formaldehyde) were distilled from the reaction cell, yields would be low. Formaldehyde has been found in the distillate, but it accounts for only about 10% of the missing formic acid. The results of end-group determinations[10] suggest that under the conditions used in these experiments about half the carbon from which formic acid is derived during oxidation of latex remains with the polymer, rather than appearing as a volatile product.

In summary, the results reported here, together with those reported previously, show that there is no significant change in the mechanism of degradation of rubber by oxygen over a wide temperature range. The over-all mechanism appears to be well established and able to account for the variations in product ratios caused by changing experimental conditions. Only the details of the final steps in the scission process remain to be clarified.[11]

Azomethine Dyes. II. Color and Constitution of Acylacetamide Azomethine Dyes

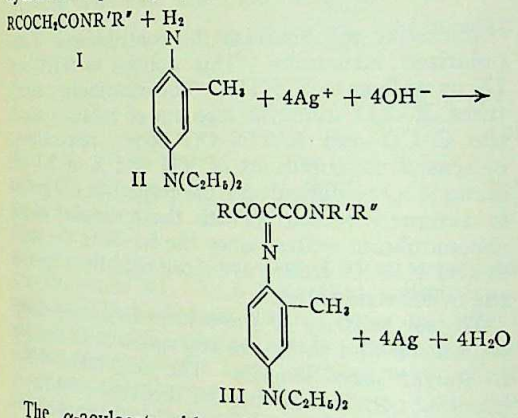
BY G. H. BROWN, J. FIGUERAS, R. J. GLEDHILL, C. J. KIBLER, F. C. MCCROSSEN, S. M. PARMERTER, P. W. VITTUM AND A. WEISSBERGER

RECEIVED JULY 2, 1956

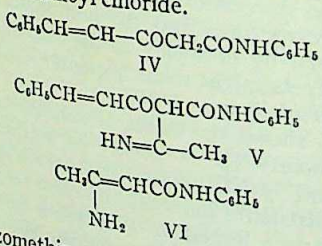
The synthesis and properties of a number of α-acylacetamides and the azomethine dyes derived from them are reported. The azomethine dyes are formed by oxidative condensation of the α-acylacetamides with 4-amino-3-methyl-N,N-diethylaniline. The effects of substituents and of changes in solvent on the absorption spectra of these dyes are interpreted on the basis of electronic and steric factors and hydrogen-bonding.

Introduction

A preceding investigation[1] dealt with the relation between color and structure of some magenta azomethine dyes derived from 5-pyrazolones. The present paper is concerned with a similar study of azomethine dyes (III) derived from acylacetamides, which are widely used as yellow-image dyes in color photography.[2]



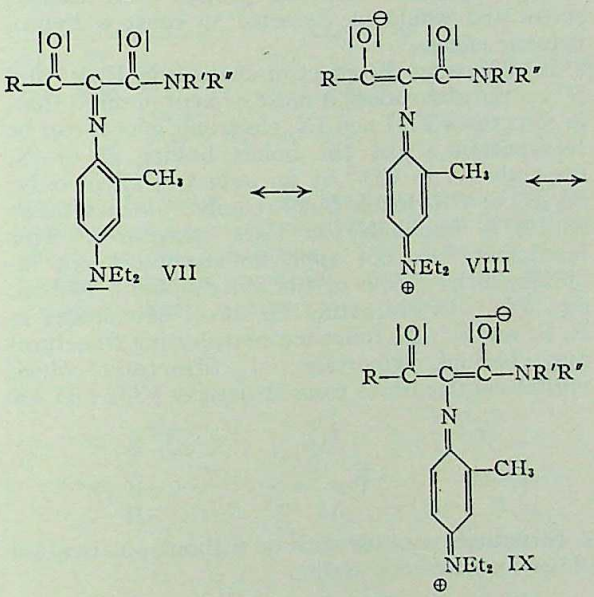
The α-acylacetamides (I) were prepared by condensing β-ketoesters with amines in boiling xylene.[3] Some vinylogs, *i.e.*, α-cinnamoylacetanilides (IV), not accessible in this manner, were prepared by solvolysis of iminoacyl compounds (V)[4] formed by acylation of β-aminocrotononanilides (VI) with cinnamoyl chloride.



The azomethine dyes (III) were prepared from the acylacetamides (I) and 4-amino-3-methyl-N,N-diethylaniline (II), using potassium ferricyanide (method A) or silver chloride (method B)[5] as the oxidant. The dyes were purified by chromatography and crystallization, and their absorption spectra in the visible region were determined in cyclohexane, *n*-butyl acetate and methanol.[6]

Discussion

Position of the Absorption Maximum.—The absorption in the visible region by the dyes under consideration can be attributed essentially to the resonance system VII, VIII, IX. Structure VII can be expected to make the preponderant con-



tribution to the resonance hybrid representing the ground state; it differs from the other major contributing structures VIII and IX by the aromaticity of the *p*-phenylenediamine moiety and by the absence of charge separation. When absorption of visible light or near-ultraviolet radiation raises the molecule to a higher-energy level, the polarized (ionic) structures VIII and IX make larger contributions to the excited state.[7] Structural changes which render the polarized structures more stable therefore decrease the energy difference between the ground and excited states and would be expected to cause a bathochromic shift. Structural changes which destabilize the polarized structures

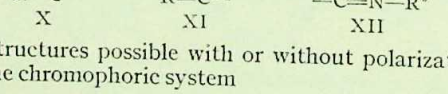
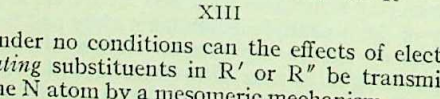
or stabilize the non-polarized structure increase the energy difference between ground and excited states and would be expected to cause a hypsochromic effect.

In discussing the effect of changes in R, R′ and R″ on the absorption, it must be kept in mind that, in structures VIII and IX, electronic effects can be transmitted across the bonds linking R or N, respectively, to $CO^{\ominus}$ by an inductive effect only; an RC or CN double bond required for mesomeric effects is impossible in these structures. This restriction does not apply to structures not involving polarization of the chromophoric system, *e.g.*, VII. In evaluating the effect of changes in R, R′ and R″, the following contributing structures may become important: 1. Structures which inhibit contributions from structures VIII and IX



X XI XII

2. Structures possible with or without polarization of the chromophoric system



XIII

Under no conditions can the effects of electron-*donating* substituents in R′ or R″ be transmitted to the N atom by a mesomeric mechanism.

Increased contributions by structures XII and X or XI will lower the energy of the ground state, interfere with contributions from structures VIII and IX and cause a hypsochromic effect. Increased contributions by structures X or XI will cause a shift in the same direction, although in one case electron-donating and in the other case electron-accepting substituents are involved.

Figure 1 shows the crowding of the dye molecule. For maximum interaction of the structures which contribute to a resonance hybrid, coplanarity of the groups connected by bonds with double-bond character is required; steric hindrance of coplanarity will diminish the contributions of the polarized structures. This applies to VIII and IX as well as to X–XIII. The contributing structures X–XII diminish freedom of rotation about the C–CO and R′R″N–CO bonds, respectively; increased contributions of XII and X or XI will make it more difficult for the respective CO groups to assume coplanarity with the remainder of the chromophoric system since the bonds to the bulky R and NR′R″ groups are more rigid than those in the other structures.

Higher polarity of the solvent facilitates charge separation and shifts the absorption of all the dyes to longer wave lengths. The magnitude of this effect is correlated with the dielectric constant of the solvent ($\epsilon_{25°}$ = 2.02 for cyclohexane, 4.94 for butyl acetate, 32.6 for methanol); its mechanism can be visualized as solvation in which neutralization of electric fields by oriented solvent dipoles and/or hydrogen-bonding play a role.

In the following interpretation of the spectra, restraint is exercised because the number of contributing structures and the additional complications caused by crowding of the molecule and by solvent effects might make a greater elaboration of details too arbitrary.

Table I shows the effect of substituents in the benzoyl moiety (R = aryl). In methanol, *p*-Cl, *m*-NO_2 and *p*-NO_2 have bathochromic effects; these substituents decrease the electron density at the ring carbon linked to –CO, which may increase the contribution of VIII and lower the energy of the excited state. The bathochromic effect of *p*-Cl is small; the mesomeric electron-donating nature of chlorine will increase the contribution of X, an effect which, by itself, would cause a hypsochromic shift. In cyclohexane and in butyl acetate *p*-NO_2 has a small hypsochromic effect, as have *o*- and *p*-methoxy and *p*-NH_2. This indicates increased contributions of X or XI under the influence of these groups. In methanol, the electron-attracting effect of NO_2 appears to be increased, probably by hydrogen-bonding of the NO_2 group [illegible] so that the greater stabilization

of VIII outweighs the effect caused by an increased contribution of XI. 2,4,6-Trimethyl substitution has a large bathochromic effect. Since the effect of mono-*o*-methyl substitution is small, we are inclined to ascribe the large bathochromic effect to steric causes. Steric interference with coplanarity of the chromophoric system would result in decreased stability of VIII and should therefore cause a hypsochromic shift. If, however, the steric interference reduces the contribution of X, the CO group will be freer to become coplanar with the rest of the chromophoric system (Fig. 1), and the bathochromic effect observed should result.

Replacement of benzoyl by acetyl (Table IIA) does not change λ_{max}, indicating a similar stabilization of structure X, by C_6H_5 and by CH_3, in which probably hyperconjugation of CH_3 plays a role. A very small hypsochromic shift by cinnamoyl (Table IIB) in cyclohexane solution may be attributed to a reduction in steric hindrance for structure X. Solvation of the vinyl system in butyl acetate may render it electron accepting and explain the bathochromic effect. *o*-Methoxy substitution in the cinnamoyl ring, as in the benzoyl derivative, results in a shift of λ_{max} to shorter wave lengths.

Substitution in the anilide ring (III, R′ = aryl) follows a similar pattern (Table III); electron-attracting groups, acting to stabilize structures XIII and to destabilize structure XII, will favor structure IX and produce bathochromic effects. Electron-donating groups (*o*- and *p*-methoxy and dimethylamino) cause very small hypsochromic shifts. At variance with substitution in the benzoyl ring, an electron-attracting substituent in the anilide ring will never interfere with polarization of the chromophoric system but will enhance it through lowering of the electron density of the amide nitrogen. One methyl group has little or no effect on the absorption. Two *o*-methyl or *o*-methoxy groups, however, cause strong hypsochromic effects, presumably because they destabilize for steric reasons structures XIII and, therefore, increase the relative contribution of structure XII.

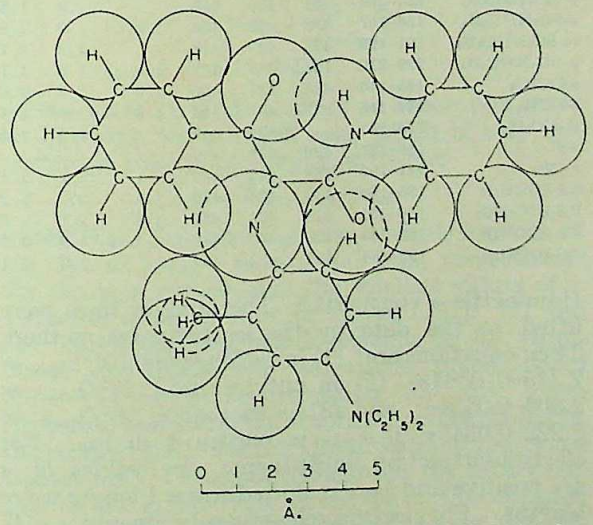

Fig. 1.—Scale drawing of α-benzoyl-α-(4-diethylamino-2-methylphenylimino)-acetanilide. The covalent bond radii and van der Waals' radii are those given by Pauling, "Nature of the Chemical Bond," Cornell Univ. Press, Ithaca, N. Y.

Hammett's σ-constants.[8] The straight lines were fitted to the data by the least-squares method. Their equations are: (1) in cyclohexane, $10^3/\lambda_{max} = 2.345–0.0564\sigma$; (2) in butyl acetate, $10^3/\lambda_{max} = 2.304–0.0554\sigma$; and (3) in methanol, $10^3/\lambda_{max} = 2.222–0.0345\sigma$, if λ_{max} is measured in mμ. For electron-attracting substituents, the values of σ are positive and λ_{max} is shifted toward longer wave lengths. For electron-releasing substituents, $\sigma < 0$, and λ_{max} shifts toward smaller values.

The marked hypsochromic effect on replacement of the phenyl ring in the anilide derivative by a methyl group or hydrogen (Table IIA) indicates that the phenyl ring acts as an electron acceptor; compared with methyl or hydrogen, phenyl stabilizes structures XIII and therefore increases the stability of structure IX. N-Methylation has a strong bathochromic effect. In view of the proximity of the amide hydrogen to the oxygen of the RCO group shown by Fig. 1, one might assume hydrogen bonding between amide hydrogen and carbonyl oxygen. Such hydrogen bonding should, however, stabilize VIII, and elimination of the chelation should cause a hypsochromic shift. The bathochromic shift observed can be explained by a decreased contribution of structure XII because of steric hindrance. It is noteworthy that the absorption of the methylanilide dye is very similar to that of the dibenzoylmethane dye, indicating a large reduction in the methylanilide dye of the contribution of structure XII.

The effects of substituents on both phenyl nuclei are roughly additive, as shown by Table IV.

It should be mentioned that geometrical isomerism about the C=N bond, if it should exist,

would influence some of the steric effects just discussed. Our observations, however, do not demonstrate the presence of this geometrical isomerism.

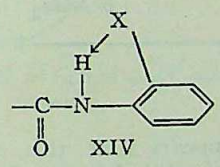
Extinction and Shape of the Absorption Curves.—Chemical constitution is better understood in its effect on the position of the absorption maximum than in its effect on extinction and shape of the absorption curve. These parameters are, however, of great importance in color photography, and some correlations can be made. The maximum extinction coefficient, ϵ_{max}, of a dye depends on the probability of the corresponding electronic transitions. Among the factors which determine this probability are the change in dipole moment accompanying the transition and the ability of the molecule to adopt the planar conformation required for excitation.[9] The change in dipole moment is not known from other data, but an effect of structural change on ϵ_{max} can be recognized, depending upon whether that change hinders or facilitates the adoption of a planar conformation of the molecule.

The anilide ring in the aroylacetanilide dyes has an intensifying (hyperchromic) effect on the absorption; ϵ_{max} of the benzoylacetanilide dye (Tables I and III) is about 20% larger than that of the benzoylacetamide dye (Table IIA). Introduction of two *o*-methyl groups in the anilide ring, however, more than obliterates this effect; the extinction coefficient of the dye from α-benzoyl-2,6-dimethylacetanilide (Table III) is lower than that of the benzoylacetamide dye and the absorption is broadened. Steric interference of the two *o*-substituents will diminish the contribution by XIII, and the electron-donating nature of methyl will stabilize XII. The latter structure is antagonistic to IX, and the observed hypochromic (and hypsochromic) effect of the *o*-methyl groups can be expected since the transition to the excited state is rendered more difficult.

N-Methylation of the anilide dye causes a hypochromic effect in cyclohexane and in butyl acetate solution, but increases the extinction coefficient in methanol (λ_{max} in all solvents is shifted to longer wave lengths). The methyl group can be expected to interfere sterically with structure XII. This will increase the relative importance of IX in agreement with the bathochromic effect observed in all three solvents and the hyperchromic effect in methanol. The hypochromic effect in the less polar solvents is not understood.

(9) E. A. Braude, F. Sondheimer and W. F. Forbes, *Nature*, **173**, 117 (1954).

Polar substituents in the anilide ring have a hyperchromic effect in cyclohexane, but the magnitude of the effect diminishes as the polarity of the solvent is increased, except in the case of *o*-substituents. Figure 2 shows that the relative effects of *m*- and *p*-substitution on λ_{max} are greater in butyl acetate or cyclohexane than in methanol, which may be connected with the proton-donating nature and the polarity of the alcohol. *o*-Substituents with lone pairs of electrons should stabilize a more nearly planar conformation[10] through hydrogen bond formation with the adjacent amide group, as shown in structure XIV. Similar chelation has been proposed by Ungnade[11] to explain certain features of the ultraviolet absorption spectra of substituted acetanilides. This chelation seems to make these substituents less susceptible to disturbances by the solvent as shown by the large hyperchromic effect in methanol (Table III).



XIV

As a measure of the slope of an absorption curve on the long wave length side, which is very important in color photography, we define

$$s = D_{(max + 60)}/D_{max}$$

where $D_{(max + 60)}$ and D_{max} are optical densities of the dye at $\lambda_{max} + 60$ mμ and λ_{max}, respectively; the sharpest curves have the smallest values of *s*. Values of *s* are reported in Tables I, IIB, III and IV. Since the band width depends on the vibrational and rotational transitions superimposed upon the electronic transition for any given electronic transition, the absorption curve should be the steeper, the fewer the vibrational and rotational transitions. Those substituents in the *ortho*-position of the anilide ring which form the chelated structures XIV should therefore narrow the absorption band and give smaller values of *s*. This is shown in Table III by the *s*-values for methanol solutions of the *o*-halo, *o*-alkoxy and *o*-alkylamino compounds. The effect is less pronounced for solutions in butyl acetate and absent in cyclohexane. The band widths and values of *s* are larger in the more polar solvents, presumably because solvation of the dye introduces new infrared fre-

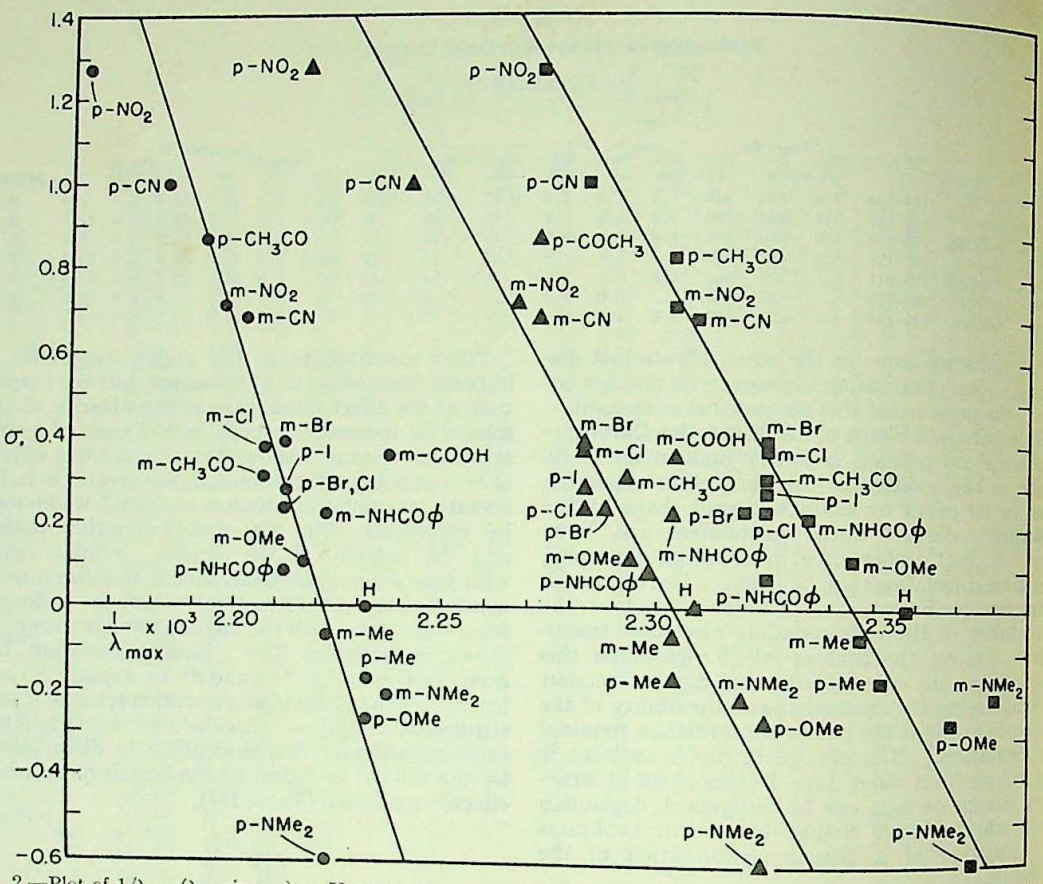

Fig. 2.—Plot of $1/\lambda_{max}$ (λ_{max} in mμ) *vs.* Hammett's σ-constants for azomethine (III) dyes substituted in the anilide ring; solvents: ■, cyclohexane; ▲, butyl acetate; ●, methanol.

quencies. It appears that this solvation does not interfere with the chelation XIV. It would be difficult to understand, however, why the chelating substituents do not cause an increase of sharpness of the dyes in cyclohexane, unless the chelation itself interferes with the solvation in methanol, *i.e.*, solvation takes place on the acetamido group.

Experimental

The requisite β-ketoesters were synthesized by previously described methods (see Table VA for references). **Anilines** needed for condensation with the β-ketoesters were generally prepared by low-pressure hydrogenation of nitro-compounds over Raney nickel rather than by the chemical methods of reduction given in the reference of Table VB. 2,4-Dimethoxyaniline[12] was obtained by hydrogenation of 2,4-dimethoxyazobenzene. *o*-Fluoroaniline was prepared by degradation of *o*-fluorobenzamide with sodium hypobromite. This reaction has been reported not to occur,[13] but gave good yields when carried out in the presence of a wetting agent (Nekal A).

***o*-Fluoroaniline from *o*-Fluorobenzamide.**—A mixture of 13 g. (0.09 mole) of *o*-fluorobenzamide and 0.5 g. of Nekal A wetting agent was added, with good stirring, to a solution containing 15 g. (0.37 mole) of sodium hydroxide and 15 g. (0.09 mole) of bromine in 325 ml. of water. The addition was carried out at room temperature, and stirring was continued at this temperature for 30 min. after addition. The mixture was heated at 70° (over a steam-bath) for 1 hr. The product was removed from the reaction mixture by steam distillation until 65 ml. of distillate was obtained, at which point 25 ml. of 40% sodium hydroxide solution was added, and steam distillation was resumed until a total volume of 200 ml. of distillate had been collected. The organic material in the distillate was extracted with benzene (100 ml. plus 2 times in 50 ml.). The combined extracts were washed with water and dried over magnesium sulfate. Fractional distillation gave 8 g. (77%) of product; colorless oil, b.p. 169–170°.

Aroylacetanilides (Tables VA, VB and VC) were prepared by condensation of equimolar amounts of β-ketoester and aniline in boiling xylene.[3,14]

Amino-substituted aroylacetanilides obtained by hydrogenation of the corresponding nitro compounds in ethanol over Raney nickel at two or three atmospheres hydrogen pressure were converted to amides with acid chlorides in sodium acetate–acetic acid solution.

Cinnamoylacetanilides (Table VI). A. Synthesis of Aminocrotonanilides.—**β-Aminocrotonanilide** and **β-amino-2-methoxycrotonanilide** were prepared by the method of Knorr[15] by reaction of acetoacetanilide and acet-*o*-anisidide, respectively, with concentrated aqueous ammonia in ethanol. The yield of β-aminocrotonanilide, m.p. 145–146° out of alcohol, was 93%. β-Amino-2-methoxycrotonanilide separated as an oil, which solidified after standing 15 months; m.p. 60–62°, yield 76%.

B. Acylation of the Crotonanilides. α-Cinnamoyl-α-(1-iminoethyl)-acetanilides (V).—The procedure of Benary and Kerckhoff[4] was employed. **α-Cinnamoyl-α-(1-iminoethyl)-acetanilide**, bright-yellow prisms, m.p. 200–201° out of

collected on a filter, washed with dilute sodium bicarbonate solution and recrystallized from 50 ml. of 95% ethanol with the addition of Darco. After washing with cold alcohol, the material was recrystallized again from alcohol to give 2.5 g. (38% yield) of pale-yellow product, m.p. 107–108°. Subsequent runs gave 17–22% yields of the anilide.

The other anilides in Table VI were prepared from the corresponding imines in the same manner.

Preparation of the Azomethine Dyes (III) (Tables I–IV).

General Procedure.—Method A is carried out as follows: In a 1-l. beaker equipped with a stirrer was placed a solution of 0.01 mole of aroylacetanilide in 200 ml. of 95% ethanol. A solution of 5 g. of sodium carbonate in 50 ml. of water was added, followed by 0.011 mole (2.35 g.) of 4-amino-3-methyl-N,N-diethylaniline hydrochloride in 50 ml. of water. To the stirred mixture was added a solution of 0.04 mole of potassium ferricyanide in 100 ml. of water. Stirring continued for 15 min., and the dye was extracted with 250 ml. of ethyl acetate. The extract was washed several times with water and the solvent removed *in vacuo*. The residue was purified by chromatography over Doucil, with benzene or a mixture of ligroin (b.p. 60–90°) and acetone for development and elution; yield of dye 30–60%.

Method B, the use of silver chloride as the oxidant for preparation of the dyes, has been described previously.[5] The absorption spectra of the azomethine dye solutions, 8×10^{-5} molar concentration, for a 1-cm. thick sample against a water blank, were obtained with a General Electric recording spectrophotometer, using a constant spectral band width of 8 mμ.

Acknowledgment.—The authors thank Mr. E. E. Richardson, of these Laboratories, for the spectrophotometric curves.

The Bromodesulfonation of Aromatic Sulfonate Salts. I. Sodium 3,5-Dibromo-4-hydroxybenzenesulfonate[1]

BY LAWRENCE G. CANNELL[2]

RECEIVED DECEMBER 20, 1956

The reaction of bromine with sodium 3,5-dibromo-4-hydroxybenzenesulfonate (I) to give tribromophenol has been studied in aqueous solution at 25.0°. Ultraviolet and visible spectra show that the reactants combine immediately to give a reaction intermediate which has a 2,6-dibromo-2,5-cyclohexandien-1-one structure. Kinetics (measured iodometrically) give additional support to a mechanism (eqs. 4 and 5) comprised of the formation of the intermediate and Br^- in a fast reversible step which is followed by the first-order decomposition of the intermediate in a rate-determining step. Specifically, the kinetics are zero order in whichever reactant, bromine or I, is in excess and first order in the other. The equilibrium of the first step greatly favors the formation of the intermediate, but the reverse reaction can be demonstrated both kinetically and spectrophotometrically when sodium bromide is added. The significance of these results in regard to the mechanism of electrophilic aromatic substitution is discussed.

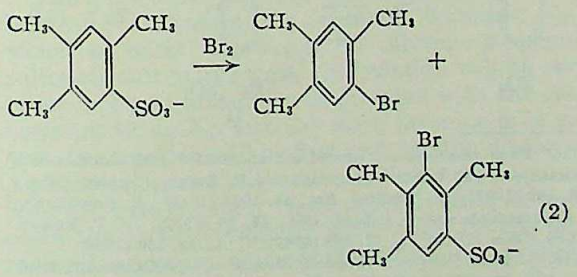
The bromodesulfonation reaction (eq. 1) has been investigated by measuring its reaction kinetics. Previous investigators have found that the reaction is greatly facilitated by amino, methoxy,

$$Br_2 + ArSO_3^- + H_2O \rightarrow ArBr + HSO_4^- + HBr \quad (1)$$

hydroxy or alkyl substituents *ortho* or *para* to the sulfonic acid group, but that these substituents in the *m*-position do not promote bromodesulfonation.[3-7] The reaction, then, appears to be an example of electrophilic aromatic substitution.

Comparable reactions have been reported with chlorine as a desulfonating agent,[8] but molecular iodine does not give the reaction.[9]

That the bromodesulfonation reaction does not proceed by a free-radical mechanism is indicated from the reaction with alkylbenzenesulfonate salts. Here bromination occurs on the aromatic ring and not on the side chain where it would be expected if the reaction takes place by a free-radical mechanism.[12]



(2)

In certain special cases the replacement of a sulfonic acid group by *chlorine* appears to be a free-radical reaction,[13] but these exceptions are charac-

(13) It was established by Kharasch and Eberly (1940) that, contrary to the claim of Eckert (*Ber.*, **58**, 313 (1925)), α- and β-anthraquinonesulfonic acids do not react with hydrochloric acid in the light to give the corresponding α- and β-chloroanthraquinones if oxygen is rigidly excluded from the system. However, if oxygen is present, the reaction studied by Eckert takes place readily. It was also established that, whereas water solutions of α- and β-anthraquinone sulfonic acids do not react with chlorine in the dark, a ready formation of the corresponding chloroanthraquinones takes place in the light. Results similar to the ones cited above have been obtained with anthraquinone-2,6-disulfonic acid. A free radical mechanism involving chlorine atoms has been postulated to explain these results. It was also established that bromine atoms do not replace sulfonic acid groups under the conditions cited above. A publication dealing with this topic in greater detail will appear shortly (private communication from M. S. Kharasch).

terized by the presence of electron-withdrawing substituents and usually require much more vigorous conditions.[14]

Many investigators, studying aromatic substitution reactions wherein hydrogen is replaced, have interpreted their results in terms of quinonoid intermediates or transition states.[15] In particular, Melander cited such intermediates to account for the isotope effects in the nitration and sulfonation of benzene,[16] and Zollinger[17] has found evidence for their existence by studying the effect of base on diazonium coupling reactions.[17,18] Grovenstein and Henderson recently have reported, in a kinetic investigation of the bromodecarboxylation of dibromo-*o*- and -*p*-hydroxybenzoic acids to give 2,4,6-tribromophenol, that the rate dependence on (Br^-) strongly suggests that there is a quasi-stable quinonoid intermediate which can react with bromide ion to give starting materials.[19]

In the present work, the bromodesulfonation of sodium 3,5-dibromo-4-hydroxybenzenesulfonate (I) was investigated, and in a subsequent paper the bromodesulfonation of various other aromatic sulfonate salts will be discussed.[20] The findings presented in this paper show that I reacts with bromine according to the scheme[21,22]

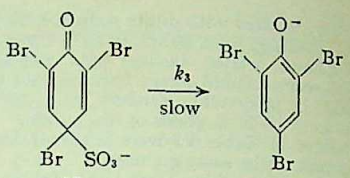
(19) E. Grovenstein, Jr., and U. V. Henderson, Jr., THIS JOURNAL, **78**, 569 (1956). Their argument has been further strengthened by isotopic fractionation work; see E. Grovenstein, Jr., and G. A. Ropp, *ibid.*, **78**, 2500 (1956).

(20) L. G. Cannell, THIS JOURNAL, **79**, 2932 (1957).

(21) Datta and Bhoumik (ref. 3) have reported that I and an equal molar amount of bromine give a quantitative yield of 2,4,6-tribromophenol.

(22) The scheme shows bromination taking place with the phenoxide anion rather than with the phenol, although experiments have not yet shown this directly. Evidence has been found[19] that ionization of the phenol precedes the bromodesulfonation of sodium 4-hydroxy-3,5-dinitrobenzenesulfonate. Also, Grovenstein and Henderson[19] found that the rate of bromodecarboxylation of 3,5-dibromo-4-hydroxybenzoic acid is inversely proportional to $(H^+)^2$ and concluded that bromination occurs after the loss of two protons.



(5)

$$SO_3 + H_2O \longrightarrow H_2SO_4 \qquad (6)$$

The intermediate II is sufficiently stable that it can be detected spectroscopically. Kinetic and spectroscopic evidence confirm the presence of the equilibrium involving bromide ion which is shown in eq. 4, and the kinetic study indicates strongly that the rate-determining step is the unimolecular decomposition of the quinonoid, II.

Results

When dilute aqueous solutions of the dibromo-*p*-phenolsulfonate I and bromine were mixed, the bromine color disappeared immediately even at 0°; however, the immediate addition of iodide gave an iodine titer equal to that of the bromine originally used. Also, when compound I was mixed with an equal molar amount of bromine, the spectrum of I disappeared and an absorption peak appeared at 280 mμ (see Fig. 1). The peak height decreased slowly over a period of several hours, and the final spectrum closely resembled that of 2,4,6-tribromophenol. The iodine titer of the solution decreased with time. The kinetics were found to be first-order in bromine and zero-order in the dibromo-*p*-phenolsulfonate when the latter was in excess (see Table I). In a 0.15 *M* sodium bromide solution, the color of the tribromide ion appeared, and the rate of reaction was decreased by a factor of 1.6. When the dibromo-*p*-phenolsulfonate was in excess, the first-order rate constant, k_3, was equal to the slope of the line obtained by plotting ln (*B*) *vs.* *t* (where B is the iodine titer of the solution in moles/l. at time, *t*). The reproducibility of the rate constants were within 3%. The experiments were carried out at a constant ionic strength in order to avoid any interfering salt effect. The effect of ionic strength was not studied except to note that changes in the region 0.6 to 0.16 μ had little effect on the rate (see experiment 5).

With bromine in excess, the kinetics were found to follow the rate equation where A_0 is the initial concn. of I (see Table II). The data show the reaction to be zero order in bromine and first order in the dibromo-*p*-phenolsulfonate. Further work, which is discussed later in this paper, was undertaken in order to relate k_3 to k'.

$$(B_0 - B)/t = k'(A_0) \qquad (7)$$

Discussion

Spectral Measurements.—Spectral measurements provide not only evidence for a reaction intermediate but make it possible to assign the intermediate a 2,5-cyclohexadienone structure. Mixing an aqueous solution of sodium 3,5-dibromo-4-hydroxybenzenesulfonate (I) with an equal molar amount of bromine in water brought about the immediate disappearance of the bromine color. Also, the spectrum of I, which has only a

k' is defined by equation 7.

small amount of absorption at longer wave lengths than 230 mμ, is replaced by a spectrum having one large peak with a λ_{max} at 278–279 mμ (see Fig. 1). On the basis that all of the dibromo-*p*-phenolsulfonate has been brominated, the new compound has an ϵ of 11,400. That the compound actually is an intermediate was shown by the observation that the absorption at 279 mμ decreased over a period of several hours and finally the spectrum closely resembled that of 2,4,6-tribromophenol, the reaction product under these conditions.

The identity of the intermediate as the 2,5-cyclohexadien-1-one (II), with the chief absorption being due to a conjugated carbonyl group, was indicated strongly by comparison with spectra previously reported by other investigators. Price has shown that 2,4,4,6-tetrabromo-2,5-cyclohexadien-1-one (III) has a λ_{max} at 280 mμ with an ϵ of 9,700 in chloroform.[23] Elston, Peters and Rowe[24] reported that 2,4,6-tribromo-4-chloro-2,5-cyclohexadien-1-one has a λ_{max} at 275–280 mμ with an ϵ of 10,000, and Denivelle and Fort have made similar observations with other structurally similar compounds.[25] The spectral evidence then shows that the formation of the 2,5-cyclohexadienone (eq. 4) is fast and indicates that the desulfonation step is rate-determining.

Kinetic Measurements with Bromine and Excess Sodium Dibromo-*p*-phenolsulfonate.—Kinetic measurements both confirm the presence of a reaction intermediate and show that the rate-determining step is its decomposition. The addition of aqueous potassium iodide to a solution of the inter-

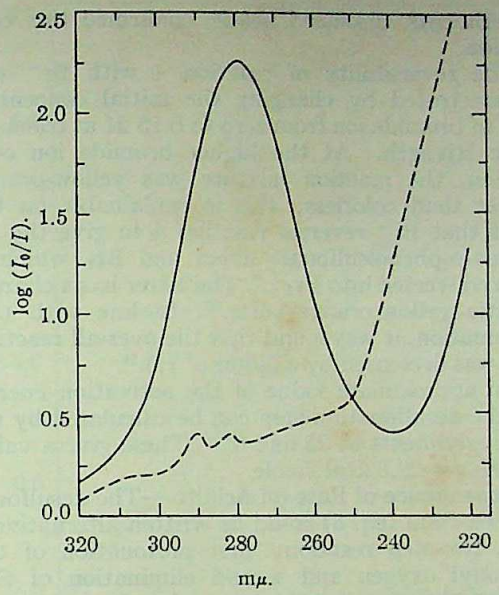

Fig. 1.—Ultraviolet spectra of quinonoid intermediate: ------, sodium 3,5-dibromo-4-hydroxybenzenesulfonate; ——, after mixing the sulfonate salt with an equal molar amount of Br_2 (taken in water at 25°).

mediate II, immediately after its preparation, liberated iodine quantitatively equal to the amount of bromine used. The amount of iodine liberated from aliquots of the reaction mixture decreased with time and so constitutes additional proof that there is a reaction intermediate. Thus it appears that iodide completely reverses eq. 4 to give iodine and I, and such an explanation is in accord with the accompanying change in the ultraviolet spectrum.[26]

The mechanism shown in eq. 4 and 5 predicts the following regarding the reaction kinetics: (a) when the initial amount of the dibromo-*p*-phenolsulfonate salt is in excess, the reaction will be zero order in I and first-order in bromine with the rate constant being k_3; and (b) when bromine is in excess, the reaction will be first order in the dibromo-*p*-phenolsulfonate salt and zero order in bromine with the rate constant being again k_3 since in both cases the rate-determining step would be the unimolecular decomposition of the intermediate quinonoid. The rates were followed iodometrically at 24.93 ± 0.02° Result (a) was kinetically verified; the initial ratio of the dibromo-*p*-phenolsulfonate salt I to bromine was varied from 2 to 15 and the first-order rate constant remained essentially constant as Table I shows. The value of k_3 is 5.51×10^{-3} min.$^{-1}$ and the intermediate has a half-life of 126 min.°. When the initial ratio of I to bromine was 15, the data followed a first-order rate law to 90% completion, but when it was 2 the first-order equation was followed only to 56% completion. This indicated that bromine was reacting further with the reaction product and subsequent

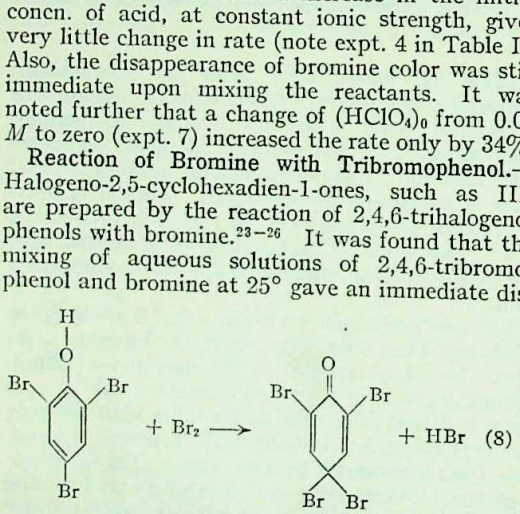
experiments, discussed below, confirmed this conclusion.

The reversibility of reaction 4 with Br^- was demonstrated by changing the initial concentration of bromide ion from zero to 0.15 M at constant ionic strength. At the higher bromide ion contration, the reaction mixture was yellow-orange rather than colorless; this is explainable on the basis that Br^- reverses reaction 4 to give the dibromo-*p*-phenolsulfonate anion and Br_2, which is then converted into Br_3^-. The latter has a characteristic yellow-orange color.[27] In line with this explanation, it was found that the over-all reaction rate was decreased by a factor of 1.6.[28]

An approximate value of the activation energy for the desulfonation step can be calculated by using experiments at 25 and 0°. These give a value of $\Delta H^{\ddagger} = 22.6$ kcal./mole.

Dependence of Rate on Acidity.—The desulfonation reaction (eq. 5) could be written alternatively as a two-step reaction: first protonation of the carbonyl oxygen and second elimination of SO_3 to give the phenol rather than the phenoxide ion. This mechanism is ruled out, however, by the observation that a threefold increase in the initial concn. of acid, at constant ionic strength, gives very little change in rate (note expt. 4 in Table I). Also, the disappearance of bromine color was still immediate upon mixing the reactants. It was noted further that a change of $(HClO_4)_0$ from 0.01 M to zero (expt. 7) increased the rate only by 34%.

Reaction of Bromine with Tribromophenol.—Halogeno-2,5-cyclohexadien-1-ones, such as III, are prepared by the reaction of 2,4,6-trihalogenophenols with bromine.[23-26] It was found that the mixing of aqueous solutions of 2,4,6-tribromophenol and bromine at 25° gave an immediate dis-



III

appearance of bromine color, appearance of a faint yellow color which could be attributed to III and appearance of an absorption max. at 279 mμ of $\epsilon = 8600$ (calculated by assuming complete reaction). The peak at 279 mμ, as discussed above, is due to the presence of the conjugated carbonyl of III. Therefore, reactions 4 and 8 are analogous in that both occur very rapidly at 25° and give a 2,5-cyclohexadien-1-one.

(27) In the ultraviolet region, Br_3^- has a large absorption peak at 267 mμ with an appreciable absorption at 279 mμ. When the reaction mixture was 0.15 M in NaBr, the spectrum showed a shift of the max. at 279 mμ to 276–278 mμ with an increase in absorption at 267 mμ. These observations are also in agreement with the above explanation.

(28) Since the analytical method gives the rate of the over-all reaction and the conversion of bromine to the intermediate 2,5-cyclohexadienone (II) was not complete at the outset of the reaction in 0.15 M NaBr, the smaller value of the rate constant serves only to show that the over-all reaction is slowed down and does not indicate a change in the value of k_1.

Kinetic Measurements with Excess Bromine and Sodium Dibromo-*p*-phenolsulfonate.—With bromine in excess the reaction kinetics are more complicated but give further support for the mechanism shown in eq. 4 and 5. All of the tribromophenol produced in reaction 5 would be converted into the tetrabromo-2,5-cyclohexadienone III in accord with equation 8. This alone, however, would not decrease the titer of the solution; nor would it decrease the concentration of the intermediate II; consequently, the rate of decomposition of the intermediate as determined by titration would be unchanged. Experimentally, however, it was found that more than twice the molar amount of bromine was consumed (per mole of the dibromo-*p*-phenolsulfonate salt initially present) and that the rate was much faster than that given by a first- or second-order expression. The data fit the empirical relationship given in eq. 7 and follow this straight line relationship beyond the point necessary for the consumption of two moles of bromine for one mole of dibromo-*p*-phenolsulfonate initially present (see Fig. 2). The data, given in Table II, show that doubling the concentration of I doubles the value of $(B_0 - B)/t$ but that doubling the amount of bromine has no effect on the rate.

The kinetics show that more reactions are occurring than those given in eq. 5 and 6, but as predicted by this reaction scheme, the rate is *zero order in bromine*. The initial rate of reaction follows eq. 7 wherein the concentration of I appears to the first power, and, therefore, the data support the further prediction of the mechanism scheme (eq. 5 and 6) that the rate should be first-order in sodium dibromo-*p*-phenolsulfonate. The one further prediction of the mechanism scheme is that k_3 will be the same whether I or bromine is in excess. In order to verify or disprove the latter, it was necessary to investigate the nature of the side reactions which become important when bromine is in excess and to find a way of comparing k' and k_3.

Decomposition of 2,4,4,6-Tetrabromo-2,5-cyclohexadienone (III) in Dilute Aqueous Solution.—Separate experiments showed that III decomposes in dilute aqueous solution to give at least two products.[29] The disappearance of III with time was followed by the decrease of iodine titer of the solution. For these experiments III was produced in aqueous solution by mixing aqueous solutions of bromine and tribromophenol at concentrations of 2×10^{-4} M or less. The ratio of the initial concentration of tribromophenol to bromine was varied from 4 to 0.5 (see Table III), and the initial concentration of III was varied by a factor of about 3.6. The reaction can be described approximately as being zero order with respect to whichever reactant (bromine or tribromophenol) is in excess and first-order with respect to the other reactant. Thus, over the range of concentrations studied, the reaction appeared to be first-order

(29) Grovenstein and Henderson[19] report that in a study of the bromodecarboxylation of 3,5-dibromo-4-hydroxybenzoic acid to give tribromophenol, the bromine consumption (as determined by the liberation of iodine with KI) after 256 hr. is just that calculated for the reaction of one mole of bromine. Therefore, under these conditions (in 80% acetic acid and 0.1 M HBr) there is no subsequent decrease in the iodine titer.

with respect to III. The kinetic relationship was followed to 60–70% reaction after which the rate increased. The rate constant for the decomposition of III was found to be 2.24×10^{-2} min.$^{-1}$ which is four times as great as that for the decomposition of quinonoid intermediate II. The identity of the products of the decomposition was not established; however, the end-point of the iodine titration indicated that at least two products were being formed. One product gave no reaction with iodide whereas the other product (pink in color) gave a slow reaction with iodide to give iodine. Thus, the immediate titration of a sample, after mixing with potassium iodide solution, required about one-third less sodium thiosulfate than that required if the solution were allowed to stand for 45 min. before titration; but further standing produced no additional increase in titer. The same instability of the end-point from titration was observed with the reaction of sodium dibromo-*p*-phenolsulfonate (I) with excess bromine. Here, for example, aliquots of the pink reaction solution, after standing alone for 15 hr., gave no immediate production of iodine; however, after 45 minutes, with iodide solution, the molar amount of iodine was equal to about one-third that of the initial amount of I. The first iodometric end-point was used to calculate the rate constants in Table III and to give the data in Table II which fit eq. 7.

Kinetic Analysis of the Complex System.—The following method was devised in order to obtain a method of comparing k' and k_3. The entire reaction scheme can be summarized as a four-step reaction series: reaction 4 followed by reactions 5 and 8 with the fourth step being the decomposition of the tetrabromocyclohexadienone III to give products, designated only as P_2, which do not give an immediate reaction with aqueous potassium iodide. With P_1 to represent tribromophenol, the scheme is

$$\begin{aligned} I + Br_2 &\xrightarrow{\text{fast}} II + Br^- \\ II &\xrightarrow[k_3]{\text{slow}} P_1 \\ P_1 + Br_2 &\xrightarrow{\text{fast}} III \\ III &\xrightarrow[k_4]{\text{slow}} P_2 \end{aligned} \qquad (9)$$

The sequence can be treated kinetically as a two-step first-order series reaction

$$I \xrightarrow{k_3} P_1 \xrightarrow{k_4} P_2 \qquad (10)$$

The decrease in the iodine titer with time ($B_0 - B$), is equal to ($P_1 + 2P_2$). Equations[30] giving the values of P_1/A_0 and P_2/A_0 as a function of time were used to calculate values of $(P_1 + 2P_2)/A_0$ by taking the values of k_3 and k_4 to be 5.51×10^{-3} min.$^{-1}$ and 2.24×10^{-2} min.$^{-1}$ (see Table III), respectively. A plot of $(P_1 + 2P_2)/A_0$ against time shows that this function gives an almost straight line having a slope of 7.0×10^{-3} min.$^{-1}$ between $(P_1 + 2P_2)/A_0$ equals zero to 0.88.[31]

(30) A. A. Frost and R. G. Pearson, "Kinetics and Mechanism," John Wiley and Sons, Inc., New York, N. Y., 1953, p. 153.

(31) Differentiation of the equations shows that the function goes through a maximum at $(P_1 - 2P_2)/A_0$ equal to 0.34 with a value of 7.3×10^{-3} min.$^{-1}$ but that in the region zero to 0.88 the average slope is about 7.0×10^{-3} min.$^{-1}$.

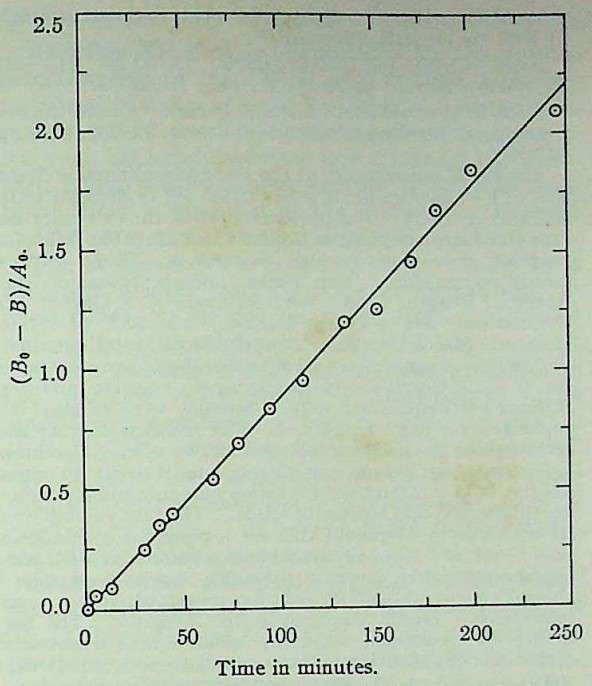

Fig. 2.—Reaction of sodium 3,5-dibromo-4-hydroxybenzenesulfonate with excess bromine; $A_0 = 1.20 \times 10^{-4}$ mole/l., $(Br_2)_0 = 5.23 \times 10^{-4}$ mole/l.

This calculated value is 16% lower than the experimental value for k' of 8.1×10^{-3} min.$^{-1}$ (the average of Table II). Because the experiments also show that there is an additional uptake of bromine which is not considered in eq. 9, the agreement is considered close enough to give support to the scheme shown in eq. 9. Therefore, the kinetics as a whole indicate that the mechanism of the bromodesulfonation of sodium 3,5-dibromo-4-hydroxybenzenesulfonate (I) is the same when bromine is in excess as it is with I in excess. The mechanism for the latter case has been shown above to be that given in eq. 4 and 5.

18	1.79	4.43	.0100	0	.1500	1.86

Experimental

Sodium 3,5-Dibromo-4-hydroxybenzenesulfonate (I).—Sodium *p*-phenolsulfonate (one mole, Eastman White Label), sodium bromide (3.5 moles) and hydrochloric acid (4.3 moles) were dissolved in one l. of hot water. An aqueous solution of sodium bromate (0.7 mole) was added dropwise to the hot reaction mixture while it was stirred vigorously with a mechanical stirrer. The mixture was cooled and most of the excess acid was neutralized with aqueous sodium hydroxide. After standing, the mixture was filtered and, following treatment with Norite, the filtrate was reduced in volume. Compound I separated upon cooling and was recrystallized from water three times and once from 90%

ethanol by cooling to −15°. When dried to constant weight at 100° the crystals pulverized.[32]

Anal. Calcd. for $C_6H_3Br_2O_4SNa$: C, 20.36; H, 0.85; Br, 45.16. Found: C, 20.17; H, 0.87; Br, 45.05.

2,4,6-Tribromophenol (Eastman Practical Grade) was recrystallized four times from ethanol, m.p. 94–95°, lit. m.p. 94°.[33]

Kinetic Measurements of the Bromodesulfonation Reaction of I.—Measurements were carried out in distilled water at 24.93 ± 0.02°. The concentrations of the reactants and rate constants are given in Tables I and II. The following reagents were used: sodium perchlorate, Fisher Purified Grade recrystallized from water; sodium bromide, Mallinckrodt Reagent Grade; perchloric acid, C.P. Grade; and the bromine was a center fraction, b.p. 58°, of refractionated Merck Reagent Grade. Stock solutions of I (0.0200 *M*), standardized perchloric acid and bromine water (*ca.* 5×10^{-3}) were used in preparing the reaction mixtures. Sodium perchlorate and sodium bromide were weighed out separately for each experiment. The reaction mixture was prepared, at the reaction temperature, by mixing a solution (a) containing sodium perchlorate and I with an equal volume (250 or 500 ml.) of a solution (b) containing bromine, perchloric acid and sodium bromide. The rate was followed by withdrawing aliquots (26.59 ml.), pipetting each aliquot into 10 ml. of 0.8% aqueous potassium iodide, and titrating the liberated iodine immediately with a standardized sodium thiosulfate (*ca.* 0.0027 *N*) solution measured from a semi-microburet. Starch was used as the indicator. The normality of the sodium thiosulfate solution was determined periodically by titrating against a standard potassium iodate solution. Sixteen to twenty points were taken in each experiment. When I was in excess, there was no problem with bromine volatility. However, when bromine was in excess, the loss of bromine became important (as determined by blank determinations) after one-third to one-half of the solution had been removed. Therefore, the volume of the solutions (a) and (b) was increased to 500 ml. and less than one-half of the mixture was used.

Reaction of 2,4,5-Tribromophenol with Bromine.—Solutions of 2.00×10^{-4} *M* tribromophenol were prepared by dissolving 0.0662 g. of the phenol in hot distilled water and then diluting to one l. upon cooling. The desired amounts of sodium perchlorate and sodium bromide were dissolved in a measured amount of tribromophenol solution. Standardized perchloric acid was added and, after bringing to 24.93 ± 0.02°, the solution was then mixed with bromine water such that the total volume was one liter. The initial concentration of tribromophenol was calculated from the volume of 2.00×10^{-4} *M* solution used to prepare the reaction mixture. The disappearance of bromine together with tetrabromocyclohexadienone III and other compounds which with iodide liberate iodine was followed. Aliquots (50 or 26.59 ml.) were withdrawn, added to 10 ml. of 0.8% potassium iodide solution, and the liberated iodine was titrated with standardized sodium thiosulfate solution. The reaction was homogeneous throughout the course of the reaction. The data are given in Table III. When tribromophenol was in excess, the values of the first-order rate constant, k_t, were taken as being equal to the slope of a plot of ln (B) *vs.* time, where B is the iodine titer in moles/l. With bromine in excess, k_4 was taken as being equal to the slope of a plot of ln ($A_0 - B_0 + B$) *vs.* time.

Ultraviolet spectra were taken in distilled water on a Cary recording spectrophotometer, model 11.

The Bromodesulfonation of Aromatic Sulfonate Salts. II. The Effect of Amino, Methoxy, Methyl and Nitro Substituents[1]

BY LAWRENCE G. CANNELL[2]

RECEIVED DECEMBER 20, 1956

The kinetics of the bromodesulfonation of a series of *p*-substituted aromatic sulfonate salts have been studied in aqueous solution at 0°. The results give additional experimental support to the theory that electrophilic aromatic substitution reactions proceed by way of quinonoid intermediates. The following *p*-substituents were studied: amino (III), methoxy (IV), methyl (V), and hydroxyl, with *m*-nitro groups (VI). All four compounds gave second-order kinetics, but they varied in regard to their dependence of rate on (Br^-). The kinetics for V showed little or no additional dependence on Br^- aside from that required by Br_3^- formation. However, with III, IV and VI it was found that decreases in rate occurred which cannot be accounted for by the Br_3^- effect alone (*cf.* Table II). The kinetics can be accounted for by a mechanism wherein bromine and the sulfonate anion undergo a *reversible* reaction to give Br^- and a "steady state" concentration of a quinonoid intermediate. To complete the reaction, the quinonoid intermediate decomposes in a unimolecular step (*cf.* eq. 1 and 2). Structural features affecting the stability of quinonoid reaction intermediates are discussed.

In a previous paper the bromodesulfonation of sodium 3,5-dibromo-4-hydroxy benzenesulfonate (I) was reported.[3] Spectral and kinetic data showed that the formation of a 3,5-cyclohexadien-1-one (II) as a reaction intermediate took place immediately upon mixing the reactants, and that the rate-determining step was the first-order decomposition of the quinonoid II to give tribromophenol.[4] Since the bromodesulfonation reaction is an example of electrophilic aromatic substitution,[3] this work constitutes a clear example of electrophilic aromatic substitution proceeding by way of a quinonoid intermediate.

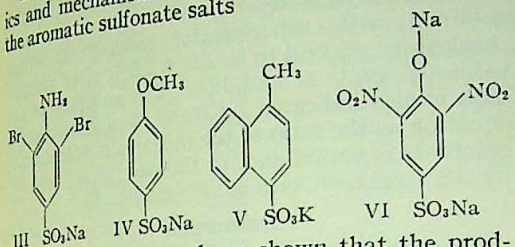
June 5, 1957

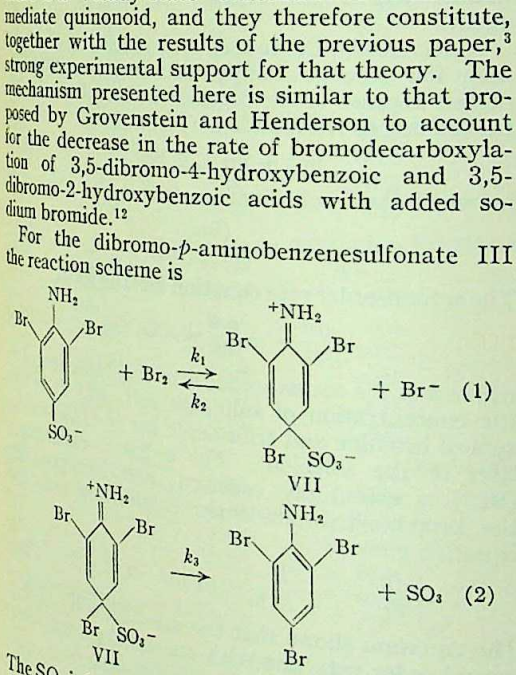
This paper reports the investigation of the kinetics and mechanism of the bromodesulfonation of the aromatic sulfonate salts



Previous investigators have shown that the products obtained in aqueous solution are, respectively: 2,4,6-tribromoaniline,[5,6] 4-bromoanisole,[7] 1-bromo-4-methylnaphthalene[8] and 4-bromo-2,6-dinitrophenol.[9-11]

A study of the rates of reaction as a function of (Br^-) shows that bromide ion retards the rate of product formation with III, IV and VI, but that the extent of this participation by bromide ion is dependent on the structure of the sulfonate salt. These results are explainable in terms of the usual mechanism for electrophilic substitution when there is a "steady state" concentration of an intermediate quinonoid, and they therefore constitute, together with the results of the previous paper,[3] strong experimental support for that theory. The mechanism presented here is similar to that proposed by Grovenstein and Henderson to account for the decrease in the rate of bromodecarboxylation of 3,5-dibromo-4-hydroxybenzoic and 3,5-dibromo-2-hydroxybenzoic acids with added sodium bromide.[12]

For the dibromo-*p*-aminobenzenesulfonate III the reaction scheme is



The SO_3 is hydrated to give sulfuric acid.

Results

Reaction Kinetics.—The kinetics for the bromodesulfonation of III, IV, V and VI have been determined in water at $-0.10 \pm 0.02°$. The reaction rates were followed by removing aliquots, quenching with an iodide solution and titrating the liberated iodine with a known sodium thiosulfate solution. Starch was used as the indicator. Tables I and III summarize the findings.

The reactions were carried out essentially at a constant acidity and bromide concentration, in most cases, by having an initial concentration of sodium bromide and perchloric acid large enough that the amounts of acid and bromide produced in the reaction were small in comparison. The equilibrium constant for the formation of Br_3^- is 19.6 at 0.0° (equation 3)[13]; and, consequently, very little of the bromide produced during a reaction was converted to Br_3^-. For example, at 90% reaction in expt. 11 and 4 the ratios of Br_3^- to Br_2 are 0.01 and 0.005, respectively.

Second-order Kinetics.—By varying the initial ratio of the sulfonate salt to bromine by factors of 31, 13, 24 and 34 for III, IV, V and VI, respectively, the kinetics of these reactions were found to be second-order, that is, first order in each reactant.

Reactions with the anisole IV were homogeneous and followed the second-order equation to points beyond 93% completion when the anisole was in a fourfold excess but only to 60% completion when it was in a twofold excess. With the bromine in excess, the second-order expression was followed to only 35–40% completion. In all cases, the apparent rate constant for bromination increased with time, and, therefore, it appeared that *p*-bromoanisole, the reaction product, was undergoing further bromination. With V, 1-bromo-4-methylnaphthalene began to separate as an oil from the solution after about 25% reaction. The rate followed the second-order expression out to 40% reaction and then the rate constant drifted to a value 6 to 10% lower presumably because of bromine adsorbed on the product which thereby reduced the amount of bromine in solution. Reactions with the amine III gave a precipitation of 2,4,6-tribromoaniline after about 30% reaction, and the kinetics followed a second-order plot out to 60–70% reaction and then the rate decreased by about 10% apparently because of adsorption of bromine on the solid. Reactions with the dinitrophenol VI were homogeneous.

Bromide Dependence.—The kinetics of the reactions were studied as a function of bromide concentration over a change in $(Br^-)_0$ from zero to 0.15 *M*. The ionic strength was maintained constant by adjusting the amount of $(NaClO_4)_0$. Upon increasing $(Br^-)_0$ the rate constants decreased as shown in Tables I and III.

Ionic Strength.—Changes in the ionic strength had little effect on the rates.[14] For example, a change in ionic strength from 0.152 to 0.012 (expt. 6 and 10) changed the rate constant for the

bromodesulfonation of sodium dibromo-*p*-aminobenzenesulfonate from 6.02 to 5.91 liters/mole-sec. Similarly, only a small effect was noted with the *p*-methoxybenzenesulfonate IV (expt. 20 and 23). The essential point of interest is that small changes in media due to the substitution of one monovalent ion for another, at constant ionic strength, will not significantly alter the interpretation of the results which rely upon changes in rates by factors of 4 to over 1,000.

Effect of Acidity.—Increasing the amount of $(HClO_4)_0$ at constant ionic strength showed that the rates of bromodesulfonation of III, IV and V are quite insensitive to acid. The amount of acid was increased by factors of 43 (expt. 2 and 7), 2 (expt. 11 and 19)[15] and 4 (expt. 29 and 33) with the sulfonate salts: III, IV and V, respectively. With the dinitro-*p*-phenolsulfonate VI, however, an increase in acid by a factor of 5 decreased the rate by a factor of 4.4 (expt. 39 and 44).

Bromination of *o*-Methoxybenzoic Acid.—The decrease in rate of bromination of *o*-methoxybenzoic acid accompanying a change in bromide concentration from 0.0025–0.15 *M* was found to be slightly greater than 4 (see Table II).

Calculation of Rate Constants.—The second-order rate constants, k_{obs}, were calculated by plotting log $(A_0 - B_0 + B)/B$ *vs.* time (see eq. 8), where A_0 is the initial concentration of the aromatic sulfonate salt and B is the apparent bromine concentration (equal to the titer of iodine in mole/l.) at a specified time. The graphical method was preferred to the direct calculation of k_{obs} for each point because it gives less weight to the value of B_0. The rate constants obtained by using experimental method 1, where checked, were reproducible to 1 to 3% of the average value. The wider variation occurred with those experiments which had shorter half-lives (*cf.* expt. 34 and 31 where the half-life was 80 sec.). The reproducibility of rate constants obtained with experimental method 2, where checked, was found to be *ca.* ±1.5% of an average value (*cf.* expt. 11 and 12). The accuracy of the data is also indicated by its fit to a second-order equation as the ratio of the initial concentration of reactants is varied and, in the case of III and IV, by the agreement with eq. 13 (see Fig. 1).

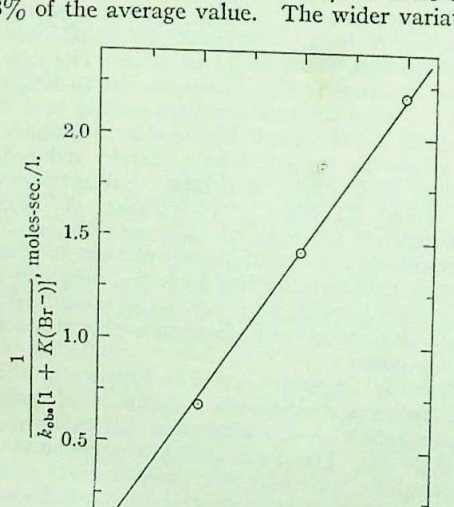

Fig. 1.—Plot of rate constants, corrected for Br_3^- effect, for the bromodesulfonation of sodium 3,5-dibromo-4-aminobenzenesulfonate *vs.* (Br^-).

(15) Also compare expt. 18 and 24 for an increase in acid by a factor of 5 but with a change of ionic strength.

Discussion

Kinetics of the Second-order Bromodesulfonation Reactions.—The second-order kinetics for the reaction of bromine with the dibromo-*p*-aminobenzenesulfonate (III), *p*-methoxybenzenesulfonate (IV) or 4-methylnaphthalenesulfonate (V), suggest a bimolecular mechanism between bromine and the aromatic sulfonate salt. Reactions with III, IV and V were insensitive to changes in acidity; this is in agreement with the expectations that the sulfonic acids would be completely ionized and that the anion would be the reactant. Further the observed independence of rate on acidity shows that neither HOBr nor H_2OBr^+ is the brominating agent.

A decrease in the rate of bromination as the bromide ion concentration is increased would be expected because of the decrease in bromine concentration due to tribromide ion formation

$$Br^- + Br_2 \rightleftharpoons Br_3^- \qquad (3)$$

for which the equilibrium constant is

$$K = \frac{(Br_3^-)}{(Br^-)\,(Br_2)} \qquad (4)$$

The second-order rate equation has the form

$$-\frac{dB}{dt} = -\frac{dA}{dt} = k(Br_2)(A) \qquad (5)$$

where k is the second-order rate constant, and A is the concentration of sulfonate salt, and B is the sum of bromine and tribromide ion (*i.e.*, the iodine titer of the solution). For a given experiment (Br^-) is essentially constant, and incorporating the bromine–tribromide ion equilibrium into the equation gives

$$-\frac{dB}{dt} = \frac{k}{1 + K(Br^-)}(B)[A_0 - (B_0 - B)] \qquad (6)$$

The equation shows that the reaction will follow a second-order rate law with an observed rate constant, k_{obs}, which obeys the relationship

$$k = k_{obs}\,[1 + K(Br^-)] \qquad (7)$$

Integration gives the rate equation used in finding k_{obs}

$$tk_{obs} = \frac{1}{A_0 - B_0} \ln\left[\frac{A_0 - B_0 + B}{B}\right]\left[\frac{B_0}{A_0}\right] \qquad (8)$$

The correction for reaction 3 has been applied to the data for the bromination of III, IV, V and *o*-methoxybenzoic acid and the corrected constants, $k_{obs}\,[1 + K(Br^-)]$, are given in Table I. It was found that $k_{obs}\,[1 + K(Br^-)]$ is nearly constant for the 4-methylnaphthalenesulfonate V and for *o*-methoxybenzoic acid. Table II summarizes the decrease in rate upon increasing $(Br^-)_0$ from 0.0025 to 0.1 *M*, with a value of $K = 19.6$,[13] eq. 7 pre-

[a] $(CH_3OC_6H_4CO_2H)_0 \times 10^4$.

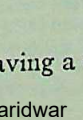
dicts a decrease by a factor of 3.76. For an increase from zero to 0.15 M $(Br^-)_0$ the factor is 3.94. The observed decrease of 4.5 and 4.8 for the 4-methylnaphthalenesulfonate V and *o*-methoxybenzoic acid, respectively, are in reasonable agreement with the calculated factor of 3.76.[16] However, for the *p*-methoxybenzenesulfonate IV and dibromo-*p*-aminobenzenesulfonate III the decrease in rate is too great to be accounted for by this correction for Br_3^- formation.

Therefore, the simple bimolecular mechanism scheme must be modified to account for this additional dependence on bromide ion. The proposed mechanism scheme is

$$ArSO_3^- + Br_2 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} Ar\begin{matrix}Br\\SO_3^-\end{matrix} + Br^- \qquad (9)$$

$$Ar\begin{matrix}Br\\SO_3^-\end{matrix} \xrightarrow{k_3} ArBr + SO_3 \qquad (10)$$

Ar is an intermediate having a quinonoid structure



(16) It appears that K would not be affected greatly by changes in ionic strength since this is the case in the closely analogous system for the formation of I_3^- from I_2 and I^-. For the latter system, the work of W. C. Bray and C. M. J. McKay (THIS JOURNAL, **32**, 914 (1910)) and L. I. Katzin and E. Gebert (*ibid.*, **77**, 5814 (1955)) indicates that the maximum variation in K for changes in the concentrations of KI, $NaClO_4$ and NaI under 0.15 M would be less than 12%. For a 12% increase in the value of K for the formation of Br_3^- from Br^- and Br_2, eq. 7 predicts a decrease of 4.2 in rate of bromodesulfonation. Experiments with *p*-methoxybenzenesulfonate III wherein (Br^-) was varied from 0.05 to 0.005 at $\mu = 0.06$ showed that the large deviations from eq. 7 were not due to a salt effect on K (see expt. 12–17).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

which is assumed to be in a "steady state" with respect to the reactants. This mechanism is basically the same as that proposed earlier for the bromodesulfonation of sodium 3,5-dibromo-4-hydroxybenzenesulfonate (I); however, the magnitude of the rate constants are such that in the absence of bromide ion the bromination step, eq. 9, is now rate-determining. If a "steady state" concentration is assumed for the quinonoid, Q, the reaction scheme given by eq. 9 and 10 predicts that

$$-\frac{dB}{dt} = k_3(Q) = \frac{k_3k_1(Br_2)(A)}{k_2(Br^-) + k_3} \qquad (11)$$

Equation 11 has then the same form as eq. 5, and by making a similar correction for the formation of Br_3^- (*cf.* eq. 6) the following expression is obtained

$$\frac{1}{k_{obs}\,[1 + K(Br^-)]} = \frac{1}{k_1}\left[\frac{k_2}{k_3}(Br^-) + 1\right] \qquad (12)$$

Equation 12 predicts that a plot of $(k_{obs}\,[1 + K(Br^-)])^{-1}$ against (Br^-) will give a straight line. When the experimental data for the bromination of the dibromo-*p*-aminobenzenesulfonate III and *p*-methoxybenesulfonate IV are plotted in this manner, straight line correlations are obtained (see Fig. 1). The agreement further verifies the correctness of the mechanism scheme given by eq. 9 and 10. The intercept at $(Br^-) = 0$ becomes equal to $1/k_1$; this value can also be determined directly. The slope is equal to k_2/k_1k_3, and it is therefore possible to determine k_2/k_3. For the anisole IV k_2/k_3 is equal to 22 l./mole, and for the amine II it is 2,200 l./mole. Since the (rate forward/rate reverse) $= k_2(Br^-)/k_3$, it follows that when $(Br^-)_0$ is 0.10 *M* the intermediate quinonoid VII, formed from the amine, returns to the initial reactants 220 times for every time it goes on to products.

When k_2/k_3 is small, eq. 12 reduces to eq. 7 (*i.e.*, the bromination step is rate-determining regardless of the bromide ion concentration).

Dibromo-*p*-aminobenzenesulfonate III. Effect of Acidity.—As noted above, the rate of bromodesulfonation of the amine III is unaffected by increasing $(HClO_4)_0$ from 0.0023 to 0.100 *M*. This indicates that the concentration of the compound undergoing bromination is not significantly changed over this range of acidity. Also, the ultraviolet spectrum of III, which has maxima at 298 and 253 mμ, does not change even though the composition of the solution is changed from 0.1 *M* $HClO_4$ to 0.1 *M* NaOH. Sodium *p*-aminobenzenesulfonate[17] undergoes a 19-fold decrease in absorption at λ_{max} 247 mμ in acid solution due to protonation of the amine group. Therefore, the data indicate that the amine III is so weak a base that it remains unprotonated even in 0.1 *M* $HClO_4$. This behavior is in line with the expected base strength of III. Gillois and Rumpf[18] have shown that the 2,6-dibromoanilinium ion has a pK_H of 0.35 at 25°; and since the pK_H for the N-protonated *p*-aminobenzenesulfonate ion is 1.35 log units less than that for the anilinium ion,[19] the expected pK_H for the N-protonated 3,5-dibromo-4-aminobenzenesulfonate ion is about −1.0. Therefore, in 0.1 *M* acid only about 1% of the amino groups would be protonated.

TABLE II

DECREASE IN RATE OF BROMODESULFONATION ON INCREASING $(Br^-)_0$ FROM 0.0025 TO 0.1500 *M* AT 0.0°

Sodium 3,5-dibromo-4-aminobenzenesulfonate	230 (1300)[a]
Disodium salt of 3,5-dinitro-4-hydroxybenzenesulfonic acid	246
Sodium 4-methoxybenzenesulfonate	16
Potassium 4-methylnapthalenesulfonate	4.5
o-Methoxybenzoic acid	4.8
Predicted decrease due to Br_3^- effect only	3.76

[a] Experimentally determined for a change from $(Br^-)_0 = 0$ to $(Br^-)_0 = 0.15$ *M*. This value should be compared to a predicted decrease for the effect of Br_3^- formation of 3.94.

Destabilization of the Quinonoid State in Phenols by *o*-Nitro Groups.—The disodium salt of 4-hydroxy-3,5-dinitrobenzenesulfonic acid (VI), in contrast to the salt of dibromo-*p*-phenolsulfonic acid I, gave a very rapid reaction with bromine even at 0°, and the kinetics showed that the decomposition of the quinonoid intermediate was not rate-determining at low bromide concentrations.

The data (see Table III) can be summarized as follows: (1) the kinetics were second order. (2) An increase in (Br^-) from 0.0025 to 0.1500 *M* decreased the reaction rate by a factor of 246; the rate constant is still decreased by bromide by a factor of 65 after taking into account the Br_3^- effect (*cf.* Table II). The dependence of the rate on bromide ion was thus very similar to that found for the dibromo-*p*-aminobenzenesulfonate (III); the bromination step is rate-determining at low $(Br^-)_0$, but as $(Br^-)_0$ is increased, the desulfonation reaction begins to become rate-determining. (3) The rate was inversely dependent on acid (an increase in acid by a factor of 5 resulted in a 4.4-fold decrease in rate), and this stands as evidence that it is the phenoxide anion which undergoes bromination. The mechanism is comparable to that given in eq. 1 and 2.

The proposed explanation is given in the form of a potential energy curve, Fig. 2, which compares the bromodesulfonation of I and VI. It is well known that the introduction of a nitro group *ortho* to an OH group greatly increases the acidity of the phenol. This is attributed largely to the resonance stabilization of the anion.[20] A similar interaction would be expected in the ground state of the doubly charged anion of VI and, therefore, Fig. 2 shows a lower energy for the ground state of VI than for I. However, in the transition state, for the bromination step this interaction is partly lost because the phenoxide anion is being converted to a carbonyl group, and the C–C double bonds are becoming localized in positions unfavorable to resonance between the phenol oxygen and the nitro groups. Therefore, in the transition state, the energy difference between I and VI is considerably reduced.

It has been shown that quinones become better

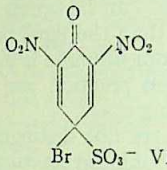
oxidizing agents when substituted with electronegative groups and that the nitro group is particularly effective in this regard.[21] Therefore, the potential energy of the tribromoquinonoid intermediate is represented in Fig. 2 as being less than that for the bromodinitroquinonoid intermediate VIII.



VIII

Finally, in the desulfonation step, as the C–S bond is broken the C–C double bonds again become delocalized and the resonance energy between the phenoxide anion and the nitro groups can again be important. Consequently, the activation energy for the desulfonation step for VI is much less than that for I. The over-all result is that in the absence of bromide ion the rate of desulfonation is increased to such a great extent that it is now no longer rate controlling. But the quinonoid has sufficient stability that with bromide ion the reverse reaction to give starting materials can take place and the desulfonation step then becomes important as the rate-determining step.

It should be noted that this change is brought about not by replacing one activating group by another but by modifying it through *ortho* substituents. The activation is clearly due to a combination of the phenoxide anion and the nitro groups and can be described as a resonance interaction. This is shown by the observation that potassium 4-methoxy-3-nitrobenzenesulfonate gives a much slower reaction with bromine than does sodium 4-methoxybenzenesulfonate (IV). The deactivating effect that introducing a nitro group has on the rate of bromination of sodium *p*-methoxybenzenesulfonate IV thus illustrates the effect which is usually observed: the nitro group retards electrophilic aromatic substitution by an inductive effect. In the bromination of the dinitrophenol VI the nitro groups must also deactivate the ring by an inductive effect, but this is completely hidden by the resonance interaction. The difference in the kinetics of bromination of the dibromophenol I and the dinitrophenol VI demonstrates that the rate-determining step in aromatic electrophilic substitution can be changed by the modification of substituents.

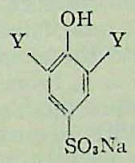
—— Y is Br, (I)
----- Y is NO_2, (VI)



Sakellarios reports that the reaction of VI with an equal molar amount of bromine water at 24–30° gives a 93% yield of 4-bromo-2,6-dinitrophenol before recrystallization.[9] Marqueyrol and Carré report that VI with an equal molar amount of bromine in water gives a crude product which contains 31.7% bromine (a bromodinitrophenol has 30.4%) wherein the main product is 4-bromo-2,6-dinitrophenol.[10] With excess bromine at room temperature they reported that the crude product contained 45% bromine (54% required for a dibromonitrophenol) from which the chief product isolated was 2-bromo-4,6-dinitrophenol[22] and a smaller amount of 2,4-dibromo-6-nitrophenol. They further showed by titration data that VI reacted with more than a molar amount of bromine. The replacement of a nitro group on 4-bromo-2,6-dinitrophenol by bromine is not surprising in view of other work which shows that picric acid will brominate in aqueous solution at room temperature to give 2-bromo-4,6-dinitrophenol.[23]

Dinitro-*p*-phenolsulfonate VI. Side Reactions.—The reaction rate measurements, reported in this

(21) L. F. Fieser, THIS JOURNAL, **52**, 5204 (1930); **51**, 3101 (1929).

(22) Marqueyrol and Carré suggest that 4-bromo-2,6-dinitrophenol, the initial reaction product, isomerizes in the presence of excess bromine into 2-bromo-4,6-dinitrophenol (*cf.*, H. E. Armstrong, *J. Chem. Soc.*, **13**, 520 (1875); H. Gordon, *Chem. News*, **63**, 221 (1891)).

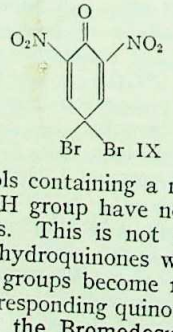
paper, also show that the dinitrophenolsulfonate VI will react with more than one mole of bromine. The reaction of VI with excess bromine followed a second-order rate law (having the same value of k as that obtained when bromine was not in excess, see Table III) until 0.5 mole of bromine had been taken up for each mole of VI initially present. The apparent rate constant then began to increase and bromination continued at a rapid rate until *ca.* 1.5 moles of bromine had disappeared and the reaction finally approached the stoichiometry of two moles of bromine consumed per mole of VI. These data suggest that, as reported by Marqueyrol and Carré, 2,4-dibromo-6-nitrophenol was a reaction product.

When the dinitrophenolsulfonate VI was in excess, the reaction followed a second-order rate to 70–75% completion after which the rate began to slow down with a very pronounced decrease occurring after 85% completion. Even though the initial ratio of VI to bromine was changed from 2 to 12, the decrease in the rate constant occurred at closely the same point in the reaction. This indicated that the reaction responsible for the decrease in rate did not involve VI but was evidently between bromine and the reaction product, 4-bromo-2,6-dinitrophenol.

In summary, it may be said that the initial reaction product is 4-bromo-2-6-dinitrophenol but that secondary bromination reactions become kinetically important after 50 to 75% reaction. It appears that 4-bromo-2,6-dinitrophenol brominates to give a reaction product, or intermediate, which slows down the rate of disappearance of bromine by tying up some of the bromine in a way such that it is less effective as a brominating agent but will, in the analytical method, still react with iodide to give iodine. With excess bromine, however, bromination occurs to give 2,4-dibromo-6-nitrophenol. In considering possible secondary bromination products it is interesting to note that 4-bromo-2,6-dinitrophenol might be expected to give the cyclohexadienone (IX) just as tribromophenol gives 2,4,4,6-tetrabromo-2,5-cyclohexadien-1-one.[24] However,



IX

apparently phenols containing a nitro group *ortho* or *para* to the OH group have not given isolable cyclohexadienones. This is not surprising since, as noted above, hydroquinones which are substituted with nitro groups become more difficult to oxidize to the corresponding quinones.

Comparison of the Bromodesulfonation Reactions.—The kinetics of the bromodesulfonation of I, III, IV and V, together with the spectral data, can be used to divide these compounds according to the stability of the intermediate quinonoid: (1) Bromination of sodium 3,5-dibromo-4-hydroxybenzenesulfonate (I) gives zero-order kinetics for the reactant (bromine or I) present in excess, and first-order kinetics for the other. The most evident explanation of the kinetics requires that the phenolsulfonic acid upon mixing with bromine is immediately transformed into a quinonoid intermediate II and demands that the *intermediate be present in large concentration.* This was verified by ultraviolet absorption spectra of the aqueous solution in this case. The rate-determining step is then the decomposition of the intermediate. Other phenols of closely similar structure would be expected to behave analogously.[25]

(2) By contrast, the kinetics for the bromination of potassium 4-methylnaphthalene-1-sulfonate (V) indicate a bimolecular mechanism between the sulfonate anion and Br_2; the reaction follows second-order kinetics which are first-order with respect to each reactant. The kinetics require *only a transition state,* and it is not necessary to propose that there is a reaction intermediate. The decrease in rate of bromodesulfonation as bromide ion concentration is increased can be satisfactorily accounted for by assuming that the equilibrium for the formation of Br_3^- from bromine is independent of the bromodesulfonation reaction and that Br_3^- is inert as a brominating agent.

These kinetics are not distinguishable from the usual bromodeprotonation reactions as is illustrated in the present work by the bromination of *o*-methoxybenzoic acid. Other workers have found similar results with bromodeprotonation reactions. Wilson and Soper[26] reported similar kinetics for the bromination of *o*-nitroanisole in water and so have Grovenstein and Henderson[12] for the bromination of 2,6-dibromophenol.

(3) The bromination of sodium *p*-methoxybenzenesulfonate (IV) and sodium 3,5-dibromo-4-aminobenzenesulfonate (III) also follows second-order kinetics, but here it was found necessary to postulate a *steady state concentration* of a reaction intermediate in order to account for the dependence of rate on (Br^-). When the observed rate constant was corrected for Br_3^- formation, the decrease in rate is only partly accounted for (see Table II). The magnitude of this additional decrease depends on the structure of the compound; the factor is 4 for sodium *p*-methoxybenzenesulfonate and 57 for sodium 3,5-dibromo-4-aminobenzenesulfonate upon changing the $(Br^-)_0$ from 0.0025 to 0.1500 *M*. This additional decrease in rate can be accounted for by a mechanism (eq. 9 and 10) which includes the reaction of bromide ion with a quinonoid intermediate to regenerate the starting sulfonate anion and Br_2. The rate-determining step is the attack of bromine on the sulfonate anion at low bromide concentrations but, as the concentration of bromide is increased, the step involving the elimination of SO_3 becomes rate-determining.

The substituent stabilizes the quinonoid structure by double bond formation with the benzene ring. The dibromo-*p*-phenolsulfonate I eliminates

(24) See ref. 3 for discussion of the displacement of [illegible]

(25) Sodium 3,5-dichloro-4-hydroxybenzenesulfonate in aqueous solution upon mixing with an equal molar amount of bromine water was found to give an immediate disappearance of the bromine color and a new absorption peak at 271–272 mμ of ϵ = 12,400. This behavior is closely similar to that for the dibromophenolsulfonate I and indicates that bromodesulfonation is by an identical mechanism.

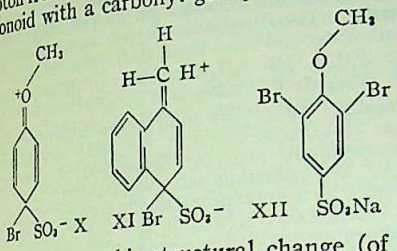
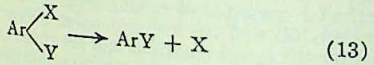
a proton from the OH group to give an intermediate quinonoid with a carbonyl group (II); the experiments show that this structural change (of those considered in this paper) is the most effective way of stabilizing a quinonoid.[27] With the dibromo-*p*-aminobenzenesulfonate III and the *p*-methoxybenzenesulfonate IV, double bond formation in the quinonoid can be brought about by forming an imine salt VII and oxonium cation X, respectively. For the methylnaphthalenesulfonate V a double bonded structure cannot be drawn but rather the transition state can be written as a resonance hybrid of various structures, one of which is the hyperconjugation structure XI.



Sodium 3,5-dibromo-4-methoxybenzenesulfonate (XII), in contrast to IV, was found to undergo no appreciable reaction with bromine at 25°, and even at 98° the reaction was slow. This fact can be explained by noting that, because of steric repulsion, the bromine atoms keep the methyl group from being planar with the ring, and therefore, the oxygen can form only a partial double bond with the ring. Much of the activating effect of the oxygen is then lost and XII is relatively unreactive.[28]

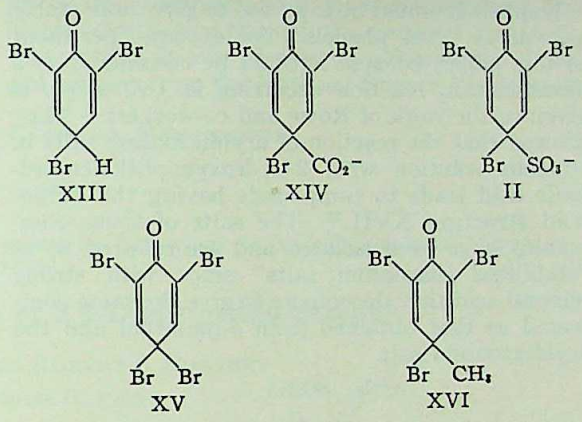
Structural Features which Favor the Formation of Stable Quinonoid Intermediates.—The decomposition of a quinonoid intermediate may be written as



(13)

where X is the group being replaced, Y is the group which became bonded to Ar in the initial step of the substitution reaction, and Ar<X Y is the reaction intermediate with a quinonoid structure. It is apparent that an additional means of increasing the stability of a quinonoid is to increase the activation energy for the decomposition step (*i.e.*, choose X such that the energy of activation for breaking the C-X bond is raised). The experimental work discussed above showed that, for bromodesulfonation at least, the OH group is more effective in stabilizing a quinonoid structure than any of a variety of other substituents. Therefore, for comparison purposes a series of phenols will be chosen wherein X is varied. Ar is chosen to be the 3,5-dibromo-4-hydroxyphenyl group; X is $-CO_2^-$, $-SO_3^-$, Br (or Cl) or $-CH_3$; and Y is Br (*i.e.*, the intermediates were derived by bromination of ArX). The various intermediates or stable compounds are XIV, II, XV and XVI, respectively, for the above-named substituents.

The relative stabilities of these quinonoids will now be compared. The work reported in this paper shows that in aqueous solution at 0° the



bromodecarboxylation of 3,5-dibromo-4-hydroxybenzoic acid was so rapid that the reaction was practically finished after 7 sec.[29] The intermediate II at 25° has a half-life of 126 min. Bromination of tribromophenol with aqueous bromine leads to the formation of the isolable 2,4,4,6-tetrabromo-2,5-cyclohexadien-1-one (XV).[24] Bromination of 2,6-dibromo-4-methylphenol leads to the cyclohexadien-1-one XVI which Fries and Oehmke have isolated and characterized.[30,31]

The increase of the stability of the intermediates where X is Br or CH_3 over those where X is $-CO_2^-$ or $-SO_3^-$ can be attributed to the higher energy of activation necessary for the breaking of the C–Br or C–CH_3 bond in the cyclohexadienones, XV and XVI, respectively, as indicated in reaction 13. The greater stability of the intermediate II where X is $-SO_3^-$ over that where X is $-CO_2^-$ can be explained in a similar manner. The case where X is hydrogen was studied by Grovenstein and Henderson[12] who found that the rate of bromination was *ca.* 200 times faster than that for X = $-CO_2^-$, and since in the latter case they demonstrated that the bromination reaction is reversible with bromide ion, whereas the former reaction showed little or no tendency for reversal, it would appear that the rupture of the C–CO_2^- bond of the intermediate XIV requires a higher activation energy than does the

(27) When the solvent is such that the phenol does not ionize appreciably, the stabilizing effect is not forthcoming. This is illustrated by the work of A. A. Yasnikov and E. A. Shilov (*Doklady Akad. Nauk S.S.S.R.*, **78**, 925 (1951); *C. A.*, **46**, 5009 (1952)) who report that 2,4,6-tribromophenol in anhydrous acetic acid will not brominate to give XV but that a small amount of water is necessary as a proton acceptor to bring about the reaction.

(28) *Cf.* ref. 20, pp. 157–160 and 238–243.

(29) XIV can be referred to here as a reaction intermediate because Grovenstein and Henderson have shown, as previously cited, that in 80% acetic acid–water 20% the kinetics of this bromodecarboxylation reaction require a "steady state" intermediate.[12]

(30) K. Fries and G. Oehmke, *Ann.*, **462**, 6 and 16 (1928); Fries and co-workers assigned this and many other closely related compounds a cyclohexadienone structure on the basis of chemical evidence (see K. Fries and E. Brandes, *Ann.*, **542**, 48 (1939); K. Fries and H. Engel, *ibid.*, **439**, 232 (1924)). In support of this view, G. M. Coppinger and T. W. Campbell (THIS JOURNAL, **75**, 734 (1953)) have assigned a compound formed by the bromination of 2,6-di-*t*-butyl-4-methylphenol as 4-bromo-2,6-di-*t*-butyl-4-methyl-2,5-cyclohexadien-1-one by means of its infrared spectrum.

(31) For examples showing the use of substituting agents other than bromine see: M. S. Newman and A. G. Pinkus, *J. Org. Chem.*, **19**, 978 (1954); J. F. Bunnett and W. C. Sears, THIS JOURNAL, **76**, 4977 (1954); H. E. Albert and W. C. Sears, *ibid.*, **76**, 4979 (1954).

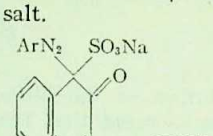
rupture of the C–H bond in XIII to give tribromophenol.

The unique feature of the intermediate II is that it is stable enough to be formed in large concentrations yet unstable enough that it will decompose at a conveniently measurable rate in a manner typical of substitution reactions (eq. 13). Thus, it is an ideal case for kinetic investigation.

Naphthols would be expected to give more stable quinonoids than phenols. An example pertinent to this paper, because it could be considered as a desulfonation reaction occurring in two steps, is given in the work of Rowe and co-workers. They showed that the reaction of aryldiazonium salts in aqueous solution with 2-hydroxynaphthalenesulfonic acid leads to compounds having the quinonoid structure XVII.[32] The salts of these compounds have been isolated and are referred to as "stabilized diazonium salts" since with strong mineral acid they decompose to give the same compound as that obtained from β-naphthol and the aryldiazonium salt.



XVII

Experimental

Sodium 3,5-Dibromo-4-aminobenzenesulfonate (III).—An aqueous solution of the salt was prepared by treating an aqueous solution of sulfanilic acid (Mallinckrodt Analytical Reagent) with sodium bromate and hydrobromic acid according to the directions of Heinichen.[6] The sodium salt was isolated by evaporation of the solution after neutralizing with sodium hydroxide and recrystallized twice from water and twice from 90% ethanol to give fine needles. The salt was dried at 200°.[33]

Anal. Calcd. for $C_6H_4Br_2NO_3SNa$: C, 20.42; H, 1.14; Br, 45.28. Found: C, 20.69; H, 1.28; Br, 45.21.

Sodium *p*-methoxybenzenesulfonate (IV) was prepared by the method of Moody[34] by sulfonating anisole (Eastman White Label). The salt was recrystallized twice from water, twice from 90% ethanol and dried at 100°.

Anal. Calcd. for $C_7H_7SO_4$: C, 40.00; H, 3.36; S, 15.25. Found: C, 40.23; H, 3.32; S, 15.01.

Potassium 4-methylnaphthalene-1-sulfonate (V) was prepared by the method of Fieser and Bowen.[8] The salt was recrystallized three times from water and twice from ethanol–water and dried at 100°, m.p. of *p*-toluidine salt 227–229° (lit.[8] m.p. 228–230°).

Sodium 3,5-dibromo-4-methoxybenzenesulfonate (XII) was prepared by treating I with a twofold excess of dimethyl sulfate in aqueous sodium hydroxide. Upon reducing the volume of the solution, XII separated out and was recrystallized twice from aqueous sodium hydroxide and once from water and dried at 200°. The product showed no violet coloration upon treating with aqueous ferric chloride.

Anal. Calcd. for $C_7H_5Br_2O_4SNa$: C, 22.84; H, 1.37; Br, 43.43. Found: C, 23.00, 23.13; H, 1.24, 1.47; Br, 43.31.

Disodium Salt of 3,5-Dinitro-4-hydroxybenzenesulfonate (VI).—By the substitution of sodium for potassium salts, the monosodium salt of the dinitrophenolsulfonic acid was prepared by the method given by Friedlaender.[35] The monosodium salt was recrystallized from water and converted into the disodium salt by the addition of sodium carbonate. No more carbonate was added than that required to neutralize the acid as was indicated by the effervescence of carbon dioxide. The disodium salt was recrystallized three times from water and dried to constant weight at 120°.[36]

Anal. Calcd. for $C_6H_2N_2O_8SNa_2$: C, 23.38; H, 0.65; N, 9.09. Found: C, 23.30; H, 0.68; N, 9.04.

Potassium 4-Methoxy-3-nitrobenzenesulfonate.—*o*-Nitroanisole (Matheson–Coleman and Bell) was sulfonated with chlorosulfonic acid by the method of Gnehm and Knecht.[37] The potassium salt was prepared from the acid and purified by recrystallization from water, m.p. of the sulfonyl chloride derivative 65.5–66.5° (lit.[37] m.p. 66°).

***o*-Methoxybenzoic acid** was prepared by treating sodium salicylate with dimethyl sulfate in aqueous base. The product was recrystallized several times from ethanol, m.p. 101–101.5° (lit.[38] m.p. 100–101°).

Sodium 3,5-dichloro-4-hydroxybenzenesulfonate was prepared from sodium *p*-phenolsulfonate (Eastman White Label) by chlorination with $NaClO_3$/HCl in a procedure similar to that used for the preparation of sodium dibromo-*p*-phenol sulfonate by bromination.[3]

3,5-Dibromo-4-hydroxybenzoic acid was prepared by the bromination of *p*-hydroxybenzoic acid (Eastman White Label) in aqueous solution by a hydrobromic acid–sodium bromate mixture. The acid was recrystallized three times from chloroform, m.p. 271.5–272.5° (cor.), lit.[39] m.p. 267–268°.

Measurement of the Bromodesulfonation Reaction.—The kinetics of the bromodesulfonation of the amine II, anisole III, methylnaphthalene IV and dinitrophenol VI were measured at −0.10 ± 0.02°. The data are summarized in Tables I and III. Distilled water was used as the solvent. The reagents were the same as previously described.[3] Solutions of the reactants were prepared by mixing at the reaction temperature equal volumes of solution (a) which contained the aromatic sulfonate salt and sodium perchlorate with solution (b) which contained bromine, sodium bromide and perchloric acid. In the case of VI, the perchloric acid was equally divided between (a) and (b). The acid was added to prevent hydrolysis of the bromine and also to determine the effect of acidity on rates. Solutions of the sulfonate salts (0.0200 *M*), standardized perchloric acid and bromine water (*ca.* 5×10^{-3} *M*) were used in preparing the reaction mixtures. Sodium perchlorate and sodium bromide were weighed out separately for each experiment.

Two methods of mixing the reactants were employed. Method 1 consisted of mixing separate 25.0-ml. portions of solutions (a) and (b) for each point taken. Method 1 was used for the faster reactions and for those in which the reaction product began to separate from solution before reaction was complete. The $(Br_2)_0$ was determined by using samples of solution (b) as blanks both at the time the experiment was started and also toward the conclusion of the experiment. It was thus shown that the loss of bromine by the volatilization was small over the time interval necessary to conduct an experiment. All reactions were carried out in glass stoppered flasks.

Method 2, which was used for the slower completely homogeneous reactions, consisted of mixing equal volumes of solutions (a) and (b), usually 250 ml. each, and then following the reaction by withdrawing a sample (26.59 ml.) by pipet. Between operations, the pipet was cooled at the bath temperature. The reaction time was taken as that from the mixing of the solutions until one-half of the pipet was emptied. The initial bromine concentration was determined by removing an aliquot immediately after mixing or by removing an aliquot from solution (b) in which case a compensating volume was taken from (a) also and discarded. Method 2 was used in expt. 11 to 29 inclusive; all other experiments in Tables I and III followed the procedure of method 1.

About 16 points were taken in each experiment. With a fast reaction, the first point was taken after 4 sec. The reaction was stopped by mixing each sample with 10 ml. of 0.8% aqueous potassium iodide in method 1 or by pipetting

an aliquot into aqueous potassium iodide in method 2. The sample was then analyzed immediately for the amount of iodine liberated by titrating against a standardized sodium thiosulfate solution measured from a semimicroburet. Starch was used as an indicator.

A reaction mixture which was 6.7×10^{-3} *M* in potassium 4-methoxy-3-nitrobenzenesulfonate and 4.3×10^{-3} *M* in bromine was kept at 50°; it was found that slightly less than half of the bromine disappeared after 17 hr. Sodium 3,5-dibromo-4-methoxybenzenesulfonate (XII) with bromine gave no appreciable reaction at 25°; but when a reaction mixture containing 6.7×10^{-3} *M* XII and 4.6×10^{-3} *M* bromine was heated in a sealed tube at 98°, the amount of bromine decreased to 2.4×10^{-3} *M* after 1.5 hr.

Bromodecarboxylation of 3,5-Dibromo-4-hydroxybenzoic Acid.—The procedure was similar to method 1 discussed above for the bromodesulfonation experiments. Solution (a) was prepared by dissolving 1.00×10^{-3} mole of the dibromohydroxybenzoic acid with 1.65×10^{-3} mole of NaOH in one l. of water. Solution (b) contained 4.84×10^{-4} mole/l. of Br_2; 25 ml. of each solution were mixed at 0°. The reaction was so rapid that with a time of 7 sec. it was over 90% complete.

Ultraviolet spectra were taken in aqueous solution on a Cary spectrophotometer, model 11.

Acknowledgment.—The author is grateful to Dr. F. H. Westheimer for his encouragement and helpful discussions through the course of this work. The author is also pleased to acknowledge financial support from the National Science Foundation.

The Free Radical Phenylation of 2,4-Dinitrotritiobenzene[1]

BY CHARLES C. PRICE AND ROBERT J. CONVERY

RECEIVED DECEMBER 15, 1956

The conversion of 2,4-dinitrotritiobenzene to 2,4-dinitrobiphenyl by treatment with benzoyl peroxide proceeds with the displacement of just one-half of the tritium. This proves that the product-determining step does not involve breaking the tritium- (or hydrogen-) carbon bond.

Two mechanisms have been advanced for free radical substitution in the benzene ring. One[2] involves initial hydrogen abstraction followed by coupling of two radicals.

$$C_6H_5\cdot + ArH \longrightarrow C_6H_6H + Ar\cdot \xrightarrow{C_6H_5\cdot} ArC_6H_5 \quad (1)$$

The other involves initial addition to the aromatic nucleus, followed by hydrogen abstraction.[2a,3]

$$C_6H_5\cdot + ArH \longrightarrow \left[\begin{array}{c} C_6H_5 \\ | \\ Ar \\ | \\ H \end{array}\right] \xrightarrow{R\cdot} RH + ArC_6H_5 \quad (2)$$

In order to obtain more unequivocal evidence, we have studied the phenylation of 2,4-dinitrotritiobenzene, since mechanism 1 should show a substantial isotope effect while mechanism 2 would have little or none.

Experimental

2,4-Dinitrotritiobenzene was prepared by dissolving 2,4-dinitrobenzoic acid (5 g.) in 5 ml. of tritiated water (20 mc./10 ml.) heated at 125°, followed by decarboxylation of 5 g. of the tritiated acid by heating to 240° in 25 ml. of quinoline with 0.02 g. of copper chromite catalyst. After thorough washing of an ether solution, evaporation and recrystallization from 95% ethanol, 1.5 g. (38%) of tritiated *m*-dinitrobenzene, m.p. 108–108.8°, was obtained. This sample was mixed with 40 g. of unlabeled material and recrystallized once more from ethanol. One sample prepared in this way assayed[4] for 51.7 ± 1.6 mμc./mg. of hydrogen, a second for 22.8 ± 0.7 mμc./mg. of hydrogen.

2,4-Dinitrobiphenyl.—A mixture of 4.3 g. of benzoyl peroxide (0.02 mole) and 29.6 g. of tritiated *m*-dinitrobenzene (0.2 mole) was heated, gradually increasing the temperature from 75 to 100° over a period of 5 hr. After dissolving in 400 ml. of ether, the product was washed with five 50-ml. portions of 10% sodium bicarbonate, with three 50-ml. portions of 15% hydrochloric acid and three 50-ml. portions of water. Drying and evaporation left a solid residue which was distilled at 0.4 mm. to remove most of the excess *m*-dinitrobenzene (b.p. 98° (0.4 mm.)). The still residue was extracted with 150 ml. of boiling methanol. After cooling to room temperature and evaporation to 10 ml., the precipitate was collected and recrystallized four times from methanol to yield 0.7 g. (16%) of 2,4-dinitrobiphenyl. Before assay, 0.1 g. of this material in 5 ml. of benzene was put through a column of magnesium oxide.[5] After development with additional benzene, elution of the purple band with benzene, followed by evaporation of the benzene and recrystallization from methanol gave material melting at 109.3–110°. The results of tritium assay are summarized in Table I.

TABLE I

TRITIUM CONTENT OF *m*-DINITROBENZENE AND 2,4-DINITROBIPHENYL (MμC./MG. OF HYDROGEN)

Sample	$C_6H_4(NO_2)_2$ (exptl.)	$C_6H_3C_6H_3(NO_2)_2$ (exptl.)	$C_6H_3C_6H_3(NO_2)_2$ (calcd.)[a]
1	51.7 ± 1.6	13.2 ± 0.4	12.9 ± 0.4
2	22.8 ± 0.7	5.54 ± 0.17	5.7 ± 0.2

[a] Calculated assuming starting material is exclusively 2,4-isomer and that replacement of hydrogen and tritium occur at identical rates.

An authentic sample of 2,4-dinitrobiphenyl was prepared by mixed Ullmann coupling of 2,4-dinitrochlorobenzene and iodobenzene in 3.5% yield,[6] m.p. 109.3–110°.[7] This showed no depression of melting point when admixed with the preceding sample.

Anal. Calcd. for $C_{12}H_8N_2O_4$: C, 59.01; H, 3.26; N, 11.47. Found: C, 58.96; H, 3.25; N, 11.39.

Discussion

The agreement of the tritium content of the

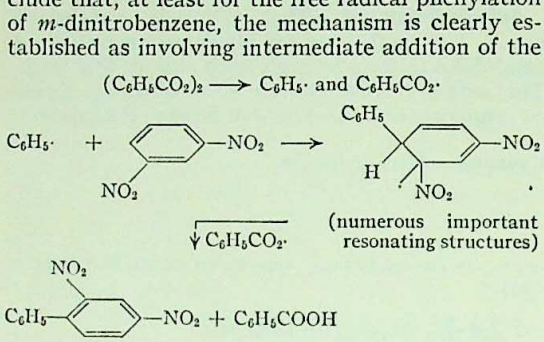
2,4-dinitrobiphenyl formed by benzoyl peroxide phenylation of 2,4-dinitrotritiobenzene with that calculated assuming no isotope effect is in accord with expectation if the phenylation occurred by mechanism 2. Mechanism 1 would have predicted a substantial isotope effect. We therefore conclude that, at least for the free radical phenylation of *m*-dinitrobenzene, the mechanism is clearly established as involving intermediate addition of the phenyl radical to the dinitrobenzene, followed by a non-rate controlling loss of hydrogen.



It should be pointed out that the mechanism demonstrated for the case of phenylation of *m*-dinitrobenzene may not necessarily hold for attack on less activated aromatic rings. For example, where resonance stabilization for the intermediate radical adduct with two groups as favorable for radical stability as the two nitro groups in *m*-dinitrobenzene is absent, radical abstraction could become more important. Such a mechanism would be particularly favored for a radical like the hydroxyl radical[2b] because of the contribution of the very strong hydrogen–oxygen bond that would be formed in the process.

Acknowledgment.—The authors wish to express their appreciation to Dr. R. C. Anderson and colleagues at Brookhaven National Laboratory, whose coöperation made this work possible.

The Mechanism of the Sandmeyer and Meerwein Reactions

BY JAY K. KOCHI*

RECEIVED SEPTEMBER 4, 1956

The Sandmeyer and Meerwein reactions are postulated to proceed *via* a common aryl radical. Reaction of the aryl radical with metal halide or its addition to olefin followed by reaction with metal halide gives Sandmeyer or Meerwein products, respectively. Evidence is given for the existence of aryl and aralkyl radicals and for the radical chain termination properties of metal halides. By utilizing these reactions, Sandmeyer and Meerwein products are obtained from sources other than arenediazonium salts.

Previous kinetic studies of the Sandmeyer[1] and related Meerwein[2] reactions have shown that these reactions are first order in both diazonium ion and cuprous salt, but they have not given complete information on the mechanisms of these reactions. We wish to give evidence for a common mechanistic path involving free radical intermediates. The essential feature of this mechanism is the role of the metal ion (copper) in acting as an effective radical chain terminator.[3] In the case of the two metal ions we studied (copper and iron), the process can be formulated as

$$R\cdot + MCl_n^q \longrightarrow RCl + MCl_{n-1}^q \qquad (1)$$

$$R\cdot + MCl_m^p \longrightarrow R^+ + MCl_m^{p-1} \qquad (2)$$

These processes represent alternate routes by which radicals can react with metal and complex-metal ions; that is, (1) directly through a ligand bridge or (2) *via* an electron transfer process.[4,5] In the Sandmeyer reaction aryl radicals react predominantly by equation 1, whereas with alkyl radical sproduced in the Meerwein reaction, processes 1 and 2 sometimes appear to be competitive.

Sandmeyer Reaction.—The free radical nature of the Sandmeyer reaction has been most consistently advocated by Waters[6a] and more recently by Pfeil,[6b] who postulate a quasi-intramolecular reaction involving one-electron transfers as

$$ArN_2^+ + Cu^I Cl_n \rightleftharpoons ArN_2CuCl_n^{7}$$

$$ArN_2CuCl_n \longrightarrow N_2 + Ar\,..\,Cl\,..\,Cu^{II}Cl_{n-1} \longrightarrow Ar\text{–}Cl + N_2 + Cu^{I}Cl_n$$

The important characteristic of this mechanism is the unique role played by cuprous ion in an oxidation–reduction capacity. We believe that it is *not*

(3) C. Bamford, A. Jenkins and R. Johnston, *Nature*, **177**, 992 (1956); F. Dainton and E. Collinson, *ibid.*, **177**, 1224 (1956); J. K. Kochi, THIS JOURNAL, **78**, 4815 (1956).

(4) The various aspects of these transfers have been elegantly presented by Taube and co-workers (H. Taube, *et al.*, THIS JOURNAL, **75**, 4119 (1953); **76**, 2103 (1954); **76**, 4053 (1954); **77**, 4481 (1955).

(5) The cupric ion alone is not wholly sufficient for its ability to act as a chain terminator. It appears that the most efficacious species is a higher chloro-complex, probably $CuCl_3^-$. Thus our experiments (*vide infra*) indicate that in the presence of limited chloride ions, an appreciable number of aryl radicals react by dimerization, while high chloride ion concentrations enhance the yields of Sandmeyer product (*cf.* references 1, 9b and 35).

(6) (a) W. Waters, "Chemistry of Free Radicals," 2nd Ed., Oxford Univ. Press, London, 1948, p. 163. (b) E. Pfeil and O. Velten, *Ann.*, **562**, 163 (1949); **565**, 183 (1949).

(7) Most mechanisms of the Sandmeyer reaction involve the intermediate formation of a diazonium–cuprous complex. This postulate is based partially on the observed formation of a colored complex when gross amounts of diazonium and cuprous salts are mixed. Whether these represent true intermediates has not been rigorously shown. For a discussion regarding the nature of these complexes see references 6b and 19a. It is not important for the purposes of what follows whether the reaction proceeds (a) through the rapid reversible formation of a complex intermediate followed by its slow decomposition or (b) by a slow bimolecular reaction of the diazonium ion (see Reaction 38). The contrary notwithstanding we shall treat the reaction as proceeding by the former path.

essential that this process be cyclic; instead a discrete two-step process may be postulated

$$ArN_2CuCl_2 \longrightarrow Ar\cdot + Cu^{II}Cl_2 + N_2 \quad (3)^{8,9}$$

$$Ar\cdot + CuCl_2 \longrightarrow ArCl + Cu^{I}Cl \quad (4)^{10}$$

Our experiments indicate that free aryl radicals are present in the catalyzed decomposition of diazonium ions (equation 3). For example, when *p*-nitrobenzenediazonium chloride is decomposed in aqueous acetone solutions with cuprous chloride in the presence of iodine, iodine is consumed rapidly to give good yields of *p*-nitroiodobenzene

$$Ar\cdot + I_2 \longrightarrow ArI + I\cdot \quad (5)$$

The possibility that the iodo compound is formed by an ionic process involving iodide ion formed by reactions such as

$$I_2 + Cl^- \longrightarrow ICl + I^-$$

$$I^- + ArN_2^+ \longrightarrow ArI + N_2$$

is made unlikely by the greater than 100% yields of *p*-nitroiodobenzene based on one mole of product per mole of iodine taken. Furthermore, any iodide formed in such reactions would probably be oxidized rapidly by the cupric ion.

When *p*-nitrobenzenediazonium bisulfate is treated with cuprous chloride in the presence of limited amounts of chloride ions in aqueous acetone solutions at −25° in the presence of oxygen, in addition to a 42% yield of *p*-nitrochlorobenzene a 46% yield of *p*-nitrophenol is obtained.

$$Ar\cdot + O_2 \longrightarrow ArO_2\cdot \xrightarrow{Cu^+} ArOH \quad (6)$$

In the absence of oxygen, cupric sulfate also precipitates from solution and *p*-nitrochlorobenzene and 4,4′-dinitrobiphenyl[12] can be isolated in 76 and 9% yields, respectively. In the presence of excess cupric chloride the formation of the Sandmeyer product is increased at the expense of the coupling product.[13] Further substantiation of the

(8) Transient aryldiazo radicals may be formed. The significance of a particular chlorocuprous ion, $CuCl_2^-$, as the catalyst[1] in the Sandmeyer reaction, in this scheme, can be attributed to the favorable half-cell potential

$$CnCl_2^- \rightleftharpoons ClCl_2 + e^-$$

compared to the other chlorocuprous ions. (See, for example, N. Sidgwick, "The Chemical Elements and Their Compounds," Oxford Univ. Press, London, 1950, p. 103 ff.)

(9) (a) S. Dickerman, K. Weiss and A. Ingberman, *J. Org. Chem.*, **21**, 260 (1956); (b) W. Waters, private communication (see also D. Nonhebel and W. Waters, Abstracts, International Congress on Catalysis, Philadelphia, Pa., 1956.)

(10) Aryl radicals appear to react by process 1 which involves a direct halogen atom transfer to form the aryl halide. The alternative two-step process is an oxidation to an arylcarbonium ion followed by reaction with halide ion. This latter route appears untenable in view of the absence of phenols when the reaction is obtained in water as solvent. If carbonium ions were intermediates, phenols would be expected since arylcarbonium ions obtained in the ionic unimolecular solvolysis of aryldiazonium ions show little selectivity[11] for nucleophiles.

(11) E. Lewis and W. Hinds, THIS JOURNAL, **74**, 304 (1952); D. DeTar, *et al.*, *ibid.*, **76**, 1680 (1954); **72**, 865 (1950).

(12) W. Waters ("Chemistry of Free Radicals," 2nd Ed., Oxford Univ. Press, London, 1948, p. 165) postulates that biaryls arise by the coupling of aryl radicals (see, however, reference 19).

(13) That the *p*-nitrophenyl radical may not react instantaneously with oxygen is indicated by the small amount of 4,4′-dinitrobiphenyl which is obtained in the oxygen run. The yield of the biaryl appears to be proportional to the rate of addition of cuprous chloride. The precedent for this deduction appears in the works of Walling and Buckler and Muller and Topel who obtained considerable amounts of biphenyl in addition to phenol in the oxygenations of Grignard and lithium reagents, respectively.[14] Wieland, furthermore, reported that some biphenyl is obtained when phenylazotriphenylmethane is decomposed in the presence of oxygen[15] (*cf.* references 16). See further for indications of the selective reactions of radicals with oxygen.

(18) W. Leonhards, Doctoral Dissertation, Marburg, Germany, 1952.

(19) (a) E. Pfeil, *Angew. Chem.*, **65**, 155 (1953). (b) An alternative route for the diaryl formation in Sandmeyer type reactions may be *via* intermediate aryl copper compounds which may arise from the reaction of aryl radicals with cuprous chloride. Aryl copper compounds are known to undergo such decomposition to diaryls (H. Gilman, "Organic Chemistry," 2nd Ed., Vol. I, J. Wiley and Sons, Inc., New York, N. Y., 1943, p. 542). Similarly, it is possible for azo compounds to result from the reaction of these nucleophilic aryl copper compounds with diazonium salts. These alternatives must be held with a certain amount of reserve since aryldimethylcarbinols are not isolated when acetone is used as solvent.

(20) Rather the reverse process is obtained (J. Baxendale and J. Magee, *Trans. Faraday Soc.*, **51**, 204 (1955)).

production of aryl radicals under these conditions is the report of Dickerman, *et al.*,[9a] that aromatic solvents can be arylated. Waters and Nonhebel[9b] have been able to polymerize acrylonitrile in aqueous solutions under the conditions of the Sandmeyer reaction in the absence of oxygen. Aryl residues as end-groups were accounted for in good yields.

Systems other than arenediazonium and cuprous salts give indications of the chain-terminating properties of metal halides. For example, *p*-nitrochlorobenzene is formed in 84% yield from the decomposition of N-nitroso-*p*-nitroacetanilide in acetone solutions of ferric chloride. Chlorobenzene and trityl chloride are formed by a similar decomposition of phenylazotriphenylmethane in the presence of ferric chloride. Analogously, azobisisobutyronitrile produces significant amounts of cuprous chloride when it is decomposed in anhydrous *t*-butyl alcohol containing cupric chloride.[17a] Under similar conditions in acetonitrile, the rate of formation of cuprous chloride was found to be zero order in cupric chloride.[17b] The use of cupric salts as inhibitors of vinyl polymerization also points to their effectiveness as radical chain terminators.

That cupric chloride reacts with aryl radicals under the usual Sandmeyer conditions was shown by Pfeil and Velten[6b] who obtained quantitative yields of *p*-nitrochlorobenzene when aqueous solutions of *p*-nitrobenzenediazonium bisulfate were treated with sufficient quantities of cupric chloride at 100°. Furthermore, Leonhards[18] has shown that the addition of cupric chloride greatly reduced the amount of cuprous chloride required in the aqueous Sandmeyer reaction from as much as 0.2 to only 0.01 mole.

In aqueous solutions the destruction of the aryl radicals can occur by several competitive paths: (1) dimerization to yield biaryl,[19] (2) reaction with diazonium ion and cuprous salt to give azo compound[19] and (3) reaction with cupric chloride to give the Sandmeyer product. The solvent water does not appear to react significantly by the energetically less favorable process[20]

$$Ar\cdot + H_2O \longrightarrow ArH + HO\cdot \quad (7)$$

CC-0. Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

In aqueous acetone solution, however, appreciable amounts of reduction (*i.e.*, chain transfer) by solvent[21] does take place to produce a more stable acetonyl radical

$$Ar\cdot + CH_3COCH_3 \longrightarrow ArH + CH_3\dot{C}OCH_2 \quad (8)^{22}$$

The resulting acetonyl radicals can either dimerize[23] or react with cupric chloride to form chloroacetone. The yields of the reduction product, ArH, are found to be approximately equal to the chloroacetone formed.[9]

$$CH_3COCH_2\cdot + CuCl_2 \longrightarrow CH_3COCH_2Cl + CuCl \quad (9)$$

In order to assess the efficiency with which cupric chloride reacts with aryl radicals, the relative amounts of reduction to substitution (equations 8 and 4) were measured by determining the amount of chloroacetone formed as a function of the cupric chloride concentration. Aqueous acetone solutions containing diazonium salt, cupric chloride and sealed breakable ampules of cuprous chloride were carefully degassed. The amounts of cuprous chloride remaining and chloroacetone formed were determined quantitatively after the diazonium decomposition was complete. As shown in Table I

TABLE I

EFFECTS OF CUPRIC CHLORIDE AND OLEFIN ON CHLOROACETONE FORMATION AND CUPROUS CHLORIDE CONSUMPTION[a]

Benzenediazonium chloride	Run	Cupric chloride, meq.	Chloroacetone,[b] meq.	Cuprous[c] chloride, meq.

[a] In acetone (25 ml.) containing 2.84 meq. of diazonium salt, 18.60 meq. of chloride, 0.128 meq. of cuprous chloride and 8 ml. of water at 0°. [b] Total chloroacetone formed, including reaction between cupric chloride and acetone (in most cases negligible at these temperatures). [c] Cuprous chloride remaining after completion of reaction. [d] Contains 25 meq. of acrylonitrile. [e] Contains 25 meq. of styrene. [f,g] Contains 1.42 meq. and 5.42 meq. of diazonium salt, respectively.

the reduction of aryl radicals (as measured by the chloroacetone formed) can be effectively decreased by increasing the amount of added cupric chloride (*cf.* runs 1, 4 and 6; 7 and 11; 12, 13 and 14) It is apparent, moreover, that with increasing cupric chloride concentration less cuprous chloride is consumed, as would be expected from the preceding argument.

(21) It has been reported[6b] that the Sandmeyer reaction in methanol produces no formaldehyde.

(22) W. Waters, *J. Chem. Soc.*, 2007 (1937); 864, 1805 (1939).

(23) In none of our experiments could we find ethylene glycol diacetate.

Meerwein Reaction.—In the presence of olefin, aryl radicals produced from diazonium salts by cuprous chloride in a process such as (3), undergo a third important reaction, *viz.*, addition

$$Ar\cdot + >C{=}C< \longrightarrow Ar{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}\cdot \quad (10)$$

In all cases known, the direction of addition to an unsymmetrical olefin corresponds to that producing the more stable radical.[24] In a subsequent reaction the aralkyl radical[25] can react with metal ion by either of the steps postulated previously (equations 1 and 2); *i.e.*, by a direct transfer of a halogen atom from copper to the radical or by an oxidation to a carbonium ion.[27] These two competitive processes are illustrated by the reaction of phenyl and *p*-nitrophenyl radicals with styrene. In the former case the exclusive product is α-chlorobibenzyl (equation 1); with the *p*-nitrophenyl radical, on the other hand, a mixture of α-chloro-*p'*-nitrobibenzyl and *p*-nitrostilbene is obtained. Under the conditions of the experiment the chloride does not eliminate to yield olefin. It is not quite certain at present whether the reactions of metal ions with radicals by these two processes involve the same complexed metal ion[4b] (*i.e.*, $m = n$). There is some evidence that the metal ion involved in the direct halogen transfer step is in a higher chloro-complex form than that involved in the electron transfer step. For example, when *p*-nitrobenzenediazonium bisulfate is decomposed in aqueous acetone solution containing styrene with cuprous chloride (*i.e.*, a limited amount of chloride ion present) a 21% yield of *p*-nitrostilbene is formed. The same reaction with an excess of chloride ion produces only 9% stilbene.

The presence of aralkyl radicals in the chain propagation step (equation 10) is shown by the trapping of this radical by iodine and oxygen. If iodine is added to a cuprous-catalyzed decomposition of *p*-nitrobenzenediazonium chloride in the presence of acrylonitrile, the intermediate hydro-

(24) (a) C. Koelsch and V. Boekelheide were the first to point out the free radical nature of this reaction (THIS JOURNAL, **66**, 412 (1944); **65**, 57 (1943)); (b) *Cf.* R. Huang, *J. Chem. Soc.*, 1749 (1956).

(25) O. Vogl and C. Rondestvedt[26] have shown in the case of the maleic–fumaric acid system that the addition to the double bond is not stereospecific, which indicates that the aralkyl radical is "free."

(26) O. Vogl and C. Rondestvedt, THIS JOURNAL, **78**, 3799 (1956).

(27) (a) Previous workers[28] have shown how it is possible for the carbonium ion to eliminate a β-proton or a β-carboxyl group to form olefins. (b) A case can be made, however, for the olefins to be formed from the aralkyl radicals by direct removal of the β-hydrogen atom by either cupric chloride or another radical. There is no precedent for cupric chloride acting in this capacity (see however reference 9 and 29). The removal of the β-hydrogen atom by radicals is analogous to the mechanism of homolytic aromatic substitution.[30] It is interesting to note that Vogl and Rondestvedt (reference 31) obtained phenylated coumarins, albeit in low yields, from aryl radical sources in the absence of metal ions. That the low yield is not due to the unreactivity of aryl radicals formed under these different conditions is borne out by the fact that the starting coumarin is isolated in poor yield. Instead it appears that the aralkyl radical resulting from the attack on coumarin disappears by reaction with solvent and/or reactants.

cinnamonitrile radical is trapped as the iodide

$$Ar{-}CH_2{-}CH{=}CN + I_2 \longrightarrow Ar{-}CH_2{-}CHICN + I\cdot$$

In a like manner *p*-nitrobenzenediazonium bisulfate and styrene do not react with cuprous chloride and oxygen at −25° to form Meerwein product. Instead the aralkyl radical reacts with oxygen to form an intermediate peroxide which in the presence of cuprous ion is reduced[32] to the ketone, *p*-nitrodeoxybenzoin

$$Ar{-}CH_2{-}CH{-}C_6H_5 + O_2 \longrightarrow$$

$$Ar{-}CH_2{-}CH{-}C_6H_5 \xrightarrow{Cu^+} Ar{-}CH_2{-}CO{-}C_6H_5 \quad (12)$$
$$\quad\quad\quad

Digitized by Arya Samaj Foundation Chennai and eGangotri

centration (*cf.* 12 and 13) neither the rate of diazonium decomposition nor cuprous titer are affected. The yields of Sandmeyer and Meerwein products, however, are markedly different in each case as was shown previously.[2]

It is apparent that at low cupric and low olefin concentrations the bimolecular reaction of aryl radicals and olefin or metal halides is subverted by reactions involving consumption of cuprous catalyst (*e.g.*, dimerization of radicals or azo compound formation). Since the reaction in aqueous acetone is extremely sensitive to cuprous catalysts,[35] a small decrease in catalyst concentration due to these catalyst-destroying reactions would lead to significant changes in rate of diazonium decomposition. At low cupric, but high olefin concentrations, the olefin effectively competes with cuprous-consuming reactions as shown by the unchanged cuprous titer.

Thus, the observed qualitative variation in rates of diazonium decomposition with various olefins can be attributed to the efficiency with which each olefin competes with oxygen[36] and other side reactions which destroy catalyst. Although earlier mechanisms involving various forms of olefin complexation cannot be entirely discounted on the basis of these results, they appear to be unnecessarily involved.

The role of acetone in the decomposition of diazonium salts is threefold: (1) reaction with cupric chloride to produce cuprous chloride,[29] (2) solvent effects favoring higher chloro-complexes of cuprous and cupric ions[5,29] and (3) acceleration of the bimolecular reaction of diazonium and complex cuprous ions.[38] It is not necessary, moreover, that acetone acts in the first capacity since it is known that diazonium acetates and chlorides can be decomposed to give aryl radicals,[40] which can react with cupric chloride in a subsequent step (equation 4) to produce autocatalytic reactions. The essential requirement of the solvent, however, is that it does not effectively compete with olefin or metal halides for the aryl or aralkyl radicals in chain-terminating processes.

The unique feature of metal halides in acting as chain-terminating agents is the efficiency and selectivity with which they react with radicals. Thus, it is well known that olefins are not polymerized to any appreciable extent under the conditions of the Meerwein reaction despite the presence of radicals such as aryl and aralkyl which are known chain initiators. The selectivity with which metal halides react with aralkyl radicals (such as growing styryl and acrylonitrile radicals) may be interpreted in terms of the life-times (reactivities)[41] of these radicals in solution. This speculation must be subjected to further scrutiny.

Acknowledgments.—I would like to thank Dr. George S. Hammond for generous research facilities and the Institute for Atomic Research, Ames Laboratory, for numerous infrared spectra.

Experimental

Sandmeyer Reaction. Decomposition of *p*-Nitrobenzenediazonium Chloride.—A stock solution of *p*-nitrobenzenediazonium chloride was made by diazotizing 69 g. (0.5 mole) of *p*-nitroaniline with 108 ml. of concentrated hydrochloric acid, 200 g. of ice and 35 g. of sodium nitrite in 100 ml. of water. Excess nitrite was destroyed with urea and the clear filtered solution made up in 500 ml.

(a) **Oxygen-free.**—A 125-ml. portion of this stock solution was added to 500 ml. of acetone in a round-bottom flask at 0°. Oxygen-free argon was swept through the solution and a solution containing 2.0 g. of cuprous chloride and 1 g. of lithium chloride in 50 ml. of anhydrous acetone was added dropwise. Nitrogen was evolved immediately. Vacuum distillation of the acetone, followed by ether extraction, yielded 13.6 g. (68%) of *p*-nitrochlorobenzene (m.p. 82–84°). The mother liquors yielded 21% nitrobenzene.

When another 125-ml. portion of the diazonium solution was subjected to the same treatment except for the addition of 26 g. (0.2 mole) of cupric chloride, 82% *p*-nitrochlorobenzene and 9% nitrobenzene were isolated. Much less cuprous solution was needed for this reaction.

(b) **With Iodine.**—To a similar deoxygenated mixture was added a solution of 10 g. (0.039 mole) of iodine in 150 ml. of acetone, followed quickly by an acetone solution containing 5 g. of cuprous chloride and 3 g. of lithium chloride. The nitrogen evolution was instantaneous and a heavy precipitate of *p*-nitroiodobenzene formed. The solution was diluted with water and filtered. The extraction of the dried solid with ether leaves nearly pure *p*-nitroiodobenzene; the ether extracts lead to a 44% (8.7 g.) yield of *p*-nitrochlorobenzene. No nitrobenzene could be detected. The combined yields of *p*-nitroiodobenzene after crystallization (ligroin, m.p. 171–173°) and careful work-up of the mother liquors is 15.6 g. (162% based on I_2). The original acetone solution darkened on standing due to the oxidation of the hydrogen iodide. It is necessary that the cuprous solution follow soon after the addition of the iodine since there appears to be a slow reaction between diazonium salts and iodine in acetone solutions (*vide infra*).

With 5 g. of iodine a 178% yield (based on I_2) of *p*-nitroiodobenzene and a 65% yield of *p*-nitrochlorobenzene (based on diazonium salt) is obtained. Similarly, 23 g. of iodine gives a 93% yield of the iodo compound (based on the diazonium salt).

Decomposition of Diazonium Bisulfates (Minimum Chloride). (a) **Oxygen-free.**—Crystalline *p*-nitrobenzenediazonium bisulfate (NBDB)[42] (12 g., 0.0485 mole) was dissolved in 40 ml. of water and added to 400 ml. of redistilled acetone. Purified argon was bubbled through the chilled solution (−25°) and an anhydrous acetone solution of cuprous chloride (10 g.) and lithium chloride (7 g.) was added slowly to the anaerobic solution. The solution, after nitrogen evolution was complete, was decanted from the precipitated cupric sulfate and vacuum distilled at room temperature. Water was added to the residue and the mixture extracted with ether. Evaporation of the ether left 6.5 g. of solid residues which consisted of 5.7 g. (76%) of *p*-nitrochlorobenzene and 0.54 g. (9.1%) of 4,4′-dinitrobiphenyl (m.p. 233–235°). Nitrobenzene could be detected in the mother liquors.

This reaction was repeated with the addition of 10 g. of cupric chloride. Much less cuprous chloride was required for complete nitrogen evolution, and the yield of *p*-nitrochlorobenzene was 85%, and only 3% of the biphenyl compound was isolated.

(35) J. Kochi, THIS JOURNAL, 77, 5090 (1955).

(36) Previous workers have taken little pains to eliminate oxygen from their reactions. The retardation of the Meerwein and Sandmeyer reactions by oxygen[2,35] is now accounted for by reactions which destroy cuprous catalyst such as equations 5, 6 and 13 in addition to the direct oxidation of the cuprous ion.

$$CH_3COCH_2\cdot + O_2 \longrightarrow CH_3COCH_2O_2\cdot^{37} \quad (13)$$

(37) I. Kolthoff and A. Medalia, THIS JOURNAL, 71, 3784 (1949).

(38) Other solvents can serve the latter two purposes with varying degrees of efficacy. Thus, lower alcohols, dimethylformamide, acetonitrile, etc., increase the rate of reaction between these oppositely charged species. Similarly, the ionic reaction of iodide ion and diazonium ion is extremely rapid in acetone, alcohol and dioxane solutions.[29]

(b) With Oxygen.—Oxygen was bubbled through a chilled (−25°) solution containing 10.8 g. of NBDB, 50 ml. of water and 400 ml. of acetone. A solution of cuprous chloride (7 g.) was added slowly over a period of several hours while oxygen was bubbled vigorously through the solution under slight pressure (5 p.s.i.). Acetone was vacuum distilled from the decanted solution at room temperature and the residue extracted with chloroform. The dried chloroform solution (sodium sulfate) yielded 5.8 g. of solid residue. Extraction with petroleum ether gave 2.9 g. (42%) of *p*-nitrochlorobenzene. Sublimation of the residue resulted in 2.8 g. (46%) of *p*-nitrophenol (from water, m.p. 111–113°) and 0.1 g. of 4,4′-dinitrobiphenyl. If the cuprous solution is added too rapidly the amount of biphenyl increases.

Decomposition of N-Nitroso-*p*-nitroacetanilide (NNAA).—Solid NNAA[43] (5 g., moist) was dissolved in 45 ml. of anhydrous acetone and the solution added to a mixture of 6 g. of ferric chloride hexahydrate, and 3 g. of lithium chloride in 75 ml. of acetone. After argon was bubbled through the solution briefly, it was heated (with the exclusion of air) in a water-bath at 60° for 24 hr. Water was added to the reaction mixture; the precipitate was filtered, dried and crystallized from petroleum ether. The yield of *p*-nitrochlorobenzene is 2.1 g. (84% based on nitrogen evolution). Insoluble unidentified material weighed 0.3 g.; the mother liquors yielded small amounts of nitrobenzene.

Decomposition of Phenylazotriphenylmethane.—An acetone solution (100 ml.) containing 5 g. (0.0142 mole) of phenylazotriphenylmethane[44] and 10 g. of ferric chloride hexahydrate was heated at 60° in a water-bath for 12 hr. The nitrogen evolution was complete in approximately 2 hr. From the reaction mixture 1.1 g. of chlorobenzene and 3.3 g. of triphenylcarbinol were isolated. The trityl chloride which was presumably formed in the reaction mixture was hydrolyzed either during the heating or subsequent work-up.

Meerwein Reaction. Decomposition of *p*-Nitrobenzenediazonium Chloride. (a) Oxygen-free.—Forty ml. (0.04 mole) of the diazonium solution mentioned previously was added to a solution of 200 ml. of acetone and 10 g. of acrylonitrile. A solution of cuprous chloride (0.5 g.) and lithium chloride (0.3 g.) in anhydrous acetone (30 ml.) was added dropwise to the deoxygenated solution at 0° with stirring. Nitrogen was evolved immediately. The solution on dilution with water yielded 8.1 g. of α-chloro-*p*-nitrohydrocinnamonitrile which was recrystallized from ligroin as colorless needles (94%, m.p. 110–111°).

Anal. Calcd. for $C_9H_7N_2O_2Cl$: C, 51.3; H, 3.36; Cl, 16.9. Found[45]: C, 51.5; H, 3.48; Cl, 16.4.

(b) With Iodine.—An acetone solution of 16 g. of iodine was added to a deoxygenated solution containing 125 ml. of stock diazonium solution, 20 g. of acrylonitrile and 500 ml. of acetone at 0°. This was followed rapidly by an acetone solution of cuprous chloride (3 g.) and lithium chloride (2.5 g.). Nitrogen was evolved immediately and a heavy precipitate formed. The solution was diluted with water and filtered. The dried (30.3 g.) solid was triturated with small portions of ether. Evaporation of the ether left 6.6 g. of a solid from which no *p*-nitrochlorobenzene could be extracted with petroleum ether (b.p. 60–70°). It consisted wholly of a mixture of α-iodo and α-chloro-*p*-nitrohydrocinnamonitrile. These related compounds could not be separated. Neither careful fractional crystallization from ligroin or benzene nor partial vacuum sublimation were successful. In every case fine colorless needles (m.p. 103–104°, mix m.p. 107–109°) were obtained which on mild treatment with triethylamine in ligroin gave *p*-nitrocinnamonitrile (m.p. 198–201°). Iodide ion was present in the aqueous extracts of the ligroin solution. The infrared spectra (in CCl_4 and CS_2) were identical with those of the chlorononitrile. The elemental analysis, calculated on the assumption that the iodonitrocinnamonitrile was the sole contaminant, indicated that 13% of the mixture consisted of this unremovable impurity.

Anal. Calcd. for 13% iodo compound: C, 49.4; H, 3.22; total halide, 20.2. Found: C, 49.7, 5.00; H, 3.12, 2.99; total halide, 20.4, 20.3.

Decompositions of Diazonium Bisulfates (Minimum Chloride). (a) Oxygen-free.—To a deoxygenated solution of 12 g. of NBDB in 50 ml. of water, 9 g. of styrene and 300 ml. of acetone was added dropwise a solution of cuprous chloride (7 g.) and lithium chloride in acetone at −20°. The nitrogen evolution occurred immediately and only on the continued cuprous chloride addition. The solution was decanted from the cupric sulfate precipitate, vacuum distilled and extracted with ether. Basic extractions of the ethereal solution were colored dark red. Acidification of the aqueous extract followed by ether partition gave only a small amount (0.1 g.) of material which was not *p*-nitrophenol. The original ether solution after drying (sodium sulfate) yielded 8.4 g. of a semi-crystalline material, which on alumina chromatography with petroleum ether and benzene yielded 1.5 g. of *p*-nitrochlorobenzene, 2.1 g. (16.5%) of α-chloro-*p*′-nitrobibenzyl (m.p. 91–92°), 0.98 g. (9%) of *p*-nitrostilbene (m.p. 154–156°) and 0.1 g. of 4,4′-dinitrobiphenyl (m.p. 230–234°).

Anal. Calcd. for $C_{14}H_{12}NO_2Cl$: C, 64.2; H, 4.62; N, 5.35. Found: C, 64.8; H, 4.70; N, 5.38.

The addition of 14 g. of cupric chloride to a similar reaction yielded 3.4 g. (27%) of the chlorobibenzyl compound and 0.35 g. of *p*-nitrostilbene. On the other hand, the addition of 26 g. of cupric nitrate trihydrate increased the proportion of *p*-nitrostilbene (2.3 g., 21%) to α-chloro-*p*′-nitrobibenzyl (0.17 g.). The reaction was accompanied by larger amounts of colored material not eluted with chloroform.

(b) With Oxygen.—A solution of styrene (9 g.) and 400 ml. of acetone containing 12.7 g. of crystalline NBDB and 40 ml. of water was chilled to −25°. Oxygen was bubbled vigorously through the solution with a fritted glass tube and maintained at 4 p.s.i. A solution of 7 g. of cuprous chloride and 5 g. of lithium chloride in 150 ml. of anhydrous acetone was added dropwise with stirring. The solution was decanted after the reaction was complete and vacuum distilled without warming above room temperature. The residue was extracted with chloroform, the light yellow chloroform solution was dried and vacuum distilled leaving a semi-solid mass (9.4 g.). This mixture was repeatedly extracted with petroleum ether at room temperature to remove the *p*-nitrochlorobenzene (19 g.) and a small amount of unidentified aldehydic material (not benzaldehyde). The residue from the petroleum ether extraction was crystallized from ethanol (1.6 g., 13%). It was identified as *p*-nitrodesoxybenzoin (m.p. 142–144°,[46] 2,4-dinitrophenylhydrazone,[47] m.p. 234–235°, oxime,[48] m.p. 104–105°). In addition, less significant amounts of *p*-nitrochlorobenzene (0.2 g.), *p*-nitrostilbene (0.05 g.) and 4,4′-dinitrobiphenyl (0.02 g.) were obtained. No *p*-nitrophenol was found.

Decomposition of N-Nitroso-*p*-nitroacetanilide.—Styrene (2.2 g.) was added to an acetone (120 ml.) solution of ferric chloride (6 g.), lithium chloride (3 g.) and NNAA (5 g., moist) and heated at 60° for 12 hr. After the completion of the nitrogen evolution, water was added to the reaction mixture and the aqueous solution decanted from the brown oil. The styrene was allowed to evaporate and the semi-crystalline residue was chromatographed directly with ligroin and benzene mixtures. The yield of α-chloro-*p*′-nitrobibenzyl is 1.8 g. (43%); *p*-nitrochlorobenzene is 0.6 g. If present, *p*-nitrostilbene was not detected. Weight of tar is 0.6 g.

When 2.0 g. of acrylonitrile was added to the reaction as indicated above, 0.85 g. of *p*-nitrochlorobenzene, 0.51 g. (15%) of α-chloro-*p*-nitrohydrocinnamonitrile and 1.4 g. of tar was obtained. That acrylonitrile was incorporated in the tar is indicated by a nitrile absorption (2250 cm.$^{-1}$) in the infrared spectrum. These results are in qualitative accord with the observations of the relative efficiency of ferric ion in terminating growing styryl and acrylonitrile radicals.[3]

The decomposition of NNAA in the presence of metal ions is complicated by side reactions involving denitrosation.[43] Cuprous chloride denitrosates quantitatively in cold acetone solutions, whereas cupric chloride and chromic chloride do so only upon heating (probably due first to the reduction of the metal ion by acetone).[29] In the case of ferric chloride, *p*-nitroacetanilide formation is at its maximum when solu-

tions in acetone are saturated with lithium chloride (*i.e.*, in a highly complexed form). Ferrous chloride does not cause the formation of nitrous oxide; the products of this reaction consist of nitrobenzene and tar and are the same as those in the absence of metal ions. Decompositions of NNAA in anhydrous dimethylformamide containing metal salts are complicated by reaction with solvent.[49]

Decomposition of Phenylazotriphenylmethane.—Argon was flushed through an acetone solution (100 ml.) containing 5 g. (0.0143 mole) of PATM, 10 g. of ferric chloride and 15 g. of styrene. As the solution was heated at 60° in the absence of air, colorless needles of ferrous chloride were deposited on the sides of the flask. The solution was decanted, diluted with water and extracted with ether. The light yellow solution after washing with dilute sulfuric acid and water was dried and vacuum distilled. The semi-solid residue was extracted repeatedly with petroleum ether; the petroleum ether solution yielded on chromatography 1.7 g. of an oil. The oil easily solvolyzed in 50% aqueous acetone to give chloride and phenylbenzylcarbinol (m.p. 60–62°). Another portion of the oil was treated with alcoholic potassium hydroxide to yield stilbene (m.p. 123–125°). Authentic α-chlorobibenzyl made *via* the carbinol was the same as the oil. This compound eliminates hydrogen chloride spontaneously on standing.[35] The yield of chloride was based on the stilbene (46%) formed by basic treatment. The petroleum ether insoluble material was nearly pure triphenylcarbinol (3.4 g., 91%, m.p. 160–162°).

Benzoyl Peroxide Decomposition.—A mixture of 25 g. (0.206 equivalent) of benzoyl peroxide, 90 g. of ferric chloride hexahydrate, 20 g. of lithium chloride and 50 g. of styrene in 800 ml. of acetone was heated at 60° for 36 hr. in the absence of air. The carbon dioxide liberated was precipitated as barium carbonate (8.1 g., 0.041 mole). The acetone was vacuum distilled at room temperature and the residue was poured into dilute sulfuric acid and then extracted with ether. The ether extract was washed several times with 5% sodium bicarbonate (13.2 g. of benzoic acid, 0.108 mole). The ethereal solution after drying was distilled; it left an oily light residue (27 g.). The oil on fractionation *in vacuo* (0.35 mm.) gave: (a) 4.5 g., boiling 50–65°, mostly styrene; (b) 125–132°, 4.5 g.; (c) 160–165°, 13.5 g.; and (d) high boiling material, 2.1 g. Fraction b partially crystallized into a mixture of stilbene (2.7 g., 0.015 mole) and α-chlorobibenzyl (1.5 g., 0.007 mole) which were separated by solubility in petroleum ether (b.p. 30–40°). Fraction c on redistillation consisted almost wholly of a compound boiling at 164–165° at 0.7 mm. This chlorine-containing compound solvolyzed readily in aqueous acetone; basic hydrolysis of the resulting oil in dioxane–water solutions yielded benzoic acid and water-soluble styrenediol (m.p. 64–64°).[50] The compound probably has the structure $C_6H_5CO_2CH_2CHClC_6H_5$.

Anal. Calcd. for $C_{15}H_{13}O_2Cl$: C, 69.0; H, 5.02; Cl, 13.6. Found: C, 69.5, 69.7; H, 4.99, 5.10; Cl, 13.3.

The yields depend to a large extent on the ratio of ferric chloride to added lithium chloride. With no added lithium chloride the decomposition in the presence of styrene leads to more high boiling residue than those reactions with added chloride. Neither stilbene nor chlorobibenzyl could be isolated from the former solutions. It has not been determined yet whether the ester arises *via* a ferric-catalyzed homolytic or heterolytic[51] process. This reaction merits further investigation.

Decomposition of Diazonium Salts in the Presence of $CuCl_2$.—Standard stock solutions were made from crystalline diazonium chlorides, reagent cupric chloride and lithium chloride as described previously.[2] Freshly crystallized cuprous chloride was dissolved in anhydrous acetone (0.064 *M*) with the aid of lithium chloride and aliquots were sealed in 1-, 2- and 3-ml. thin walled ampules. The aqueous cupric chloride solution was placed in the center well of the reaction vessel; the diazonium salt, lithium chloride and vial of cuprous chloride solution together with acetone were placed in the outer well. The vessel was degassed by the standard procedure. The evacuated flask was then shaken at 0° to break the ampule containing cuprous chloride. After the reaction was complete (test with β-naphthol solution), acidic ferric ammonium sulfate solution was added and the solution vacuum distilled into a Dry Ice trap. Under these conditions acetone, chloroacetone and water were collected. To the thawed solution was added 4 g. of sodium iodide and the volume made up to 50 ml. with acetone. The iodoacetone was analyzed by acidifying an aliquot with aqueous perchloric acid and quickly titrating with standard sodium thiosulfate solution. Control runs proved to be accurate within 3%. The stoichiometry of the reactions are[52]

$$ClCH_2COCH_3 + I^- \longrightarrow ICH_2COCH_3 + Cl^-$$

$$ICH_2COCH_3 + HI \longrightarrow CH_3COCH_3 + I_2$$

The residual ferrous ion was titrated with standard ceric solution. The extent of oxidation of the ferrous salt during the distillation is negligible.

The Optical Rotation and Configuration of a Pure Enantiomorph of Ethanol-1-*d*[1,2,3]

BY H. RICHARD LEVY,[4] FRANK A. LOEWUS AND BIRGIT VENNESLAND

RECEIVED NOVEMBER 26, 1956

A method is described for the preparation of gram quantities of a pure enantiomorph of ethanol-1-*d*. CH_3CDO is reduced to ethanol-1-*d* by glucose in the presence of alcohol dehydrogenase, glucose dehydrogenase and a catalytic amount of DPN. The ethanol-1-*d* was shown by enzymatic analysis to contain no more than 0.1 % of its enantiomorph and the optical rotation was determined. A discussion is presented of the configuration of the ethanol and of the factors contributing to the steric specificity of the enzyme reaction.

Introduction

The reaction catalyzed by yeast alcohol dehydrogenase previously has been shown to involve a direct and reversible transfer of hydrogen between ethanol and diphosphopyridine nucleotide (DPN).[5,6] This transfer has been shown to be sterically specific, both for the DPN[6] and for the ethanol.[7] Loewus, *et al.*,[7] have used alcohol dehydrogenase to prepare both enantiomorphs of ethanol-1-*d*. In these experiments, one enantiomorph was prepared by reducing acetaldehyde-1-*d* (CH_3CDO) with unlabeled reduced DPN (DPNH), and the other enantiomorph was prepared by reducing unlabeled acetaldehyde with monodeuterio-reduced DPN (DPND). The enantiomorphs were identified by examining the products of their enzymatic reoxidation. Thus, the ethanol formed by reducing CH_3CDO with DPNH transferred only *hydrogen* back to DPN, forming CH_3CDO and DPNH; whereas the ethanol formed by reducing CH_3CHO with DPND transferred *deuterium* back to DPN, forming CH_3CHO and DPND. In both cases the cost of large quantities of reduced DPN set a practical limit to the quantities of ethanol-1-*d* which could be prepared conveniently, and insufficient quantities were obtained to determine optical rotation. Since the latter value is of some interest and since the ethanol-1-*d* may provide a useful tool for studying the mechanism of displacement reactions on primary alcohols,[7-9] a method was sought whereby gram quantities of this substance might be economically prepared. This report describes such a procedure.

Procedures, Results and Discussion

The synthesis of gram quantities of ethanol-1-*d* was carried out by reducing CH_3CDO with glucose in the presence of alcohol dehydrogenase (ADH), glucose dehydrogenase (GDH) and a catalytic amount of DPN (equation 1). By the use of such

$$CH_3CDO + \text{glucose} \xrightarrow[\text{GDH, ADH}]{\text{DPN}} CH_3CDHOH + \delta\text{-gluconolactone} \quad (1)$$

a coupled system, the requirement for stoichiometric quantities of DPN was avoided. In the coupled reaction, DPN is reduced by the glucose dehydrogenase reaction (equation 2) and reoxidized by CH_3CDO in the presence of ADH. The

$$\text{glucose} + DPN^+ \longrightarrow \delta\text{-gluconolactone} + DPNH + H^+ \quad (2)$$

GDH system was chosen to regenerate DPNH partly because the equilibrium of the reaction (equation 2) is favored in the direction of reduction of DPN. The non-enzymatic hydrolysis of the gluconolactone also helps to drive the reaction to completion.[10] The GDH has, of course, no effect on the steric specificity of the reaction for ethanol. This steric specificity is determined entirely by the ADH.

The ethanol-1-*d* formed by equation 1 was separated from the reaction mixture by distillation, as described in the Experimental section. The enantiomorphic purity of the ethanol was determined essentially as previously described,[7] *i.e.*, the material was oxidized to acetaldehyde by DPN in the presence of yeast ADH. Since the ethanol was prepared from CH_3CDO and DPNH, it should form CH_3CDO on reoxidation, and, if completely uncontaminated by its enantiomorph, it should transfer no excess deuterium to the DPNH. To determine the deuterium content of the DPNH with maximum accuracy, the DPNH was oxidized by pyruvate in the presence of lactic dehydrogenase (LDH), and the lactate was isolated as the phenacyl derivative and analyzed for deuterium. As demonstrated previously,[11] all the deuterium transferred to DPN from ethanol is in turn transferred to lactate when the DPND is reoxidized by pyruvate in the presence of LDH. This is because both enzyme reactions involve direct transfer of hydrogen and both have the same steric specificity for DPN.

The reactions involved in the synthesis and analysis of ethanol-1-*d* are summarized by equations 3–6.

$$\text{glucose} + \text{DPN}^+ \xrightarrow{\text{GDH}} \text{gluconic acid} + \text{DPNH} + \text{H}^+ \quad (3)$$

$$CH_3CDO + \text{DPNH} + \text{H}^+ \xrightarrow{\text{ADH}} CH_3CDHOH + \text{DPN}^+ \quad (4)$$

$$CH_3CDHOH + \text{DPN}^+ \xrightarrow{\text{ADH}} CH_3CDO + \text{DPNH} + \text{H}^+ \quad (5)$$

$$\text{DPNH} + CH_3COCO_2^- + \text{H}^+ \xrightarrow{\text{LDH}} CH_3CHOHCO_2^- + \text{DPN}^+ \quad (6)$$

The italicized compounds were converted to suitable derivatives and analyzed for deuterium.

Table I shows the results of the deuterium analyses obtained with two separate preparations, described as experiments 1 and 2 in the Experimental section. These preparations differed only in the scale on which they were carried out and in the source of the enzymes. The results given in Table I show that the original acetaldehyde, the ethanol-1-*d* formed from it and the acetaldehyde formed from the ethanol-1-*d* on enzymatic reoxidation, all contained about one atom of deuterium per molecule, as expected. The deviations from unity are all within the limit of experimental error. The results in Table I also show that the amount of excess deuterium in the lactate was negligible, as

Table I

Deuterium Content of Starting Materials and Products

Expt.	Equation	Substance analyzed	Dilution factor	Atom % excess D Found	Atom % excess D Cor. for diln. factor	Atom D per molecule
1	4	Acetaldehyde[a]	12.1	0.316	3.82	1.00

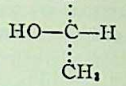
	5	Acetaldehyde[a]	13.4	.284	3.80	.99
	6	Lactate[c,d]	6.34	.0035	0.022	.003
2	4	Acetaldehyde[a]	23.4	.161	3.76	.98
	5	Acetaldehyde[a]	24.6	.141	3.46	.90
	6	Lactate[c]	2.13	.000	0.000	.000

[a] Analyzed as ethylidine dimethone; theory for 1 atom D per molecule, 3.84 atom % excess. [b] Analyzed as ethyl *p*-nitrobenzoate; theory for 1 atom D per molecule, 11.1 atom % excess. [c] Analyzed as phenacyl lactate; theory for 1 atom D per molecule, 8.33 atom % excess. [d] Derivatives not recrystallized.

expected from previous results.[7] The deuterium content of the lactate from experiment 1 appeared to be just above normal by an amount which was barely beyond the limit of detectability with the experimental method employed. The derivative had not been recrystallized, however. Since the amount of excess deuterium in the lactate is a measure of the maximum amount of "racemization" occurring in equations 4 and 5, special precautions were taken to obtain a more accurate analysis of the lactate of experiment 2. Larger quantities of ethanol were employed so that the dilution factor could be lower than in experiment 1. Under the conditions of analysis 0.005 atom % excess D in the sample, which could have been detected with certainty, would correspond to 0.001 atom D per molecule. The fact that no excess deuterium was found indicates that the sum of the racemizations occurring in equations 4 and 5 was less than one part in 1000.

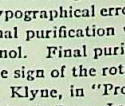
Prior to the final determination of optical activity, the ethanol-1-*d* was purified by vapor phase chromatography on a Carbowax column, a procedure which removed essentially all of the water and two other minor impurities. The ethanol-1-*d* (99+%) had $[\alpha]^{28}D$ $-0.28 \pm 0.03°$.[12] The enantiomorphic purity of the ethanol is more accurately established than the magnitude of the optical rotation.

From the sign of the rotation and some reasonable assumptions, one may conclude that the (−)-ethanol-1-*d* has the configuration



where the Fischer convention is used for the projection formula. (This may be designated ethan-1*L*-ol-1-*d* if italic capitals are used to designate configurations, as described by Mills and Klyne.[13] The choice of convention is of course arbitrary, and it should be noted that by the "sequence rule" of Cahn and Ingold, the configuration would be D[14] or R[14a]).

The above conclusion regarding configuration is based on the assumption that (−)-ethanol-1-*d* has the same configuration as (−)-butanol-1-*d*. This assumption seems reasonable in view of the correlations between sign of rotation and configuration which have been established for secondary alcohols.[13,15] Streitwieser[9] has prepared (−)-butanol-1-*d* by the reduction of butyraldehyde with (+)-2-octyl-2-*d* oxymagnesium halide. The reducing agent must be octan-2*D*-ol[13] since the configuration of (+)-octan-2-ol has been related to that of (+)-butan-2-ol which has in turn been shown to be butan-2*D*-ol.[13,15,16] (Note again that italic capital letters are used to represent configuration as described by Mills and Klyne.[13]) The rule deduced by Doering and Young[17] states that in a partially asymmetric Meerwein–Ponndorf–Verley reduction, the configuration of the reducing alcohol and the predominating enantiomer of the reduced alcohol are the same. If this rule is assumed to apply, then the configuration of the (−)-butanol-1-*d* prepared by Streitwieser should be



(12) In preliminary reports[1] the sign of the rotation was erroneously reported to be + due to a typographical error. This preliminary value was determined prior to final purification with a solution later found to contain about 70% ethanol. Final purification increased the magnitude but did not affect the sign of the rotation.

since the H must be regarded as equivalent to the methyl groups of the secondary alcohols studied by Doering and Young. It seems preferable to write the projection formula with the deuterium on top, however, and thus to identify this configuration by use of the symbol *L* to indicate the position of the hydroxyl function, *viz.*, butan-1*L*-ol-1-*d*.

If the normal direction of enzymatic hydrogen transfer to CH_3CDO resulting in (−) CH_3CDHOH is represented by diagram (a), then diagram (b) represents the relative positions of the atoms leading to the enantiomorphic (+)-CH_3CHDOH. The high enantiomorphic purity of the ethanol-1-*d*

a b

formed by yeast alcohol dehydrogenase bears witness to the forces which must orient the substrate during the enzyme reaction. As pointed out previously,[7] the "normal" orientation of acetaldehyde probably is achieved by a combination of several factors. Thus, the acetaldehyde probably is bound by the polar oxygen atom, and, in addition, the methyl group may be held in a particular position by van der Waals attractive forces, "squeezed" out of the solution on to the protein by the cohesive force of the water molecules[18] and prevented by steric hindrance from occupying the position normally occupied by hydrogen (or deuterium). In this connection it is of interest that yeast ADH can catalyze the reduction of acetone to isopropyl alcohol.[19,20] In acetone, a methyl group occupies the position occupied by hydrogen (or deuterium) in acetaldehyde. The reduction of acetone thus resembles, in part, the reduction of acetaldehyde in the unnatural position shown in diagram (b),[21] where a methyl group also occupies a position "normally" occupied by hydrogen.

An examination of the kinetics of the oxidation of isopropyl alcohol (or the reduction of acetone) should indicate the extent to which steric hindrance to the methyl group may contribute to the normal orientation of acetaldehyde. The kinetics of the oxidation of methanol (or the reduction of formaldehyde) as catalyzed by alcohol dehydrogenase[19] are also of interest, since they might reflect the effect of the absence of the methyl group in the normal position.

No adequate kinetic studies of either the enzymatic oxidation of methanol and isopropyl alcohol or of the enzymatic reduction of formaldehyde and acetone could be found in the literature. Measurements were therefore made of the relative velocities of the reduction of DPN by ethanol, isopropyl alcohol and methanol at a series of different alcohol concentrations. Some measurements with ethanol-1,1-d_2 were included for comparison. The data obtained are assembled in Table II in the form of the calculated Michaelis constants (K_s)[22] and the relative maximum velocities.[23] The Michaelis constants were determined in the usual way from plots of the reciprocal of the velocity against the reciprocal of the substrate concentration.[22]

TABLE II

KINETIC MEASUREMENTS

Substrate	K_s, mole/liter	Maximum velocity relative to ethanol
Ethanol	2.1×10^{-3}	100
Isopropyl alcohol	1.4×10^{-1}	39
Methanol	1.3×10^{-1}	4
Ethanol-1,1-d_2	3.0×10^{-3}	69

For the purpose of this discussion, the K_s values may be regarded as a measure of the dissociation constants of the various enzyme–substrate complexes. Though this assumption is not strictly correct, it simplifies the discussion and introduces no apparent error in the nature of the conclusions drawn from the data of Table II. Comparison of the data for ethanol and isopropyl alcohol shows that the Michaelis constants differ by more than a hundred-fold, whereas the difference between the maximum velocities is only 2–3-fold. Thus the large difference noted in the relative velocity of the reactions at low alcohol concentrations is due mainly to the fact that isopropyl alcohol has a much lower affinity for the enzyme than does ethanol. The large dissociation constant for the enzyme–isopropyl alcohol complex can be most easily explained in terms of steric hindrance rather than in terms of the absence of any group which can be responsible for enzyme–substrate binding.

The data in Table II show that methanol also has a low affinity for the enzyme relative to ethanol, and this can most easily be explained in terms of the absence of the binding due to the methyl group. The maximum velocity of the oxidation of methanol is only one-twentieth of that of the ethanol, but the difference between the K_s-values is even larger. The data for methanol must be regarded with reservations, however, since the velocities measured tended to decline rapidly with time, and poor fits for the Lineweaver–Burke plots were the rule. Never-

(21) The DPN has not been included in diagrams (a) and (b) because its orientation with respect to the acetaldehyde is not known. The DPN should, however, be understood to occupy the same relative position in (a) and in (b), and it is assumed that this position does not change when acetone is substituted for acetaldehyde. The unlikely possibility that the isopropyl alcohol reaction has a different steric specificity for DPN than does the ethanol reaction was ruled out by observing that deuterium, introduced into DPND by enzymatic reduction of DPN with ethanol-1,1-d_2 was removed when the DPND was oxidized enzymatically by acetone (unpublished experiment, H.R.L.).

(23) A. P. Nygaard and H. Theorell, *Acta Chem. Scand.*, **9**, 1300 (1955), have made a detailed kinetic study of the reaction catalyzed by yeast ADH, and have shown that the measured rates of ethanol oxidation in the presence of enzyme deviate from the theoretical Michaelis equation at very high ethanol concentrations. The maximum velocities calculated from the Michaelis equation are therefore open to some question. The values given in the second column of Table II were therefore obtained from the maximum velocities actually observed and not from the calculated maximum velocities. Use of the calculated maximum velocities gives similar values for the relative velocities, however, so the conclusions are not affected. The K_s values of Table II were calculated from the part of the curve which is the Michaelis relation.

theless, the kinetic data are, on the whole, consistent with and reinforce the view that the "normal" orientation of acetaldehyde, shown in diagram (a), is due both to binding of the methyl group and to steric hindrance at the site occupied by hydrogen.

The effect of the substitution of deuterium in the ethanol is small relative to the effect of interchanging methyl groups and hydrogen, but the velocity of oxidation is definitely lower for dideuterioethanol than for ethanol at all alcohol concentrations. The transfer of hydrogen must therefore be at least partially rate-limiting in the enzyme reaction.[24] Nygaard and Theorell[23] have concluded that their kinetic data are consistent with a mechanism in which a ternary enzyme–coenzyme–substrate complex is converted into a second ternary complex in a rate-limiting reaction. This reaction may be the transfer of hydrogen between substrate and DPN. The effect of deuterium on the reaction kinetics has been investigated in more detail by Mahler.[25] An interesting and recent discussion of other facts which have a bearing on the question of the enzyme reaction mechanism can be found in a paper by Kosower.[26]

Experimental

Enzymes.—Yeast alcohol dehydrogenase prepared according to Racker[27] was used in experiment 1. A sample purchased from Nutritional Biochemicals Co. was used in experiment 2. Lactic dehydrogenase was prepared from heart muscle according to Straub.[28]

The glucose dehydrogenase used in experiment 1 was prepared according to Strecker and Korkes.[10] A fraction containing 220 units per mg. of protein[10] was stored as a solution at −15°. For experiment 2, the glucose dehydrogenase was prepared according to Brink.[29] The report that this procedure gives enzyme of higher specific activity than the procedure of Strecker and Korkes could not be verified. After the first two ammonium sulfate fractionations, the enzyme did not precipitate at the ammonium sulfate concentrations reported by Brink. Further fractionation was continued with recovery of the enzyme first between 25 and 30% saturation and then from a more dilute solution between 26 and 36% saturation. The specific activity in the units defined by Strecker and Korkes was 120 units per mg. of protein. The preparation was devoid of acetaldehyde dehydrogenase activity, but it contained both a DPNH oxidase activity and a DPN destroying enzyme which was not inhibited by nicotinamide. These latter enzyme activities were only partially removed by high speed centrifugation. Their presence complicates the use of the enzyme for the preparation of ethanol-1-*d*, and the procedure of Brink for the preparation of the glucose dehydrogenase is consequently not recommended.

Procedures.—Acetaldehyde-1-*d* was prepared as described by Loewus, *et al.*[7] The preparation of ethyl *p*-nitrobenzoate,[7] ethylidine dimethone,[7] and phenacyl lactate[11] were also carried out as previously described. Sigma Chemical Co. Cozymase "90" (*i.e.*, DPN) was employed. Enzymatic assays for acetaldehyde, ethanol and oxidized and reduced DPN were carried out spectrophotometrically, as previously described.[6]

The deuterium analyses were carried out by burning the samples to water, converting the water to H_2 plus HD[30] and analyzing the gas for deuterium with a mass spectrometer.[31]

Experiment 1.—The reaction mixture contained 40 ml. of 2 *M* phosphate of *p*H 7.1, 15 g. of glucose, 5 mg. of DPN, 44 ml. of a solution of GDH containing 9000 units per ml. and 0.1 ml. of a solution of ADH containing 6×10^5 units per ml. The acetaldehyde-1-*d* was freshly distilled before use and added to the reaction mixture as an aqueous solution containing 42 mg. of acetaldehyde-1-*d* per ml. The reaction was initiated by addition of 2 ml. of this acetaldehyde solution. When the acetaldehyde was almost entirely reduced, another 2-ml. portion was added, and this addition of small portions was continued until 43 ml. of the acetaldehyde solution had been added (corresponding to 1.8 g. of acetaldehyde reduced). This required a period of 405 minutes. The disappearance of the acetaldehyde after addition of each increment was most conveniently followed by making use of the fuchsin aldehyde reagent spot test. During the course of the reaction, the *p*H was checked periodically and readjusted to 7 with 5 *N* NH_4OH solution, whenever this was necessary. Toward the end of the reaction, further addition was made of 70 ml. of GDH solution, 0.15 ml. of ADH solution, 10 mg. of DPN and 5 g. of glucose.

At the conclusion of the reaction the flask containing the reaction mixture was connected to a receiving flask by a wide U-tube with a glass-stoppered outlet through which the system was evacuated. The reaction mixture was frozen before evacuation. Then the ethanol was distilled into the receiving flask by slowly raising the temperature of the reaction mixture. The receiving flask was cooled with Dry Ice–acetone. Three fractions were collected, and found by enzymatic analysis to contain the theoretical yield of ethanol. The first fraction from the vacuum distillation was distilled on a Vigreux column, and the fraction distilling between 72 and 95° was collected separately.

This fraction contained 78% of the total yield of ethanol with relatively little water. A small portion was withdrawn for enzymatic analysis of enantiomorphic purity and for preparation of a sample of ethyl *p*-nitrobenzoate for deuterium analysis. After a preliminary determination of optical rotation, the main portion of the ethanol-1-*d* was further purified by vapor phase chromatography as described below. The ethanol-1-*d* in the other fractions of the vacuum distillate was also fractionated on a Vigreux column and obtained in aqueous solutions of varying concentrations.

The *p*-nitrobenzoate of the ethanol-1-*d* was prepared by dissolving 0.05 ml. in 0.5 ml. of anhydrous pyridine, adding 40 mg. of *p*-nitrobenzoyl chloride and then 6 ml. of water. After gentle warming, the solution was cooled slowly. The crystals of ethyl *p*-nitrobenzoate were collected by centrifugation, washed with 5% sodium carbonate and dried under vacuum. For deuterium analysis, 1.26 mg. was diluted with 54.26 mg. of unlabeled ethyl *p*-nitrobenzoate.

For the enzymatic analysis of the enantiomorphic purity of the ethanol-1-*d*, the reaction mixture was made up as follows: 226 mg. of $Na_4P_2O_7 \cdot 10H_2O$ and 108 mg. of DPN were dissolved in 4.0 ml. of water, and 0.25 ml. of 1 *N* NaOH was added to adjust the *p*H to 9–9.5. The volume was adjusted to 5.0 ml. with water, and 20 μl. of ADH solution (1.2×10^5 units) was added. The reaction was initiated by addition of 0.1 ml. of the ethanol-1-*d*, and the course of the reduction of DPN was followed by measuring the optical density of dilutions of suitable aliquots at 340 mμ with a Beckman spectrophotometer. The *p*H was readjusted to 9.0–9.5 with 1 *N* NaOH when necessary. After 30 minutes, the reaction mixture was frozen and the acetaldehyde and most of the water were distilled *in vacuo* into saturated dimedon. The ethylidine dimethone obtained was recrystallized, and 4.07 mg. was diluted with 50.41 mg. of unlabeled ethylidine dimethone prior to analysis for deuterium. The remaining reaction mixture was restored to its original volume by addition of water and brought to 100° in a boiling water-bath to inactivate the enzyme. The *p*H was carefully adjusted to 7 by addition of dilute HCl. Enzymatic analysis showed that 83.0 μmoles of DPNH was present. Then 10 μl. of LDH solution (1×10^5 units) was added, followed by 83.0 μmoles of pyruvate. The oxidation of DPNH was complete in 10 minutes. The enzyme was heat-inactivated and 39.2 mg. of lithium L-lactate was added as a diluent. The lactic acid was extracted with ether and converted to the phenacyl derivative as previously described.[11]

Experiment 2.—This experiment was planned essentially as a repetition of experiment 1, except that the GDH and ADH were of different origin. Mainly because of the DPN-destroying activity of the GDH preparation, considerable

difficulties were experienced. A total of 163 mg. of DPN was eventually added in increments during the course of the reaction, and after 405 minutes only 450 mg. of acetaldehyde-1-*d* was reduced. The ethanol was distilled out of the reaction mixture *in vacuo* and redistilled on a Vigreux column. The fraction collected between 70 and 98° was used entirely for the enzymatic analysis of enantiomorphic purity as described in experiment 1. The ethylidene dimethone and phenacyl lactate were analyzed for deuterium after suitable dilution.

Purification and Optical Rotation of Ethanol-1-*d*.—The ethanol was separated on a vapor phase chromatography column[32] in 0.1-ml. batches. A 5-foot column packing of Carbowax 1540 on pulverized magnesia was used with t = 100° and a helium flow rate of 50 ml. per min. Two minor impurities (probably acetaldehyde and acetic acid) appeared before the ethanol peak. The ethanol was collected in a trap chilled in alcohol–Dry Ice. The ethanol appeared about 4 to 5 minutes after injection of the alcohol mixture, and the water peak appeared after 8–9 minutes. Collection of the ethanol was interrupted the moment the water peak began to appear, or earlier. Control experiments with 95% and absolute alcohol showed that complete separation of the azeotrope was achieved. A total of 0.9 ml. of purified ethanol-1-*d* was obtained.

The rotation was determined visually in a 1-dm. polarimeter tube of 0.25-ml. capacity, with a Rudolph precision polarimeter that could be read to 0.001° under ideal conditions. The readings were taken at maximum sensitivity, but due to the small bore of the polarimeter tube, a precision of about 10% was the best that could be achieved. The zero point reference was determined with unlabeled absolute ethanol under conditions comparable to those used for taking readings with the ethanol-1-*d*. The average of a large number of readings gave $\alpha^{28}D$ −0.22 ± 0.02° (l 1). If the density at 28° is assumed to be 0.80, the ethanol-1-*d* has $[\alpha]^{28}D$ −0.28 ± 0.03°.

The rotation was also determined with a Keston polarimeter attachment[33] on a Beckman DU spectrophotometer. The rotations measured at 26° in a 0.5-dm. tube were $\alpha_{460\ m\mu}$ − 0.123°, $\alpha_{546\ m\mu}$ − 0.095°, $\alpha_{584\ m\mu}$ −0.066°. These values are regarded as only approximate.

Kinetic Measurements.—The Michaelis constants for the various alcohols were determined by measuring the initial velocity of reduction of DPN in the presence of suitable amounts of a commercial sample of alcohol dehydrogenase with a specific activity of 86,200.[27] The K_s-values were calculated from Lineweaver, Burk plots.[22] The reactions were carried out in 3 ml. of 0.05 M pyrophosphate buffer of pH 9.3. The DPN was 1.35×10^{-3} M. In each series, four to six different concentrations of alcohol were used. The measurements were made at 340 mμ in a Beckman spectrophotometer with attached thermoregulator for the cell compartment to maintain the temperature at 25°. The reaction was initiated by addition of the enzyme, the contents of the cuvette were mixed rapidly, and readings were taken every 10 or 15 seconds for at least one minute. The amount of DPNH formed was calculated from the increase in optical density.

The isopropyl alcohol and the methanol were purified according to Gilson.[34]

Acknowledgments.—The authors acknowledge with gratitude the stimulating discussions of Professor F. H. Westheimer. The purification of the ethanol-1-*d* by vapor phase chromatography was carried out by F.A.L. under the guidance of Dr. K. Dimick, whose generous assistance is gratefully acknowledged. The authors are also indebted to Dr. Frank Young for the use of the Rudolph polarimeter and to Dr. Clinton Ballou for the use of the Keston polarimeter attachment to the Beckman spectrophotometer.

The lithium aluminum deuteride was purchased on allocation from the Atomic Energy Commission. The funds for the purchase of the mass spectrometer used in this research were supplied by the Atomic Energy Commission under contract No. At(11-1)-92.

The Mannich Reaction of 2,2-Dinitro-1-alkanols with Ammonia, Glycine and Hydrazine[1]

BY MILTON B. FRANKEL AND KARL KLAGER

RECEIVED NOVEMBER 8, 1956

The Mannich condensation of 2,2-dinitro-1-alkanols with ammonia, glycine and hydrazine has been studied and the importance of the pH in these reactions has been shown. 2,2-Dinitro-1-alkanols condense readily with ammonia in a buffered medium to give the corresponding bis-substituted amines. The condensation of these nitroalcohols with glycine gives a mono substituted product at a pH of 7 and a disubstituted product at a pH of 9. The reaction of methyl 5-hydroxy-4,4-dinitropentanoate with glycine results in the formation of 5,5-dinitro-2-piperidone-N-acetic acid. The condensation of 2,2-dinitropropanol with hydrazine gives bis-N,N′-(2,2-dinitropropyl)-hydrazine.

The Mannich reaction with *gem*-dinitroparaffins was first reported by Feuer and co-workers[2] who described the condensation of 2,2-dinitro-1,3-propanediol and sodium 2,2-dinitroethanol with glycine and ethanolamine. Feuer reported that the pH, the reaction temperature and the mole ratio of the reactants have a pronounced effect on the course of this reaction. Independent of this work, we studied the Mannich reaction of various 2,2-dinitro-1-alkanols with ammonia, glycine and hydrazine.

Inasmuch as the 2,2-dinitro-1-alkanols are converted in basic medium to the corresponding aci salts of 1,1-dinitroalkanes and formaldehyde,[3] this work was directed to a study of the influence of pH on the Mannich reaction in these systems. We observed that the reaction of 2,2-dinitro-1-alkanols with ammonium hydroxide gave little or no yield of the Mannich condensation product. However, it was found that if the solution was buf-

fered by using ammonium acetate instead of ammonium hydroxide, the condensation occurred readily. Thus, if an aqueous solution of ammonium acetate and the 2,2-dinitro-1-alkanols was warmed to 60°, quantitative yields of the bis-(2,2-dinitroalkyl)-amines separated on cooling. In this manner were prepared 2,2,6,6-tetranitro-4-azaheptane (Ia), 3,3,7,7-tetranitro-5-azanonane (Ib) and 4,4,8,8-tetranitro-6-azaundecane (Ic).

$$2RC(NO_2)_2CH_2OH + NH_3 \xrightarrow[\text{Buffer}]{\text{HOAc}} [RC(NO_2)_2CH_2]_2—NH$$

Ia, R = CH_3
Ib, R = CH_3CH_2
Ic, R = $CH_3CH_2CH_2$

Condensation of methyl 5-hydroxy-4,4-dinitropentanoate and ammonium acetate gave dimethyl 4,4,8,8-tetranitro-6-aza-1,11-undecanedioate (II). Compound II was prepared more conveniently by the direct condensation of the aci-sodium salt of methyl 4,4-dinitrobutyrate, formaldehyde and ammonium acetate.

$$2CNO_2CH_2CH_2CO_2CH_3 \\ \| \\ NO_2Na$$

$$+ 2CH_2O \longrightarrow 2HOCH_2C(NO_2)_2CH_2CH_2CO_2CH_3$$

$$\xrightarrow[\text{HOAc}]{\text{NH}_3} [CH_3O_2CCH_2CH_2C(NO_2)_2CH_2]_2—NH \quad (\text{II})$$

When amino acids or their esters were used in the condensation with 2,2-dinitro-1-alkanols, the importance of the *p*H in determining the course of the reaction was strikingly illustrated. The condensation of 2,2-dinitropropanol and methylglycine at a *p*H of 7 gave methyl 5,5-dinitro-2-azahexanoate (III), while the condensation of 2,2-dinitropropanol and glycine at a *p*H of 9 or higher, gave bis-(2,2-dinitropropyl)-glycine (IV). The structure of IV was confirmed by analysis and by the preparation of the corresponding methyl ester and acid chloride.

When methyl 5-hydroxy-4,4-dinitropentanoate was condensed with the sodium salt of glycine the expected methyl 4,4-dinitro-6-azaoctanedioic acid (V), cyclized to form 5,5-dinitro-2-piperidone-N-acetic acid (VI). The structure of VI was confirmed by analysis and by conversion into a monomethyl ester derivative VII.

2,2-Dinitropropanol and hydrazine react under buffered *p*H conditions to form bis-N,N′-(2,2-dinitropropyl)-hydrazine (VIII).

Oxidation of VIII with bromine in methanol solution yielded azo-(2,2-dinitropropane) (IX), a remarkably stable compound melting without decomposition at 101–101.5°. The results of the study of the decomposition of IX were rather surprising, since it is known that aliphatic azo compounds are thermally unstable and decompose into free radicals with the liberation of nitrogen.[4] However, azo-(2,2-dinitropropane) was almost quantitatively recovered after two hours refluxing in either toluene or chlorobenzene. Even after refluxing for 90 minutes in *o*-dichlorobenzene, 50% of the starting material was recovered. In the latter solvent the evolution of nitrogen dioxide was observed.

The physical properties and yields of the Mannich condensation products are listed in Table I.

Experimental[5,6]

3,3,7,7-Tetranitro-5-azanonane (Ib).—This preparation is typical of the condensation of 2,2-dinitro-1-alkanols and ammonium acetate. A mixture of 30.0 g. (0.18 mole) of 2,2-dinitrobutanol,[7] 50 ml. of water and 30.0 g. (0.39 mole) of ammonium acetate was warmed to 60° for 20 minutes. The reaction mixture was cooled and the product was collected and dried, giving 28.0 g. (99%) of a cream-colored solid, m.p. 57–61°. Recrystallization from isopropyl alcohol gave white plates, m.p. 66–67°.

Dimethyl 4,4,8,8-Tetranitro-6-aza-1,11-undecanedioate (II). (a) From Methyl 5-Hydroxy-4,4-dinitropentanoate.—A mixture of 30.0 g. (0.13 mole) of methyl 4,4-dinitro-5-hydroxypentanoate,[8] 75 ml. of water and 30.0 g. (0.39 mole) of ammonium acetate was heated on the steam-bath for 10 minutes, on cooling a cream-colored solid separated. The product was collected, washed with water and dried to give 25.4 g. (88.6%) of a cream-colored solid, m.p. 65–69°. Recrystallization from methanol gave white needles, m.p. 79–80°.

(b) From Aci-sodium Salt of Methyl 4,4-Dinitrobutyrate.—Five hundred ml. of concentrated ammonium hydroxide, 800 ml. of water and 500 ml. of glacial acetic acid were mixed together. The temperature was allowed to rise to 60–70°, at which point a solution of 1000 g. (equivalent to 850 g. or 3.97 moles of dry salt containing 15% moisture) of the aci-sodium salt of methyl 4,4-dinitrobutyrate,[8] 2000 ml. of water and 324 g. (4.0 moles) of 37% formalin was added over a period of 15 minutes. The reaction mixture was stirred at 60° for one hour and then cooled to 10°. The solid product was collected, washed with water and dried *in vacuo* over potassium hydroxide to give 480 g. (56.8%) of cream-colored solid, m.p. 66–69°. Recrystallization from methanol gave white needles, m.p. 79–80°.

Methyl 5,5-Dinitro-3-azahexanoate (III).—A mixture of 12.6 g. (0.1 mole) of methylglycine hydrochloride,[9] 65 ml. of water, 15 g. (0.1 mole) of 2,2-dinitropropanol[7] and 8.2 g. (0.1 mole) of sodium acetate was heated at 70–85° for one hour. The reaction mixture was cooled and extracted with methylene chloride. The extracts were dried and concentrated *in vacuo* leaving 17.1 g. (77.3%) of a yellow oil.

The amine was identified by conversion to the corresponding nitraza derivative. Methyl 5,5-dinitro-3-azahexanoate, 2.2 g. (0.01 mole), was dissolved in 20 ml. of acetic anhydride and added to 20 ml. of 99% nitric acid at 0–5°. After stirring for 10 minutes the mixture was poured onto ice. The product was collected, washed with water and dried *in vacuo* over potassium hydroxide to give 1.64 g. (61.4%) of white solid, m.p. 76–79°. Recrystallization from isopropyl ether raised the melting point to 80–81°.

Bis-(2,2-dinitropropyl)-glycine (IV).—A solution of 7.5 g. (0.1 mole) of glycine, 4.0 g. (0.1 mole) of sodium hydroxide and 50 ml. of water was mixed with 15.0 g. (0.1 mole) of 2,2-dinitropropanol. The temperature rose to 42° and the yellow solution formed was allowed to stand overnight. Upon addition of dilute sulfuric acid a viscous, colorless oil separated and solidified on standing. The product 15.6 g. (92.0%) was collected and recrystallized from methanol-water to give white crystals, m.p. 123–124°.

Methyl Bis-(2,2-dinitropropyl)-glycine.—A mixture of 20 g. (0.059 mole) of bis-(2,2-dinitropropyl)-glycine, 100 ml. of methanol and 10.0 ml. of concentrated sulfuric acid was refluxed for 90 minutes. The solution was diluted with 250 ml. of methylene chloride and washed with water, 5% sodium carbonate solution and water. The solvent was evaporated to yield 14.0 g. (67.3%) of white solid. Recrystallization from methanol–ether gave crystals, m.p. 94–95°.

Anal. Calcd. for $C_9H_{16}N_3O_{10}$: C, 30.60; H, 4.24; N, 19.83; OCH_3, 8.78. Found: C, 31.17; H, 4.49; N, 20.11; OCH_3, 8.19.

Bis-(2,2-dinitropropyl)-glycyl Chloride.—A mixture of 78 g. (0.23 mole) of bis-(2,2-dinitropropyl)-glycine and 190 ml. of thionyl chloride was refluxed overnight. The solution was evaporated to dryness *in vacuo*, leaving a brown solid. Recrystallization from chloroform gave white crystals, 41.0 g. (50%), m.p. 64–65°.

Anal. Calcd. for $C_5H_{12}N_5O_9Cl$: C, 26.86; H, 3.38; N, 19.14; Cl, 9.91. Found: C, 27.48; H, 3.68; N, 19.27; Cl, 9.70.

5,5-Dinitro-2-piperidone-N-acetic Acid (VI).—A solution of 7.5 g. (0.1 mole) of glycine, 4.0 g. (0.1 mole) of sodium hydroxide and 50 ml. of water was mixed with 22.2 g. (0.1 mole) of methyl 5-hydroxy-4,4-dinitropentanoate. A yellow solution was formed and the temperature rose to 38°. The mixture was allowed to stand overnight. Acidification with dilute sulfuric acid caused an oil to separate, which soon crystallized. The product was collected, washed with water and dried to give 15.2 g. (61.5%) of white solid. Recrystallization from methanol–water and ether gave colorless crystals, m.p. 128–130°. This compound gave a negative test for the methoxyl group.

Methyl 5,5-Dinitro-2-piperidone-N-acetate (VII).—A mixture of 20.0 g. (0.081 mole) of 5,5-dinitro-2-piperidone-N-acetic acid, 150 ml. of methanol and 10 ml. of concentrated sulfuric acid was refluxed for 90 minutes. The solution was diluted with 250 ml. of methylene chloride and washed with water, 5% sodium carbonate solution and water. After drying over sodium sulfate, the solvent was evaporated leaving crystals. Recrystallization from methanol gave 16.0 g. (75.8%) of product, m.p. 126–130°. The mixed melting point with the free acid (m.p. 128–130°) was depressed to 105–111°.

Anal. Calcd. for $C_8H_{11}N_3O_7$: C, 36.79; H, 4.26; N, 16.09. Found: C, 37.51; H, 4.33; N, 16.32.

Bis-(2,2-dinitropropyl)-hydrazine (VIII).—A solution of 52.0 g. of 85% hydrazine hydrate, 300 ml. of water and 75 ml. of glacial acetic acid was heated to 60°. At this temperature a solution of 50.0 g. (0.33 mole) of 2,2-dinitropropanol in 150 ml. of methanol was added within 15 minutes. A viscous oil immediately separated. The mixture was stirred at 60° for one hour. After cooling the oily layer crystallized to give 36 g. (73.0%) of white solid, m.p. 83–85°. Recrystallization from ether or chloroform gave colorless prisms, m.p. 85–86°.

Azo-(2,2-dinitropropane) (IX).—A solution of 5.0 g. (0.017 mole) of bis-(2,2-dinitropropyl)-hydrazine in 50 ml. of methanol was cooled to 0° and bromine was added with vigorous stirring until the bromine was no longer bleached. The temperature was kept below 5° by means of external cooling. After a short time crystals precipitated, which were collected and washed with absolute ether. Recrystallization from methanol gave 2.3 g. (46.3%) of colorless crystals, m.p. 101–101.5°.

Anal. Calcd. for $C_6H_{10}N_6O_8$: C, 24.49; H, 3.43; N, 28.57. Found: C, 24.85; H, 3.49; N, 28.80.

Sodium and Potassium Alkoxides as Catalysts for Carbanion Reactions of Hydrocarbons[1]

BY HERMAN PINES AND LUKE SCHAAP[2]

RECEIVED DECEMBER 3, 1956

Sodium and potassium alkoxides, when heated to decomposition temperatures, catalyze carbanion reactions such as the dehydrogenation of *d*-limonene, double bond isomerization of olefins, and the side chain alkylation of alkylarenes. Alkoxides of tertiary alcohols are far more effective than those of primary or secondary alcohols. A mechanism for the alkoxide decomposition is proposed, and some similar reactions are discussed.

Organosodium compounds and sodium hydride have been reported to be catalysts for certain reactions that apparently proceed by carbanion mechanism: (a) isomerization of olefins, (b) dehydrogenation of monocyclic terpenes, (c) side chain alkylation of alkylarenes by olefins.[3]

It has been found that potassium *t*-butoxide can promote reactions a, b as well as c at temperatures of 250–300°, which cause alkoxide decomposition, but that it is most effective for b. Reaction c is promoted by a trace of hydroxide ion with the *t*-alkoxide. An autoclave was used, the experiments being of 4–12 hours duration. Limonene changed into *p*-cymene in yields of 95–97% using either potassium *t*-butoxide or *t*-pentoxide, whereas it dropped to 3–4% with the isopropoxide, 1.5% with the methoxide, and 0% with the phenoxide or with no alkoxide. The experimental data obtained are summarized in Table I. The solid residue from the *t*-butoxide experiments, on acidification, yielded some 3,5-dimethylphenol and isovaleric acid.

Potassium *t*-butoxide caused 8% isomerization of 1-*p*-menthene on heating for 5.5 hours at 260–265°. The same catalyst, containing a trace of potassium hydroxide, was effective for the formation of *n*-propylbenzene from ethylene and toluene at 279–291°, or *t*-pentylbenzene (containing a trace of 1,1-dimethylindan) from cumene and ethylene. The experimental conditions and yields are summarized in Table II.

Methane was found in the reactions catalyzed by potassium *t*-butoxide while small amounts of ethane as well as methane were obtained from the experiments carried out with potassium *t*-pentoxide. The presence of methane is due to the decomposition of the alkoxide at 280° as shown in Experiment 8. No methane was produced however when powdered potassium hydroxide in *t*-butyl alcohol was heated to the same temperature (ex-

[a] 68.1 g. (0.5 mole) of *d*-limonene, $\alpha^{25}D$ +100, was used in each experiment with an alkoxide prepared from 0.10 g. atom of sodium or potassium. [b] Small amounts of ethylene ranging from 0.001 to 0.002 mole were obtained from reactions with catalysts prepared from isopropyl, *t*-butyl and *t*-pentyl alcohols. [c] 0.50 g. of *t*-pentyl alcohol was recovered when the solid material from this reaction was treated with water. [d] About 15% of the liquid product consisted of limonene polymers boiling above 150° at 2 mm. [e] A similar experiment carried out at 290° for 4.3 hr. yielded 75% *p*-cymene.

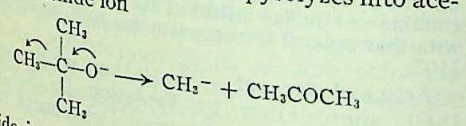
TABLE II

REACTION OF AROMATIC HYDROCARBONS WITH OLEFINS IN THE PRESENCE OF POTASSIUM *t*-BUTOXIDE

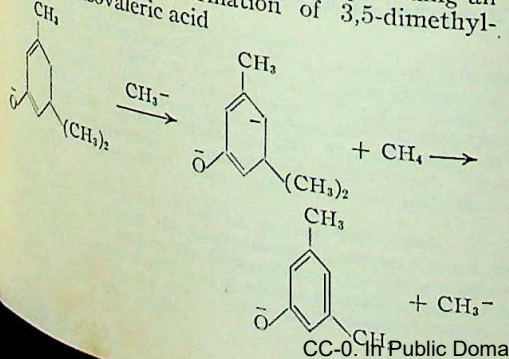
Expt.	Hydrocarbons charged: Aromatic[a]	Olefin (moles)		Catalyst[b]	Temp., °C.[c]	Product formed (moles)	Methane[d] (moles)
10	Toluene	C_3H_6	0.35	*t*-BuOK	279	0.0054[e]	...
11	Toluene	C_2H_4	.2	*t*-BuOK[f]	291	.026[g]	0.163
12	Benzene	C_2H_4	.2	*t*-BuOK	284 ± 4	.0031[h]	.160
						.0001[i]	
13	Isopropylbenzene	C_2H_4	.2	*t*-BuOK	285 ± 3	.132[j]	.162

[a] One mole of aromatic hydrocarbon was used in each experiment. [b] The catalyst, *t*-BuOK, was prepared using *t*-BuOH with 0.4 g (0.022 mole) of water added and 4 g. (0.1 g. atom) potassium. [c] The reaction was carried out for 4–5 hours at the given temperature. [d] Hydrogen was produced in amounts varying from 0.002 to 0.004 mole. [e] The product was isobutylbenzene. The low yield can in part be ascribed to stoppage of the stirrer during the reaction. [f] A similar reaction carried out with potassium *t*-butoxide prepared from anhydrous *t*-butyl alcohol produced insufficient *n*-propylbenzene to purify by distilling on a 12 in. column. [g] The product was *n*-propylbenzene. [h] Biphenyl: m.p. 68–70°, λ_{max} 246 mμ, ϵ_{mol} 16,500. [i] *p*-Terphenyl, m.p. 205–211°, λ_{max} 276 mμ, ϵ_{mol} 30,000. [j] The product was composed of *t*-pentylbenzene containing a very small amount of 1,1-dimethylindan. In check reactions carried out under apparently similar conditions the yields were smaller.

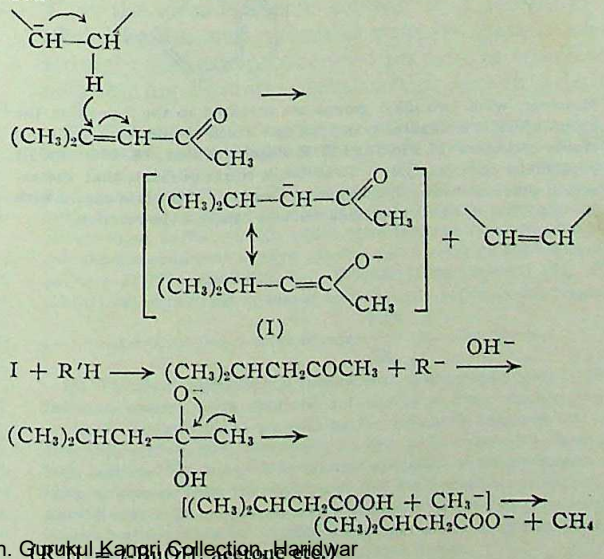
periment 9). To explain these observations it is assumed that the *t*-butoxide ion pyrolyzes into acetone and methide ion



Methide ion then promotes the dehydrogenation, side-chain alkylation, and isomerization effects which were noted. It (or *t*-butoxide) promotes aldolization in part of the acetone forming mesityl oxide, isophorone and water, thereby providing an explanation for the formation of 3,5-dimethylphenol and isovaleric acid



This explains the phenol. To explain the acid, it is assumed that mesityl oxide is changed to 4-methyl-2-pentanone by hydride transfer, after which this ketone is cleaved by the hot hydroxide ion



CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

It will be recalled that acetone is cleaved[4] into acetate ion by fused alkali at 250°. A similar type of decomposition takes place in the Guerbet reaction and when alcohols are heated with alkali.[5]

Alkoxide decomposition is not suitable for studying relative carbanion stabilities because subsequent condensation and elimination reactions make it impossible to study the primary elimination products, but it is evident from the gases recovered from potassium *t*-pentoxide reaction that the ethyl carbanion is eliminated much less readily than a methyl carbanion. Very little ethane was produced from potassium *t*-pentoxide at 250°.[6]

Experimental

Preparation of Alkoxides.—The *t*-pentyl, *t*-butyl, isopropyl and methyl alkoxides were prepared by refluxing 0.1 g. atom of sodium or potassium with 200 ml. of the corresponding anhydrous alcohol in a 500-ml. flask equipped with a reflux condenser and a drying tube. Water, 0.4 g. (0.022 mole) was added to the *t*-butyl alcohol used in making catalysts for the side-chain alkylation of alkylarenes. When a clear solution of the alkoxide was obtained, the excess of the alcohol was distilled off and the remaining alcohol was removed at 100° and at about 10 mm. of pressure. The white solid was then pulverized and introduced into the reaction vessel containing a weighed quantity of the liquid hydrocarbon. The alkoxides thus produced were not completely free of alcohol; no quantitative estimation of the alcohol content was made however.

The potassium phenoxide was prepared from phenol and potassium hydroxide.

Apparatus and Procedure.—A 250-ml. capacity Magne-Dash[7] autoclave was used for all the experiments. The liquid hydrocarbon and the alkoxide were placed in the autoclave. After sealing it the air was displaced from it by means of nitrogen. When required measured amounts of ethylene or propylene were introduced into the autoclave.

The reaction was judged to be finished when the pressure remained constant. The gases were then released, measured and analyzed by a mass spectrometer. The liquid product was filtered and distilled.

Experiments 1–7.—The *d*-limonene used was purified according to the method reported previously.[3c] It had the following physical constants: b.p. 71° at 20 mm.; $n^{25}D$ 1.4724, $\alpha^{25}D$ +100. The C_{10} fraction of the liquid product from each reaction was obtained by distillation at 20 mm. pressure using a 10 in. Vigreux column. Infrared spectra were used to show the presence of *p*-cymene and, in some cases, *p*-menthadienes. The percentage of *p*-cymene was determined using ultraviolet spectra in 95% ethanol according to the method reported previously.[3c]

Experiment 8.—*t*-Butyl alcohol, 37 g. (0.5 mole) with 1 g. (0.025 g. atm.) of potassium dissolved in it, when heated at 280° for 3.3 hr. yielded 0.087 mole of methane and 0.001 mole of hydrogen.

Experiment 9.—*t*-Butyl alcohol, 37 g. (0.5 mole) with 5.6 g. (0.1 mole) of powdered potassium hydroxide was heated at 292° for 1 hr. but yielded no gas.

Experiment 14.—1-*p*-Menthene had the following physical constants: $\alpha^{25}D$ +93.5, $n^{20}D$ 1.4560. This hydrocarbon, 34.5 g. (0.25 mole), was heated at 260–265° for 5.5 hr. with potassium *t*-butoxide prepared from 2 g. (0.05 g. atom) of potassium. The gaseous product consisted of 0.160 mole of methane and 0.003 mole of hydrogen. The C_{10} fraction obtained, $\alpha^{28}D$ +35, $n^{20}D$ 1.4560, was composed of 92% 1-*p*-menthene 1.5% 2-*p*-menthene, 2.0% 3-*p*-menthene and 4.5% 8-(9)-*p*-menthene. The analytical procedure was the same as reported previously.[3d]

Alkoxide Decomposition Products.—The white solid recovered from a potassium *t*-butoxide reaction with limonene was neutralized with 10% hydrochloric acid and acidic and phenolic fractions were extracted. A 3,5-dinitrobenzoate was prepared from the phenolic fraction according to the method of Keenan and Phillips.[8] Only 13.7 mg. of a cream-colored solid was obtained which when recrystallized twice from 95% ethanol melted at 192–194°. Mixed melting point with an authentic sample of the 3,5-dinitrobenzoate of 3,5-dimethylphenol was 192–194°; literature[8] 195.4°.

The acid fraction obtained gave an anilide which melted at 108°. A synthetic sample prepared from isovaleryl chloride and aniline melted at 107°. Mixed melting point with that isolated from reaction was 107°; literature[9] 109–110°.

Acknowledgment.—The authors wish to express their appreciation to Professor D. F. Mason of the Chemical Engineering Department for the mass spectral analysis.

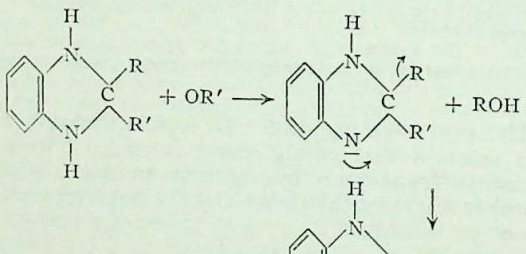
(6) A mechanism similar to the elimination of carbanion by alkoxides has been proposed by Elderfield and co-workers for the elimination of alkyl groups from 2,3-dialkylbenzimidazolenes [R. C. Elderfield, *et al.*, THIS JOURNAL, (a) **70**, 44 (1948); (b) **73**, 975 (1951); (c) **76**, 1883 (1954)]. Alkoxides have been reported to catalyze the reaction for which the presumed mechanism is



However, when two alkyl groups are attached to the 2-position the group which is eliminated is not the one which should form the more stable carbanion (H. Pines and H. E. Eschinazi, *ibid.*, **78**, 5950 (1956)) even under base catalysis. Therefore it seems probable that the reaction proceeds by a radical type mechanism. This is in accord with the fact that di-*t*-butyl peroxide will also catalyze the reaction.[6c]

The Reaction of *dl*- and *meso*-2,3-Dibromobutane with Silver Nitrate in Acetonitrile. Failure of the Nitrate Ester Grouping to Exhibit the Neighboring Group Effect[1]

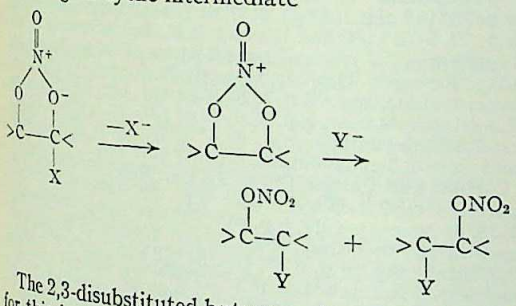
BY LEON FISHBEIN[2]

RECEIVED AUGUST 6, 1956

The reaction of *dl*-2,3-dibromobutane with silver nitrate in acetonitrile gives the mononitrate ester (of *threo*-2-bromo-3-butanol), and this in a somewhat slower reaction is then converted to the dinitrate of *meso*-2,3-butanediol. In other words, the first step occurs with retention of configuration, the second step with inversion. Precisely the same stereochemical results are obtained when *meso*-2,3-dibromobutane is treated with silver nitrate in acetonitrile; retention in the first step, inversion in the second. It is thus clear that while neighboring bromine participates, the neighboring nitrate ester group does not exhibit the neighboring group effect.

Winstein, Lucas and their co-workers have established the fact that an over-all retention of configuration results when an atom or a group of atoms participates in the displacement of a second functional group on an adjacent carbon atom.[3] The neighboring group reaction has been demonstrated for a large number of atoms or groups of atoms and include the following: $-I$, $-Br$, $-Cl$, $-CO_2^-$, $-OCOCH_3$, $-OCH_3$, $-OH$, O^-, $-NH_2$, $-NR_2$, $-SR$, benzamido and aryl.

This paper concerns itself with a study, by stereochemical means, of the effectiveness of a β-nitrate ester group as a neighboring group in the reaction of alkyl bromides with silver nitrate. The nitrate ester group, in a formal way, closely resembles an acetoxy group and this suggested the possibility of an analogous cyclic intermediate



The 2,3-disubstituted butane system was selected for this investigation because of the known configurational relationships of the *dl*- and *meso*-dibromides,[4] diols,[5] *cis*- and *trans*-epoxides[3a] and *erythro*- and *threo*-bromohydrins.[3c]

Discussion

The reaction of *meso*-2,3-dibromobutane with silver nitrate in acetonitrile for 24 hr. at room temperature yielded as the only product a bromonitroxybutane[6] which was identical with that obtained by the direct nitration of *erythro*-2-bromo-3-butanol (see Chart 1) as shown by their refractive indices and infrared spectra.

When either *meso*-2,3-dibromobutane or *erythro*-2-bromo-3-nitroxybutane was treated with silver nitrate in acetonitrile for *ca.* 45 days, there was formed a dinitrate ester of 2,3-butanediol which was identical with that obtained by the direct nitration of *dl*-2,3-butanediol (see Chart II)[7] as shown by their refractive indices and infrared spectra.

Complete duplication of results was obtained employing *dl*-2,3-dibromobutane. Thus, the reaction with silver nitrate for *ca.* 24 hr. yielded *threo*-2-bromo-3-nitroxybutane. Upon treating the *dl*-dibromide or the *threo*-bromonitrate with silver nitrate for *ca.* 45 days, there was obtained the dinitrate ester of *meso*-2,3-butanediol.

The demonstration that either *dl*- or *meso*-2,3-dibromobutane could be recovered unchanged from a mixture consisting of dibromide, silver bromide and acetonitrile dismisses the possibility that these dibromides undergo isomerization prior to the reaction which produces bromonitroxybutane. Similarly, no isomerization could be demonstrated to occur for the diastereomeric-2-bromo-3-nitroxybutanes.

These facts can be rationalized in the following manner: The first step in the reaction of *dl*-2,3-dibromobutane with silver nitrate consists in the formation of *threo*-2-bromo-3-nitroxybutane by a neighboring group participation of a bromine atom. That the *threo* isomer is formed with retention of configuration and unmixed with its diastereomer[8] strongly suggests a concerted process, in which the neighboring bromine atom participates in a back-

(5) H. J. Lucas and C. E. Wilson, *ibid.*, **58**, 2396 (1936).

(6) The reaction of the diastereomeric 2,3-dibromobutanes with silver nitrate to prepare the bromonitroxybutanes is a rapid one (*ca.* 24 hr.) compared with that in which a dinitrate is obtained (*ca.* 45 days). This enables one to isolate the bromonitroxybutane uncontaminated with dinitrate.

(7) That nitration occurs with a retention of configuration and no loss in optical purity was demonstrated by A. F. McKay, R. H. Meen and G. F. Wright [THIS JOURNAL, **70**, 430 (1948)]. Levorotatory 2,3-butanediol, $[\alpha]^{20}D$ $-12.89°$ was nitrated with a mixture of fuming nitric acid and concentrated sulfuric acid to yield the levorotatory dinitrate ester, $[\alpha]^{20}D$ $-0.88°$, which upon hydrogenolysis employing a palladium-on-charcoal catalyst produced levorotatory 2,3-butanediol, $[\alpha]^{20}D$ $-12.90°$. Similarly, S. J. Cristol, [THIS JOURNAL, **77**, 2512 (1955)] has shown that no loss in optical purity occurs in the sequence

$$(-)\text{-2-octanol} \rightarrow (-)\text{-2-octyl nitrate} \xrightarrow[H_2]{PtO_2} (-)\text{-2-octanol.}$$

(8) The *threo* compound is formed with a stereospecificity > 95%. Infrared spectra were obtained for the pure *threo*- and *erythro*-2-bromo-3-nitroxybutanes as well as for synthetic mixtures of 95% *threo*–5% *erythro*, 90% *threo*–10% *erythro*, 95% *erythro*–5% *threo* and 90% *erythro*–10% *threo*. The infrared spectrum of the bromonitroxybutane, isolated from the reaction of *dl*-2,3-dibromobutane with silver nitrate over a 24-hr. period, was identical with that of pure *threo*-2-bromo-3-nitroxybutane. A similar high stereospecificity was observed for the reaction which produced the *erythro* isomer.

CHART I.—PREPARATION OF THE DIASTEREOMERIC 2-BROMO-3-NITROXYBUTANES

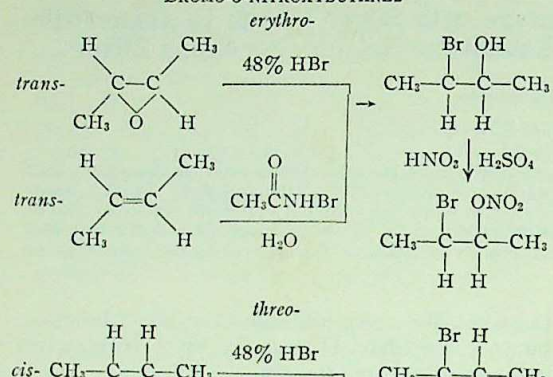

CHART II.—PREPARATION OF THE DIASTEREOMERIC 2,3-DINITROXYBUTANES

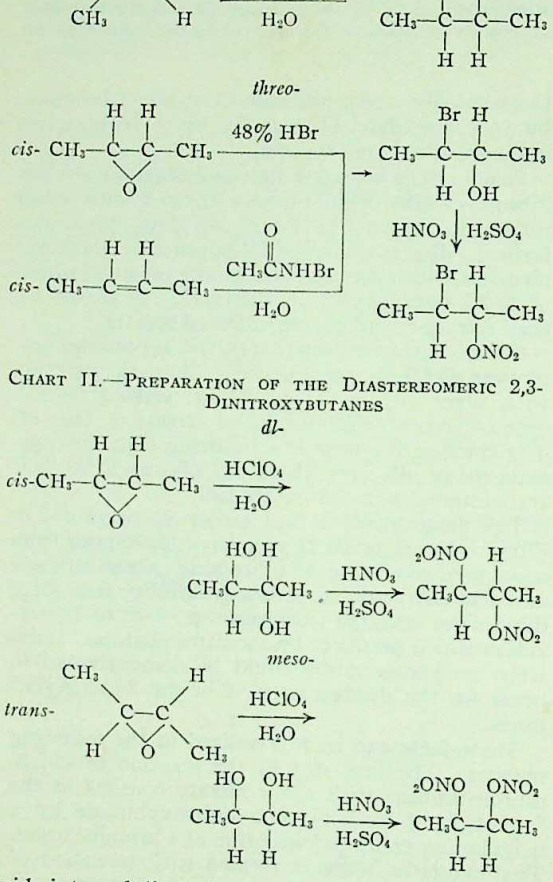
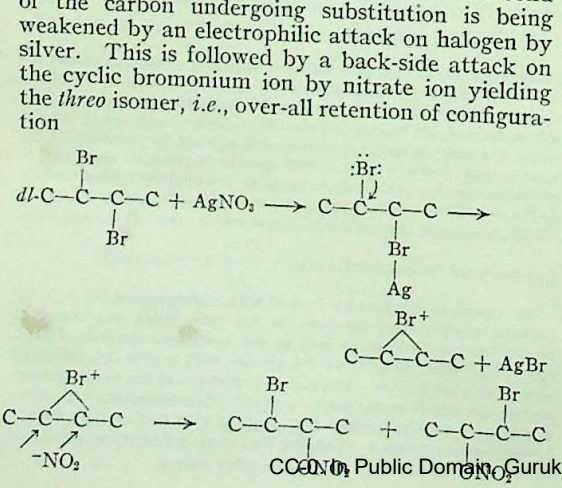


side internal displacing action while the C–Br bond of the carbon undergoing substitution is being weakened by an electrophilic attack on halogen by silver. This is followed by a back-side attack on the cyclic bromonium ion by nitrate ion yielding the *threo* isomer, *i.e.*, over-all retention of configuration



In the next step of the reaction sequence, the *threo*-2-bromo-3-nitroxybutane reacts with silver nitrate to yield the dinitrate ester of *meso*-2,3-butanediol, that is with inversion of configuration. Also noteworthy is the fact that the reaction occurs with complete stereospecificity: the *meso*-dinitrate contains less than 5% of the racemic stereoisomer.[9]

Kornblum, Smiley, Blackwood and Iffland[10] have as a result of a careful examination of the reaction of silver nitrite with 2-octyl halides provided a demonstration that this reaction proceeds *via* a transition state possessing both SN1 and SN2 character. The results of the present investigation are fully consonant with their pull–push mechanism.

Of special interest is the observation that the *threo*-bromonitrate reacts with silver nitrate with clean inversion for it serves to emphasize, once again, the importance of the push exerted by the anion in the reactions of silver salts with strictly aliphatic halides.[9]

The reaction of the 2-bromo-3-nitroxybutanes with silver nitrate is exceedingly slow being *ca.* 90% complete after 45 days.[11] It is to be expected that in this reaction, as well as those involving α-halocarbonyl compounds, α-haloesters and 1,2-dichloride,[12] the SN1 contribution to the transition state is minimized because of adjacent charge considerations.

Experimental

Preparation of Intermediates.—*dl*-2,3-Dibromobutane, b.p. 73° (47 mm.), n^{20}D 1.5147, and *meso*-2,3-dibromobutane, b.p. 71.5–72° (50 mm.), n^{20}D 1.5116, were prepared by the bromination of *cis*- and *trans*-2-butene (Phillips Petroleum Co., Research Grade), respectively [reported[4] *dl*-2,3-dibromobutane, b.p. 75.6–75.8° (50 mm.), n^{20}D 1.5147; *meso*-2,3-dibromobutane, b.p. 72.7–72.9° (50 mm.), n^{20}D 1.5116]. *cis*-2,3-Epoxybutane, b.p. 60.5° (747 mm.), n^{20}D 1.3826, and *trans*-2,3-epoxybutane, b.p. 55° (747 mm.), n^{20}D 1.3736 (Carbide and Carbon Chemicals Co., Research Grade) [reported[3a] *cis*-2,3-epoxybutane, b.p. 60° (742 mm.), n^{20}D 1.3828; *trans*-epoxide, b.p. 54° (742 mm.) n^{20}D 1.3736] were used in the procedure of Lucas and Wilson[5] to prepare *dl*-2,3-butanediol, m.p. 6.5°, b.p. 54° (2 mm.), $n^{19.4}$D 1.4320, and *meso*-2,3-butanediol, m.p. 33–34°, b.p. 60–61° (2 mm.) [reported[5] *dl*-2,3-butanediol, m.p. 7.6°, b.p. 86° (16 mm.); *meso*-diol, m.p. 34.4°, b.p. 89° (16 mm.)]. *threo*-2-Bromo-3-butanol, b.p. 49–50° (13 mm.), n^{25}D 1.4752, and *erythro*-2-bromo-3-butanol, b.p. 53–54° (13 mm.), n^{25}D 1.4763, prepared by the reaction of *cis*- and *trans*-2,3-epoxybutane, respectively, with 48% HBr[3a] were identical with the bromohydrins obtained from the reaction of the isomeric 2-butenes with N-bromoacetamide,[3c] as shown by their boiling

(9) N. Kornblum, L. Fishbein and R. A. Smiley [THIS JOURNAL, 77, 6261 (1955)] have shown that the reaction of optically active 2-octyl halides with silver nitrite (in diethyl ether) occurs with clean inversion. Also relevant is a recent report by N. Kornblum and D. Hardies [Abstracts of the 130th National Meeting of the American Chemical Society, Atlantic City, N. J., September 16–21, 1956, page 2-O] that in acetonitrile 2-octyl halides react with silver nitrite (and with silver nitrate) with inversion.

(10) N. Kornblum, R. A. Smiley, R. K. Blackwood and D. C. Iffland, *ibid.*, **77**, 6269 (1955).

(11) It is interesting to note that 2-bromobutane reacts quantitatively with silver nitrate in acetonitrile within 5 minutes, 1-bromobutane in 20 hr. and 1,4-dibromobutane in 20 hr. (*cf.* Experimental).

(12) The extreme inertness of vicinal dichlorides is illustrated by experiments involving *dl*- and *meso*-2,3-dichlorobutane. When these dichlorides were treated with silver nitrate in acetonitrile under the identical conditions as described for the diastereomeric dibromides, the *meso*-dichloride was *ca.* 1% reacted in 5 months, the *dl*-isomer was completely unreacted in the same period. This is to be contrasted with the following reactivities: 1-chlorobutane, 55% reacted in 12 days; 2-chlorobutane, 86% in 10 days; 1,4-dichlorobutane, 80% in 33 days (*cf.* Experimental).

points, refractive indices and infrared spectra [reported[3a] *threo*-2-bromo-3-butanol, b.p. 50.5° (13 mm.), n^{25}D 1.4756; *erythro* isomer, b.p. 53.1° (13 mm.), n^{25}D 1.4767].

threo-2-Bromo-3-nitroxybutane.—To a nitrating mixture consisting of 4 ml. (0.09 mole) of fuming nitric acid and 3.2 ml. (0.06 mole) of concentrated sulfuric acid at −20° was added dropwise over a 45-minute period, 9.18 g. (0.06 mole) of *threo*-2-bromo-3-butanol (prepared by the reaction of *cis*-2,3-epoxybutane with 48% HBr). After the addition was complete, the reaction mixture was kept at −15° for 10-minutes, then at 0° for 45 minutes, after which it was poured onto *ca.* 50 g. of crushed ice. The oily phase which separated was taken up in methylene chloride. The methylene chloride extract was successively washed with ice-water, aqueous 5% sodium bicarbonate solution, water, then dried over anhydrous magnesium sulfate. The methylene chloride extract was concentrated by removing the solvent *in vacuo* at room temperature. The residue was then distilled *in vacuo* yielding 10.2 g. (86% yield) of product having b.p. 58° (8 mm.), n^{20}D 1.4685.

Anal. Calcd. for $C_4H_8BrNO_3$: C, 24.24; H, 4.04; N, 7.07. Found: C, 24.45; H, 4.05; N, 7.32.

In a similar manner the nitration of the *threo*-bromohydrin (prepared from *cis*-2-butene and N-bromoacetamide) gave a 73% yield of product having b.p. 60.5–61.5° (8–9 mm.), n^{20}D 1.4686.

Anal. Calcd. for $C_4H_8BrNO_3$: C, 24.24; H, 4.04; N, 7.07. Found: C, 24.51; H, 4.21; N, 6.80.

The infrared spectrum of *threo*-2-bromo-3-nitroxybutane displayed absorption bands at 1065 and 1135 cm.$^{-1}$ which were absent in that of the *erythro* isomer.

erythro-2-Bromo-3-nitroxybutane.—When *erythro*-2-bromo-3-butanol (prepared by the reaction of *trans*-2,3-epoxybutane with 48% HBr) was nitrated in the same manner as that outlined for the *threo* isomer, there was obtained an 81% yield of product having b.p. 54° (6–7 mm.), n^{20}D 1.4695.

Anal. Calcd. for $C_4H_8BrNO_3$: C, 24.24; H, 4.04; N, 7.07. Found: C, 24.52; H, 4.26; N, 7.27.

The nitration of the *erythro*-bromohydrin (prepared from *trans*-2-butene and N-bromoacetamide) gave a 63% yield of product having b.p. 58° (8–9 mm.), n^{20}D 1.4694.

Anal. Calcd. for $C_4H_8BrNO_3$: C, 24.24; H, 4.04; N, 7.07. Found: C, 24.25; H, 4.17; N, 6.83.

The infrared spectrum of *erythro*-2-bromo-3-nitroxybutane exhibited bands at 1055, 1098 and 1155 cm.$^{-1}$ which were absent in that of the *threo* isomer.

dl-2,3-Dinitroxybutane.—To a nitrating mixture consisting of 17 ml. (0.4 mole) of fuming nitric acid and 16.3 ml. (0.3 mole) of concentrated sulfuric acid at −10° was added portionwise over a 30-minute period, 8.7 g. (0.097 mole) of *dl*-2,3-butanediol. After the addition was complete, the reaction mixture was kept at 0° for 2 hr., then poured onto *ca.* 100 g. of crushed ice. The oily phase which separated was taken up in methylene chloride and successively washed with ice-water, aqueous 5% sodium bicarbonate solution, water, then dried over anhydrous magnesium sulfate. The methylene chloride extract was concentrated by removing the solvent *in vacuo* at room temperature. The residue was then distilled *in vacuo* yielding 13 g. (75%) of colorless product having b.p. 71° (3 mm.), n^{20}D 1.4412.

Anal. Calcd. for $C_4H_8N_2O_6$: C, 26.67; H, 4.44; N, 15.56. Found: C, 26.68; H, 4.32; N, 15.55.

The infrared spectrum of this material exhibited bands at 1015, 1025 and 1145 cm.$^{-1}$ which were absent in the *meso* isomer.

meso-2,3-Dinitroxybutane.—The nitration of *meso*-2,3-butanediol by the procedure as outlined for the *dl*-isomer, yielded 75% of product having b.p. 65–66° (2 mm.), n^{20}D 1.4414.

Anal. Calcd. for $C_4H_8N_2O_6$: C, 26.67; H, 4.44; N, 15.56. Found: C, 26.94; H, 4.21; N, 15.56.

The infrared spectrum of this material displayed absorption bands at 1000, 1100 and 1175 cm.$^{-1}$ which were absent in the racemic isomer.

Reaction of *dl*-2,3-Dibromobutane with Silver Nitrate in Acetonitrile. Isolation of *threo*-2-Bromo-3-nitroxybutane.—To a solution of 10.8 g. (0.05 mole) of *dl*-2,3-dibromobutane in 25 ml. of acetonitrile at 25° was added in one portion a solution of 25.5 g. (0.15 mole) of silver nitrate in 40 ml. of acetonitrile. The reaction mixture was kept at room temperature in the absence of light for 24 hr., then filtered, producing a 96% yield of silver bromide as a by-product. This residue was washed with fresh portions of acetonitrile. The filtrate and washings were combined and poured into 100 ml. of distilled water. The oily phase which separated was taken up in methylene chloride. The aqueous solution was further extracted with two 20-ml. portions of methylene chloride. The methylene chloride extracts were combined, washed twice with 25-ml. portions of water, dried over anhydrous sodium sulfate and concentrated by removing the solvent *in vacuo* at room temperature. The residue was then distilled *in vacuo* yielding 7.3 g. (72%) of colorless product having b.p. 58° (8 mm.), n^{20}D 1.4680, and possessing an infrared spectrum identical with that of *threo*-2-bromo-3-nitroxybutane prepared by the nitration of *threo*-2-bromo-3-butanol.

Anal. Calcd. for $C_4H_8BrNO_3$: C, 24.24; H, 4.04; N, 7.07. Found: C, 24.52; H, 3.89; N, 6.92.

The Reaction of *meso*-2,3-Dibromobutane with Silver Nitrate in Acetonitrile. Isolation of *erythro*-2-Bromo-3-nitroxybutane.—This reaction was carried out in the same manner as that described for the *dl*-isomer. There was obtained a 73% yield of product having b.p. 58° (8–9 mm.), n^{20}D 1.4698, and possessing an infrared spectrum identical with that of *erythro*-2-bromo-3-nitroxybutane prepared by the nitration of *erythro*-2-bromo-3-butanol.

Anal. Calcd. for $C_4H_8BrNO_3$: C, 24.24; H, 4.04; N, 7.07. Found: C, 24.50; H, 4.08; N, 7.07.

The Reaction of *dl*-2,3-Dibromobutane with Silver Nitrate in Acetonitrile. Isolation of *meso*-2,3-Dinitroxybutane.—To a solution of 26 g. (0.120 mole) of *dl*-2,3-dibromobutane in 20 ml. of acetonitrile at 25° was added in one portion a solution of 60 g. (0.353 mole) of silver nitrate in 60 ml. of acetonitrile. The reaction mixture was kept at room temperature in the absence of light for 45 days then filtered, producing a 92% yield of silver bromide as a by-product. This residue was washed with small portions of acetonitrile. The filtrate and washings were combined and poured into 150 ml. of distilled water. The oily phase which separated was taken up in methylene chloride. The aqueous phase was washed with fresh portions of methylene chloride. The methylene chloride extracts were combined, washed twice with 25-ml. portions of water, dried over anhydrous sodium sulfate and concentrated by removing the solvent *in vacuo* at room temperature. The residue was then distilled *in vacuo* yielding 16.7 g. (80%) of colorless product having b.p. 55–56° (1 mm.), n^{20}D 1.4414, and identical with the dinitrate ester of *meso*-2,3-butanediol (prepared by the nitration of *meso*-2,3-butanediol) as shown by their infrared spectra.

Anal. Calcd. for $C_4H_8N_2O_6$: C, 26.67; H, 4.44; N, 15.56. Found: C, 26.67; H, 4.56; N, 15.62.

The Reaction of *meso*-2,3-Dibromobutane with Silver Nitrate in Acetonitrile. Isolation of *dl*-2,3-Dinitroxybutane. This reaction was carried out in the same manner as that outlined for the *dl*-isomer. There was obtained a 75% yield of product having b.p. 60° (2 mm.), n^{20}D 1.4412. The infrared spectrum of this material was identical with that of the dinitrate ester of *dl*-2,3-butanediol (prepared by the nitration of *dl*-2,3-butanediol).

Anal. Calcd. for $C_4H_8N_2O_6$: C, 26.67; H, 4.44; N, 15.56. Found: C, 26.77; H, 4.51; N, 15.56.

The Reaction of *threo*-2-Bromo-3-nitroxybutane with Silver Nitrate in Acetonitrile.—To a solution of 6.58 g. (0.0346 mole) of *threo*-2-bromo-3-nitroxybutane (prepared by the nitration of the *threo*-bromohydrin) in 5 ml. of dry acetonitrile, was added in one portion a solution of 7.36 g. (0.0433 mole) of silver nitrate in 10 ml. of acetonitrile. The reaction mixture was kept at room temperature in the absence of light for 40 days, then filtered, producing a 90% yield of silver bromide as a by-product. This residue was washed with fresh portions of acetonitrile. The filtrate and washings were combined and poured into 30 ml. of distilled water. The oily phase which separated was taken up in methylene chloride. The aqueous phase was washed with fresh portions of methylene chloride. The methylene chloride extracts were combined, washed with water, dried over anhydrous sodium sulfate and concentrated by removing the solvent *in vacuo* at room temperature. The residue was then distilled *in vacuo* yielding 7.9 g. (67%) of colorless prod-

uct having b.p. 58° (1–2 mm.), $n^{20}D$ 1.4417, and possessing an infrared spectrum identical with that of pure dinitrate ester of *meso*-2,3-butanediol.

Anal. Calcd. for $C_4H_8N_2O_6$: C, 26.67; H, 4.44; N, 15.56. Found: C, 26.47; H, 4.23; N, 15.35.

The Reaction of *erythro*-2-Bromo-3-nitroxybutane with Silver Nitrate in Acetonitrile.—This reaction was carried out in the same manner as that described for the *threo*-isomer. There was obtained a 74% yield of product having b.p. 50° (1 mm.), $n^{20}D$ 1.4416, and possessing an infrared spectrum identical with that of pure dinitrate ester of *dl*-2,3-butanediol.

Anal. Calcd. for $C_4H_8N_2O_6$: C, 26.67; H, 4.44; N, 15.56. Found: C, 26.57; H, 4.67; N, 15.70.

The Attempted Isomerization of *meso*-2,3-Dibromobutane with Silver Bromide in Acetonitrile.—To a solution of 108.2 g. (0.5 mole) of *meso*-2,3-dibromobutane, b.p. 71° (50 mm.), $n^{20}D$ 1.5116, in 100 ml. of dry acetonitrile at 25° was added in one portion a solution of 42.4 g. (0.25 mole) of silver nitrate in 50 ml. of acetonitrile. The reaction mixture was stirred at room temperature in the absence of light for 24 hr. The reaction mixture was filtered and the silver bromide residue washed with fresh portions of acetonitrile. The filtrate and washings were combined and poured into 250 ml. of distilled water. The oily phase which separated was taken up in diethyl ether. The aqueous phase was washed with fresh portions of ether. The ether extracts were combined, washed with water, dried over sodium sulfate and concentrated by removing the solvent at atmospheric pressure. The residue was then distilled *in vacuo* through a 18" column packed with glass helices, a total of 10 fractions being collected.

Fractions 1–6 (48 g.) having b.p. 35–43° (8–9 mm.), $n^{20}D$ 1.5100–1.5040, were combined and rectified twice *in vacuo* yielding a 75% recovery of unreacted *meso*-dibromide, b.p. 61–62° (34 mm.), $n^{20}D$ 1.5112. The infrared spectrum of this material showed it to be 98% pure.

The infrared spectrum of pure *meso*-2,3-dibromobutane exhibits an absorption band at 1160 cm.$^{-1}$ which is absent in the racemic dibromide; the *dl*-2,3-dibromobutane displays an absorption band at 1100 cm.$^{-1}$ which is absent in the *meso*-dibromide. It was found that the isomeric dibromides could be detected to less than 2% in the presence of the other.

The Attempted Isomerization of *dl*-2,3-Dibromobutane with Silver Bromide in Acetonitrile.—Employing the procedure as described for the *meso* isomer led to an 80% recovery of the *dl*-dibromide. Infrared analysis showed this material to contain 3% of the isomeric impurity.

The Attempted Isomerization of *erythro*-2-Bromo-3-nitroxybutane with Silver Bromide in Acetonitrile.—A mixture of 15 g. (0.075 mole) of *erythro*-2-bromo-3-nitroxybutane, b.p. 54° (6–7 mm.), $n^{20}D$ 1.4695, and 18.8 g. (0.1 mole) of freshly precipitated silver bromide in 30 ml. of acetonitrile was allowed to stand at room temperature in the absence of light for 15 days. The reaction mixture was filtered and the residue washed with fresh portions of acetonitrile. The filtrate and washings were combined and poured into 75 ml. of water. The organic layer was separated and taken up in methylene chloride. The aqueous solution was further extracted with small portions of methylene chloride. The methylene chloride extracts were combined, washed with three 20-ml. portions of water, dried over anhydrous sodium sulfate and concentrated by removing the solvent at atmospheric pressure. The residue was then rectified *in vacuo* yielding 12.2 g. (82%) of *erythro*-2-bromo-3-nitroxybutane, b.p. 55° (7 mm.), $n^{20}D$ 1.4698. Infrared analysis of this material showed it to contain less than 5% of the *threo* isomer.

A complete duplication of results was obtained when *threo*-2-bromo-3-nitroxybutane was treated with silver bromide in the same manner as that described for the *erythro* isomer.

Reaction of 1-Bromobutane, 2-Bromobutane, 1,4-Dibromobutane, 1-Chlorobutane, 2-Chlorobutane, 1,4-Dichlorobutane, *dl*- and *meso*-2,3-Dichlorobutane with Silver Nitrate in Acetonitrile at Room Temperature.—A solution consisting of 0.025 mole of alkyl halide, 25 ml. of acetonitrile and a 25% molar excess of silver nitrate was maintained at room temperature (24–28°) in the absence of light. The extent of the reaction was determined by isolating the silver halide formed. The silver halide was separated by filtration, washed twice with acetonitrile and dried. Table I records the results.

TABLE I

REACTION OF SILVER NITRATE WITH BROMO- AND CHLOROBUTANES IN ACETONITRILE AT ROOM TEMPERATURE

Halide	Extent of reacn., %	Hours
2-Bromo	Quant.	0.1
1-Bromo	Quant.	20
1,4-Dibromo	Quant.	20
1-Chloro	55	288
2-Chloro	86	244
1,4-Dichloro	80	792
dl-2,3-Dichloro	No reacn.	3720
meso-2,3-Dichloro	1	3720

Infrared absorption spectra were obtained with a Perkin-Elmer model 21 double beam spectrophotometer using homogeneous samples, NaCl prism and cell thickness of 0.025 mm.

Acknowledgment.—The author wishes to thank Mrs. P. P. Wheeler for the analyses; Dr. G. B. Wilmot and Mrs. N. F. Lyons for the infrared spectra. He also wishes to acknowledge the many helpful comments of Professor Nathan Kornblum of Purdue University.

Synthesis and Properties of an Allenic Nitrile

BY LEE IRVIN SMITH AND JACK S. SWENSON[1]

RECEIVED DECEMBER 5, 1956

Synthesis of the allenic nitrile, 2-cyano-2,3-pentadiene (I), has been achieved. The structure of the nitrile has been proved, and its behavior toward certain reagents has been studied. A combination of reduction and hydrolysis converted the allenic nitrile into 2-methylpentanamide, but reaction of the nitrile with Grignard reagents, phenyllithium or ethyl sodiomalonate all resulted in polymerization of the nitrile and no compounds formed by simple addition of these reagents could be isolated. The key to the synthesis of the allenic nitrile was the facile prototropic shift, occurring with 2-cyano-3-pentyne (IV) whereby the acetylenic nitrile rearranged into the allenic nitrile.

As a part of a program having as its object the synthesis of an allenic ketone, synthesis of the allenic nitrile I, 2-cyano-2,3-pentadiene, was undertaken. The route to the allenic nitrile involved the sequence of steps

$$CH_3C{\equiv}C\ Mg\ Br + CH_3CHO \longrightarrow CH_3C{\equiv}C\ CH(OH)\ CH_3$$

$$\text{Mixture of IV + I} \xrightarrow[\text{dry ether}]{NaOCH_3} \text{I}$$

Synthesis of 2-hydroxy-3-pentyne (II) was achieved *via* known reactions. The product, obtained in 64% yield, had the physical properties reported in the literature.[2] The infrared spectrum showed a strong absorption at 3360 cm.$^{-1}$ (hydroxyl) and a spilt absorption of medium intensity at 2250 and 2220 cm.$^{-1}$ (triple bond).

The acetylenic alcohol II was converted into 2-bromo-3-pentyne (III) by action of phosphorus tribromide. The bromide III, obtained in 68% yield, boiled at 42° (20 mm.), and the infrared spectrum showed a strong absorption at 2250 cm.$^{-1}$ (triple bond) and was very similar to spectra reported for analogous propargyl bromides.[3]

The reaction between the bromide III and cuprous cyanide required very careful control of conditions and led to a mixture boiling at 55–61° (30 mm.) in yields of 0 to 37%, depending upon the experimental conditions. Infrared spectra of these mixtures indicated that the principal constituents were the acetylenic nitrile IV and a product (I) resulting from a rearrangement. A brown polymer was also present, and often some of the starting bromide III was recovered. The infrared spectra of the mixtures distilling at 55–61° (20 mm.) showed several characteristic bands which could best be explained by the presence in the mixture of an acetylenic nitrile IV and its allenic isomer I. The intensities of the weak band at 2270 cm.$^{-1}$ and the medium band at 2250 cm.$^{-1}$ always appeared in direct proportion to each other; these bands arise from the acetylenic linkage in IV. The sharp and relatively strong band at 2220 cm.$^{-1}$ probably arises from the nitrile group of IV and I, but the intensity of the band at 2220 cm.$^{-1}$ generally was proportional to that of the band at 1970 cm.$^{-1}$ arising from the allenic linkage in I. This band at 1970 cm.$^{-1}$ varied in intensity according to the amount of I present in the mixture. There was a very strong band at 1445 cm.$^{-1}$ and a fairly strong band at 1380 cm.$^{-1}$; these bands are characteristic of methyl groups, and their intensities are proportional to the number of methyl groups present. The intensities and positions of these two bands were the same in the spectra of all the mixtures, and in the spectra of the samples of pure allenic nitrile—as would be expected of mixtures of IV and I, both compounds containing two methyl groups. There was a sharp band at 1305 cm.$^{-1}$, characteristic of the acetylenic nitrile IV, and varying in intensity with the amount of IV present in the mixture. This band varied inversely in intensity with the band at 1000 cm.$^{-1}$, characteristic of the allenic nitrile. There was also a band at 790 cm.$^{-1}$, very characteristic of the allenic nitrile. The intensities of the three bands at 790, 1000 and 1970 cm.$^{-1}$ varied in direct proportion with the amount of I present in the mixtures, and the ratio of these intensities to those of pure I was used in estimating the amount of I present in the mixtures. As determined in this way, the amount of the allenic nitrile in the mixtures varied from 20 to 55%; in the mixtures obtained under optimum conditions for maximum yields, the amount of I present was usually about 50%.

The mixture of I and IV could not be separated into pure constituents by careful distillation through a modified semi-micro wire column[4] or through a Piros–Glover spinning band column, although the distillations had to be performed under 20 mm. because of the sensitivity of the allenic nitrile to heat. Likewise, no separation resulted when the mixture was chromatographed using either anhydrous magnesium sulfate or potato starch in the columns.

The key to isolation of I in the pure state was the discovery that the acetylene IV could be rearranged by means of a base-catalyzed prototropic shift into the allene I as the only distillable product. The finely powdered base was suspended in a dry ethereal solution of the mixture, and the product was recovered after removal of the base and evaporation of the solvent. Of several bases tried—sodamide, potassium carbonate, potassium hydroxide and sodium methoxide—the last was found to be the most effective. The crude product from this reaction, distilled through a spiral wire column, was the pure allenic nitrile I which boiled at 55° (19 mm.), 39° (8 mm.), 31° (3.5 mm.) and had $n^{25}D$ 1.4647; d^{25}_4 0.860. The yield of pure I was 28–38%; the over-all yield of I based on methylacetylene was about 4%.

The nitrile I gave analytical values in good agreement with those required for C_6H_7N. Proof of the carbon skeleton in I was achieved by reduction of the allenic linkage and hydrolysis of the nitrile to the saturated amide, 2-methylpentanamide (V), which was identical with an authentic specimen independently synthesized. The reduction was carried out in steps, and conversion of I into V proceeded as

$$\text{I} + H_2 \xrightarrow[\text{30 lb., 12 hr.}]{\text{Raney Ni}}$$

$$[CH_3CH{=}CH{-}CH(CH_3)CN] \xrightarrow{KOH\text{–}H_2O_2}$$

$$[CH_3CH{=}CHCH(CH_3)CONH_2] \xrightarrow[\text{500 lb., 2 hr.}]{H_2,\ \text{Raney Ni}}$$

$$\underset{\text{V}}{CH_3CH_2CH_2CH(CH_3)CONH_2}$$

The stability of I toward catalytic reduction was remarkable; even at 30–50 lb., it appeared that only one of the double bonds was reduced. As the reduction proceeded, the intensity of the allenic band at 1970 cm.$^{-1}$ in the infrared spectrum de-

creased, and a band of medium intensity appeared at 1640 cm.$^{-1}$, the region of absorption of unconjugated double bonds. Therefore, the structure of a β,γ-unsaturated nitrile was chosen for this first reduction product, although this structure was not proved. When this product was subjected to the action of hydrogen peroxide in 25% aqueous potassium hydroxide, a white crystalline material resulted. This was not a pure compound, for it had a wide melting point range of 62–76°. The infrared spectrum of this material still showed a band at 1640 cm.$^{-1}$, hence it is probably the β,γ-unsaturated amide. Finally, when this amide was subjected to action of hydrogen under 500 lb. at 100° in the presence of Raney nickel, a pure compound, melting at 77–80°, resulted. That this was 2-methylpentanamide was shown by its identity with a product synthesized from methyl-*n*-propylmalonic acid.

Having established the carbon skeleton of the nitrile I, the position of the allenic linkage follows from the fact that the same nitrile I was obtained as a result of two different types of propargylic rearrangement: formation of I from III by the carbonium type, or *via* an S$_N$2′ mechanism, and the carbanion type (IV → I).[5] The only structure consistent with this fact and with the other properties of the nitrile is I, 2-cyano-2,3-pentadiene. The bromide III underwent no rearrangement when subjected to action of base under the conditions used for rearrangement of IV into I.

The reactions of the nitrile I were disappointing; as mentioned before, it was hoped that I could be converted into an allenic ketone by action of organometallic compounds. In general, all attempts to add ethyl sodiomalonate, *p*-biphenylmagnesium bromide, ethylmagnesium bromide or phenyllithium to the nitrile resulted in production of high boiling polymeric materials.

Other experiments were carried out in the hope of obtaining an allenic ketone, as indicated below

$$C_6H_5C{\equiv}CCH_2OH\ (VI) \xrightarrow{PBr_3} \underset{VII}{C_6H_5C{\equiv}CCH_2Br}$$

$$VII + Zn + C_6H_5CHO \longrightarrow \underset{VIII}{C_6H_5C{\equiv}CCH_2CHOHC_6H_5}$$

$$VIII + CrO_3 \longrightarrow \underset{IX}{C_6H_5C{\equiv}CCH_2COC_6H_5}$$

$$IX + base \longrightarrow \underset{X}{C_6H_5CH{=}C{=}CHCOC_6H_5}$$

When γ-phenylpropargyl alcohol (VI) was subjected to action of phosphorus tribromide, the bromide VII was obtained in 85% yield; the physical properties of the bromide were in agreement with those reported by Lai[6] for this compound. The Reformatsky reaction between the bromide VII and benzaldehyde gave oils which boiled in the range 150–160° (0.3 mm.). The infrared spectra of these oils showed a band of medium intensity at 3430 cm.$^{-1}$ (hydroxyl) and a strong band at 1700 cm.$^{-1}$ (carbonyl) but no band arising from an acetylenic linkage. The carbonyl band arose from benzaldehyde, which was isolated as the 2,4-DNP from all the oils. No derivative which could be identified as the 2,4-DNP of an α,β-unsaturated ketone could be isolated; the transformation into an α,β-unsaturated ketone has been reported as a general reaction of β,γ-acetylenic alcohols.[7] Nevertheless, some of these oils were oxidized by action of chromic acid. The products were oils which contained a small amount of solid; the infrared spectra of these materials showed weak hydroxyl bands at 3430 cm.$^{-1}$, strong carbonyl bands at 1685 cm.$^{-1}$ but no significant bands arising from an acetylenic linkage. In one experiment, on a larger scale, the oxidation product, on standing, deposited several grams of a solid melting at 146–147° and identified as diphenacyl. This could arise from hydration of the triple bond in IX under the strongly acidic conditions used for the oxidation. Since isolation of diphenacyl indicated the presence of some IX in the mixture, the oil was subjected to action of bases in the hope that the prototropic shift would convert IX into the allenic isomer X. But action of the bases—potassium carbonate, potassium hydroxide, sodium methoxide and activated alumina[8]—again gave oils which were indistinguishable from the starting materials in any way and whose spectra in the infrared showed no bands arising from an allenic linkage.

An attempt was also made to condense the acetylenic bromide III with benzaldehyde in a Reformatsky type reaction and so to obtain the acetylenic alcohol XI which could be oxidized to the β,γ-acetylenic ketone XII.

$$C_6H_5CHO + III + Zn \rightarrow \underset{XI}{CH_3C{\equiv}CCH(CH_2)CHOHC_6H_5}$$

$$XI + CrO_3 \rightarrow \underset{XII}{CH_3C{\equiv}CCH(CH_3)COC_6H_5}$$

Again the Reformatsky reaction gave oils whose spectra in the infrared showed no acetylenic bands and from which only the 2,4-DNP of benzaldehyde could be isolated.

Experimental[9]

2-Hydroxy-3-pentyne (II) (268 g., 64%) was prepared from methylacetylene (210 g., 5.25 moles), ethylmagnesium bromide (from 554 g., 5.1 moles of ethyl bromide and 122 g., 5.0 gram atoms of magnesium) and acetaldehyde (230 g., 5.23 moles) essentially as reported in the literature.[5] The product boiled at 50–55° (16 mm.), had $n^{25}D$ 1.4467; d^{25}_4, 0.904.

Anal. Calcd. for C_5H_8O: C, 71.39; H, 9.59. Found: C, 71.01, 71.30; H, 10.04, 10.13.

2-Bromo-3-pentyne (III).—The alcohol II (100 g., 1.19 moles), dry pyridine (20 cc.) and dry ether (500 cc.) were placed in an apparatus equipped with a dropping funnel, reflux condenser with calcium chloride guard tube and a stirrer. Phosphorus tribromide (150 g., 0.56 mole) was added dropwise, with stirring and cooling (0°). After an initial period of five minutes, the cooling bath was removed and the ether was allowed to reflux while the rest of the phosphorus tribromide was added (30 minutes). The mixture, consisting at this point of a white precipitate and a clear yellow solution, was stirred and heated at 55° for 3 hr., after which it was cooled (0°) and ice was cautiously added to hydrolyze excess phosphorus tribromide. The ether

layer was removed, the water layer was extracted three times with 100-cc. portions of ether. All the ether solutions were combined, washed successively with saturated aqueous sodium bicarbonate, saturated aqueous sodium chloride and water and then dried (magnesium sulfate). Ether was removed by distillation, and the residual yellow oil was distilled through a short (4″) column packed with glass helices. The bromide III (119 g., 68%) was collected at 41–44° (20 mm.). It had n^{25}D 1.4903; d^{20}_4 1.335.

Anal. Calcd. for C_5H_7Br: C, 40.84; H, 4.80. Found: C, 40.99, 40.60; H, 5.39, 5.37.

2-Cyano-3-pentyne (IV) and 2-Cyano-2,3-pentadiene (I).—The reaction between the bromide III and cuprous cyanide required very careful control of reaction conditions in order to obtain good yields of the mixture of IV and I. The reaction was carried out twenty-four times; the optimum conditions from the point of view of reproducibility, ease of control and yields were as follows: the apparatus (dried in a steam heated oven and assembled while still warm to ensure anhydrous conditions) consisted of a 500-cc. three-necked flask equipped with reflux condenser with calcium chloride guard tube, a mechanical stirrer with a sealed joint and a thermometer with the bulb suspended just above the level of the liquid in the flask. In the flask were placed dry cuprous cyanide (43 g., 0.48 mole, dried for one day under vacuum and 100° and stored under vacuum over phosphorus pentoxide), the bromide III (71 g., 0.48 mole) and dry benzene (71 cc., dried over sodium). The mixture was stirred just rapidly enough to bring the cuprous cyanide into good suspension and then an oil-bath, preheated to 120°, was placed in position so that the level of the liquid in the bath was even with that of the liquid in the flask. Stirring and heating at 120° were maintained for 3.5 to 4 hr. after the temperature of the vapors reached 90°, or until the solids began to coagulate and settle noticeably in spite of the stirring. The mixture was cooled to room temperature, and the solution was decanted from the solids through a filter. The solids were washed three times with ether, and the extracts were decanted through a filter into the benzene solution. At this point a brown polymeric material separated; it was removed by filtration. Solvents were removed from the filtrate by distillation under reduced pressure, and the residual yellow oil was distilled through the spiral wire column.[4] The product was collected at 55–61° (20 mm.). Normally some unchanged III was recovered at 40–45° (20 mm.). The product (IV + I) weighed 14.5 g. (32.5%) and contained about 50% of I as shown by the infrared spectrum. No separation of this mixture into pure components could be achieved by any of several distillation procedures or by chromatography.

Rearrangement of IV to I. 2-Cyano-2,3-pentadiene.—This reaction, carried out 37 times, also required very careful control of conditions. The best procedure was as follows: in a 500-cc. three-necked flask equipped with a mechanical stirrer and reflux condenser were placed fresh (commercial) sodium methoxide (1.5 g.) and dry ether (100 cc.). A solution of the mixture of IV and I (14.5 g.) in dry ether (50 cc.) was added all at once to the stirred suspension of the base. The reaction mixture soon acquired a yellow color, and the base became rust colored. After ten minutes a second portion of base (1.5 g.) was added; after another ten minutes a third portion (1.5 g.), and at this point the mixture was cooled (0°). After another ten minutes (total time 30 minutes), the ether solution was decanted through a filter, the solids were washed three times with ether, the extracts were decanted through the filter and the solvent was removed under reduced pressure from the combined ethereal solutions. The residual oil was distilled through the spiral wire column (with cold finger condenser, Dry Ice–acetone).[4] The product, I (4.1 g., 28%), collected at 31–35° (3.3 mm.), boiled at 55° (19 mm.), 39° (8 mm.), 31° (3.5 mm.) and had n^{25}D 1.4650, d^{25}_4 0.0860.

Anal. Calcd. for C_6H_7N: C, 77.38; H, 7.58; N, 15.04. Found: C, 77.10; H, 7.60; N, 15.00.

Hydrogenation of I. 2-Methylpentanamide (V).—A solution of I (1 g.) in dry ether (20 cc.) was subjected to the action of hydrogen (30 lb.) for 11 hr. in the presence of an active Raney nickel catalyst. The product, a yellow oil, was distilled under 0.05 mm. and collected in a receiver cooled with Dry Ice. The infrared spectrum of the resulting colorless oil showed no band at 1970 cm.$^{-1}$ (allene) but did show a band at 1640 cm.$^{-1}$ (unconjugated double bond). This material, probably the β,γ-ethylenic nitrile, was stirred vigorously for 1 hr. with potassium hydroxide (1 cc., 25%) and hydrogen peroxide (1 cc., 30%) at 75°. The mixture was extracted three times with ether, and the solvent was removed under reduced pressure from the combined extracts. The residual oily material, crystallized several times from petroleum ether (b.p. 30–60°), gave a white solid which melted in the range 62–76°. The infrared spectrum of this material (in chloroform) showed the band at 1640 cm.$^{-1}$; it was probably the β,γ-ethylenic amide. This crystalline solid was dissolved in a few cc. of dry ether, and the solution was subjected to action of hydrogen (500 lb.) at 100° for 2 hr. in the presence of Raney nickel catalyst. After removal of the catalyst and solvent, the residual oily material gave a white crystalline product from petroleum ether (b.p. 30–60°). After three recrystallizations from the same solvent, the solid melted at 77–80°, alone or when mixed with a synthetic specimen of V. The infrared spectrum of this product was superimposable on that of synthetic V.

Ethyl *n*-propylmalonate (150 g., 74%) was synthesized from ethyl malonate and *n*-propyl bromide essentially according to directions in the literature.[10] The product boiled at 111–120° (19 mm.) and had n^{25}D 1.4180.[11]

Ethyl methyl-*n*-propylmalonate was prepared by methylation of the *n*-propylmalonate using methyl iodide and sodium ethoxide. The product (130 g., 80%) was collected at 114–120° (19 mm.). It had n^{25}D 1.4200.[12]

Methyl-*n*-propylmalonic acid was prepared by hydrolysis of the ester; the yield of acid was 35%, and, after crystallization from benzene, it melted at 106–108°.[13]

2-Methylpentanoic acid (18 g., 78%) was prepared by decarboxylation of the above malonic acid. The product was collected at 101–103° (20 mm.); it had n^{25}D 1.4117 and d^{20}_4 0.917.[12]

2-Methylpentanamide (V) was prepared from the above acid *via* the acid chloride. The product crystallized in colorless plates from petroleum ether (b.p. 30–60°) which melted at 80–81°[12] alone or when mixed with V obtained from I.

Action of Grignard Reagents upon I.—A Grignard reagent prepared from magnesium (1.9 g., 0.078 gram atom), *p*-bromobiphenyl (10.4 g., 0.043 mole) and ethyl bromide (0.5 g.) in ether was added through a glass wool filter to a stirred and cooled (Dry Ice) solution of I (1 g., 0.0107 mole) in ether. The reaction mixture immediately became yellow, and a yellow solid separated. The mixture was refluxed for ten minutes, then poured onto Dry Ice to carbonate the excess reagent, and the whole was poured into iced, saturated aqueous ammonium chloride. The solution was extracted twice with ether; the aqueous layer was acidified with hydrochloric acid and again extracted with ether. Both ether extracts were washed with aqueous sodium hydroxide (10%), then with water, dried (magnesium sulfate) and the ether was evaporated. From the ether extract after acidification, only a small scum of residue was obtained. From the extract before acidification, the residue was a thick yellow oil from which no crystalline material could be obtained and which, when heated under vacuum, gave a small sublimate of biphenyl. In a similar fashion, two experiments were made to determine the action of ethylmagnesium bromide and of phenyllithium upon I. The results were essentially the same.

Action of Ethyl Sodiomalonate upon I.—To a solution of ethyl sodiomalonate (from sodium, 0.3 g., 0.013 gram atom, ethyl malonate 2.1 g., 0.013 mole, and dry ethanol (30 cc.) there was added under nitrogen and at −80° a solution of I (1 g., 0.0107 mole) in ethanol (5 cc.). After addition was complete, the mixture was stirred at −80° for an hour and then was allowed to come to room temperature. At this point the mixture was a pale yellow solution with a white solid suspended in it. Ethanol was removed by distillation, under nitrogen, at 30–40° (20–25 mm.). The residual yellow material was dissolved in cold water (25 cc.) and the solution was extracted three times with ether. The combined ether extracts were dried (magnesium sulfate), and ether was removed under reduced pressure, leaving a yellow oil which gave only a few drops of distillate up to 380° (0.3 mm.). The infrared spectrum of the yellow oil (before

Digitized by Arya Samaj Foundation Chennai and eGangotri

attempted distillation) showed bands at 2240, 2210, 1730, 1670 and 1630 cm.$^{-1}$ but no band at 1970 cm.$^{-1}$. The few drops of distillate from the oil was saponified with hot aqueous potassium hydroxide (25%), but the only product was a brown oil containing a small amount of a white solid which melted between 140–340° with evolution of gas. In a second experiment similar to the above, the solution of ethyl sodiomalonate was added to a solution of I. The results, however, were essentially the same.

γ-Phenylpropargyl alcohol (VI) (128.7 g., 77.5%), prepared according to Bartlett and Rosen,[14] boiled at 121–123° (8 mm.), and had n^{25}D 1.5835.[15]

γ-Phenylpropargyl bromide (VII) (160 g., 85%) was prepared from VI (128.7 g.) by action of phosphorus tribromide (137 g.) and pyridine (15 cc.) in ether (250 cc.). The product boiled at 110–120° (8 mm.) and had n^{25}D 1.6172.[6]

The Reformatsky reaction between VII and benzaldehyde was first carried out according to an analogous procedure in the literature.[7] Dry, freshly etched zinc (70 g., 1.07 gram atoms) and enough dry benzene to cover the metal were placed in an apparatus equipped with a stirrer, reflux condenser with calcium chloride guard tube and a dropping funnel. A solution of VII (154.2 g., 0.79 mole) and benzaldehyde (100 g., 0.94 mole) in dry tetrahydrofuran (100 cc.) was added dropwise to the stirred mixture at such a rate as to maintain gentle refluxing. After the addition was completed (70 minutes), the mixture was refluxed for 30 minutes, cooled and poured into a mixture of acetic acid and ice. The orange oil was removed, the aqueous layer was extracted three times with ether, the extracts were combined with the orange oil and the whole was washed successively with saturated sodium bicarbonate, aqueous potassium iodide, three times with water and dried (magnesium sulfate). The solvent was removed and the residual dark oil was fractionated through a 10″ Vigreux column. The product (60.6 g., 34.4%) boiled at 157–161° (0.2 mm.) and had n^{25}D 1.5900.

Anal. Calcd. for $C_{16}H_{14}O$ (VIII): C, 86.45; H, 6.35. Found: C, 86.73; H, 6.54.

The infrared spectrum of this material showed a medium hydroxyl band at 3430 cm.$^{-1}$, a strong carbonyl band at 1700 cm.$^{-1}$ but no acetylenic band.

Some of the above material (59.2 g.) in acetone (300 cc.) was oxidized by action of a solution of chromic oxide (200 cc., 1 *M* in CrO_3 and 1.5 *M* in H_2SO_4) according to a procedure reported in the literature for similar oxidations.[16] The reaction mixture was poured into water (1 l.), the orange oil was removed and the green aqueous layer was extracted four times with ether, and the extracts were combined with the oil. This solution deposited a solid which was removed; then the solution was washed successively with aqueous sodium carbonate, aqueous potassium iodide, twice with water and dried (magnesium sulfate). The ether was removed by distillation and the residual oil was cooled in a Dry Ice-bath, when it deposited more solid. This was removed and the oil was then fractionated through a spiral wire column; the distillate (11.68 g., 20%) was collected in two fractions: A, b.p. 130–155° (0.05 mm.), n^{25}D 1.6212; B, b.p. 155–175° (0.05 mm.), n^{25}D 1.6153.

Anal. Calcd. for $C_{16}H_{12}O$ (IX): C, 87.24; H, 5.49. Found (fraction A): C, 87.52; H, 5.54; (fraction B), C, 87.05; H, 5.90.

The infrared spectra of these fractions showed a medium hydroxyl band at 3430 cm.$^{-1}$, a medium carbonyl band at 1710 cm.$^{-1}$, a strong carbonyl band at 1680 cm.$^{-1}$ but no significant band in the region typical of an acetylenic linkage. The material gave a 2,4-DNP melting at 126–127°, but this could not be identified and was certainly not a simple derivative of IX.

Anal. Calcd. for $C_{22}H_{16}O_4N_4$ (2,4-DNP of IX): C, 65.99; H, 4.03; N, 13.99. Found: C, 45.68; H, 4.68; N, 22.72.

The solids isolated above were the same substance. After several crystallizations from ethyl acetate, the material melted at 146–147° and gave an oxime which melted at 205–208°. These are the melting points of diphenacyl (144–145°)[17] and its dioxime (203–204°).[18] The substance gave a green solution in sulfuric acid, changing to a reddish brown with blue-green fluorescence when heated, as reported for diphenacyl.

Ten different experiments were conducted in an effort to rearrange the above oils (containing IX?) into the allenic ketone X. Attempts to bring about the rearrangement by action of bases (potassium carbonate, potassium hydroxide, sodium methoxide) patterned after similar work by Jones and his associates[19] with acetylenic acids, or by the chromatographic technique developed by Jacobs and Singer,[8] led in every case to products where infrared spectra were very similar to those of the starting materials and showed no bands in the allenic region.

The Reformatsky reaction between benzaldehyde (246 g.) and III (305 g.) was conducted essentially as described above for the reaction between VII and benzaldehyde. The product, a dark oil, was separated into two fractions by distillation through a 4″-column packed with glass helices. Fraction A (66.3 g., 18%) boiled at 88–106° (1 mm.) and had n^{25}D 1.5238. Fraction B (53 g., 15%) boiled at 106–116° (1 mm.) and had n^{25}D 1.5354.

Anal. Calcd. for $C_{12}H_{14}O$ (XI): C, 82.72; H, 8.10. Found: fraction A, C, 79.47; H, 7.71, fraction B, C, 79.45; H, 8.17.

The infrared spectrum of A had no absorption in the region characteristic of hydroxyl or acetylenic group but did show carbonyl bands, weak at 1710 cm.$^{-1}$, strong at 1675 cm.$^{-1}$. The spectrum of B showed no acetylenic band, but there was a weak hydroxyl band at 3425 cm.$^{-1}$ and a weak carbonyl band at 1710 cm.$^{-1}$. Both fractions gave the same 2,4-DNP melting, after several crystallizations from ethanol, at 141–143°; fraction B also yielded the 2,4-DNP of benzaldehyde, m.p. and mixed m.p. 236–237°.

Anal. Calcd. for $C_{18}H_{18}O_4N_4$ (2,4-DNP of XI): C, 61.01; H, 5.12; N, 15.81. Found: 2,4-DNP from A: C, 59.14; H, 5.64; N, 14.70. 2,4-DNP from B: C, 59.21; H, 5.69; N, 14.52.

Attempts were made to obtain pure XI from fraction B by chromatography using alumina in the column, but the results were indefinite and the infrared spectrum still showed a carbonyl band at 1700 cm.$^{-1}$. Quantitative catalytic hydrogenation of fraction B over Raney nickel at room temperature and atmospheric pressure resulted in uptake of 110% of the theoretical amount for addition of one mole of hydrogen; when platinum oxide was used as the catalyst under the same conditions, the uptake of hydrogen was 119% of the theoretical amount for addition of two moles of hydrogen. Fraction B liberated 0.975 mole of methane from methylmagnesium iodide, showing the presence of one active hydrogen atom per mole (assuming fraction B to consist largely of XI).

Oxidation of fraction B (3 g.) by action of chromic oxide in sulfuric acid, as described above for the oxidation of VIII, gave only 0.26 g. of a pale yellow oil boiling at 100–135° (30 mm.), with n^{25}D 1.5208.

Anal. Calcd. for $C_{12}H_{12}O$ (XII): C, 83.69; H, 7.02. Found: C, 73.57; H, 6.97.

From this oil, the 2,4-DNP of benzaldehyde could be obtained. The infrared spectrum showed weak hydroxyl bands at 3450 and 2240 cm.$^{-1}$, and a strong carbonyl band at 1700 cm.$^{-1}$.

Oxidation of fraction B (5 g.) by action of the pyridine–chromium oxide complex[20] gave a product (1.80 g., 36%) boiling at 70–85° (0.1–0.2 mm.), whose infrared spectrum showed no hydroxyl or acetylenic bands, although there were two strong carbonyl bands at 1700 and 1685 cm.$^{-1}$. This product obviously was not XII.

COMMUNICATIONS TO THE EDITOR

THE METHYL GROUP OF METHIONINE AS A SOURCE OF C_{28} IN ERGOSTEROL[1]

Sir:

It was reported recently that formate can serve as a source of C_{28} in the biosynthesis of ergosterol[2] or of eburicoic acid.[3] We have incubated cell-free yeast homogenates with labelled sodium bicarbonate, formaldehyde, propionate-(1 or 2)-C^{14} and methionine-methyl-C^{14} and have found that more C^{14} is incorporated into the non-saponifiable lipids and the digitonin-precipitable sterols from methionine than from any of the other compounds. Thus, in one experiment 20.2% of the methionine-methyl-C^{14} radioactivity was found in the non-saponifiable fraction, as compared to 1.2% for acetate-1-C^{14}, 1.0% for $NaHCO_3$, 0.4% for formaldehyde and 0.5% for propionate. In comparative experiments with the same yeast homogenate which we ran after the paper of Danielson and Bloch[2] came to our attention, methionine-methyl-C^{14} gave four times as much radioactivity in the digitonin-precipitable sterol fraction as sodium formate-C^{14}.

To determine whether the radioactivity is concentrated in C_{28}, samples of ergosterol from incubations with acetate-1-C^{14} and methionine-methyl-C^{14} were ozonized according to Hanahan and Wakil.[4] Comparison of the figures obtained with ergosterol made from acetate and from methionine by a yeast homogenate (Table I, Expt. 1) shows that in the

TABLE I

DEGRADATION OF ERGOSTEROL-C^{14}

Expt.	Substance	Source of C^{14}, counts/mmole carbon/min. Acetate-1-C^{14}	Methionine-methyl-C^{14}
1[a]	Ergosterol	5,540	3,843
	Steam volatile fraction[c]	6,220	11,480
	Residue from steam distillation		
2[c]	Ergosterol acetate	7,545	655
	α,β-Dimethylbutyraldehyde[b]	...	946
	Acetone[b] ($C_{25,26,27}$)	...	1,044
	C_{28}	...	165
	C_{28}[d]	...	110
		...	3,210

[a] The two samples of ergosterol in Expt. 1 are not directly comparable, since much more C^{14} was used in the case of acetate. [b] Isolated as dinitrophenylhydrazone. [c] All samples counted after combustion to $BaCO_3$, corrected to infinite thickness. [d] Combustion of CHI_3 reportedly gives $BaCO_3$ of low specific activity.[5]

first case the steam-volatile fraction, α, β-dimethyl-butyraldehyde, contains less radioactivity than the residue, representing the ring system. In the second case this relationship is reversed, as expected if the main incorporation of radioactivity were in C_{28}. In experiment 2, the ergosterol, obtained from incubation of whole yeast with methionine-methyl-C^{14}, although recrystallized to constant specific activity, was subsequently found to be impure. However, the dinitrophenylhydrazone of the α,β-dimethyl-butyraldehyde was carefully purified before counting. Further degradation of this aldehyde shows that a predominant portion of the total radioactivity is located in C_{28}. When the correction factor suggested by Ehrensvard, *et al.*,[5] for the combustion of $C^{14}HI_3$ to $BaC^{14}O_3$ is applied, the observed activity of C_{28} is in acceptable agreement with the figure calculated from the specific activity of the α,β-dimethyl-butyraldehyde. Carbon 28 contains 20–30 times the radioactivity of the other carbon atoms in the molecule. Such a randomization of radioactivity was also observed by Dauben, *et al.*, in the incorporation of C^{14} from formic acid into the analogous position in eburicoic acid.[3]

The major incorporation of C^{14} into C_{28} of ergosterol in our experiments may be accounted for by the well-known oxidation of the methyl group of methionine to formate in biological systems.[6] However, transmethylation from sulfur to carbon, which has not been observed up to now, cannot be excluded since we find that aminopterin decreases the incorporation of C^{14} into ergosterol from formate-C^{14} but not from methionine-methyl-C^{14}. Other experiments indicate that squalene, but not zymosterol, is converted to ergosterol in yeast homogenates.

DIFFUSION OF O^{18} AND OF PROTIUM IN D_2O–H_2O MIXTURES[1]

Sir:

We wish to report some interesting and unexpected results obtained in this Laboratory in the course of studies on diffusion in liquid systems.[2]

The data were obtained for 25 ± 0.02° by means of the diaphragm cell technique.[2] Deuterium analyses were made pycnometrically, and those for O^{18} by the gradient tube density method,[3] after first converting the samples of D_2O^{18}-H_2O^{18} to H_2O^{18}. This last was accomplished by vaporizing

a few cc. of the mixture to be analyzed, and passing the vapor over hot copper wire; the resulting CuO^{18} was then converted to water and Cu by reaction with hydrogen gas.

Since the O^{18} data yielded essentially self-diffusion coefficients, these are plotted in the figure as points (reproducibility, ± 2%). The protium diffusion data were treated as giving *integral* diffusion coefficients, and the values are given as lines drawn between the average compositions of the upper and lower compartments of the diffusion cell (reproducibility, ± 4%).

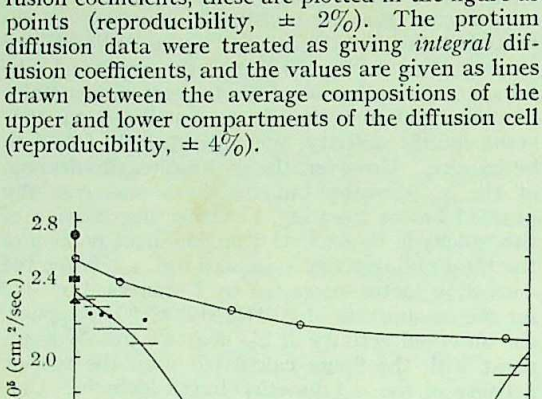

Fig. 1.—Variation of the diffusion coefficient with deuterium enrichment in water mixtures: present work, ○ O^{18} as tracer, — H_2O–D_2O; Longsworth, ●, H_2O–D_2O; Wang, *et al.*, ● O^{18} as tracer, ▲ H_2O–D_2O, ■ H^3 as tracer.

Considering first the region of low D_2O content, there has been a considerable fluctuation in literature values, but our results are in agreement with those of Wang, *et al.*,[4] and of Longsworth,[5] within experimental error. The point of interest, however, is that while the O^{18} diffusion coefficients varied with composition almost exactly as the inverse of the viscosity, the protium diffusion coefficients showed a marked minimum which, if corrected for the viscosity effect, fell at 50% D_2O content.

The explanation for these findings must be that somewhat different mechanisms are available for oxygen than for protium diffusion. For the former, there is the possibility of oxygen exchange between clusters, and for the latter, there is a variety of ways for a similar exchange to occur, since either long or short protium bonds and either a four or a five coördinated transition state may be involved. In any event, the results cannot be explained in terms of the usual assumption that diffusion in water occurs only by motion of individual molecules as units.

Site of Vanadium Inhibition of Cholesterol Biosynthesis

Sir:

Vanadium compounds have been shown to inhibit the incorporation of radioacetate into cholesterol by rat and rabbit liver *in vitro* and *in vivo*.[1,2]

The following compounds have been generally accepted as intermediates in the biosynthesis of cholesterol from acetate: acetoacetate,[3] β-hydroxy-β-methyl glutarate (HMG),[4] β-methyl crotonate (BMC),[5] squalene,[6] lanosterol[7] and zymosterol.[8] Recently β,δ-dihydroxy-β-methyl valeric acid (mevalonic acid)[9] has been proposed as an intermediate because of its extremely efficient rate of conversion to cholesterol. This communication demonstrates that the inhibition by vanadium occurs between the six and five carbon intermediates.

Rat liver slices were incubated for two hours in phosphate buffer[1] containing 10 mg. of sodium acetate-1-C^{14} (1.0 mc./mM.) or 1 mg. of mevalonic acid-2-C^{14} (0.005 mc./mM.).[10] Aliquots of the same batch of slices were used for each experiment. Vanadium in a final concentration of 10^{-4} *M* was added to one flask as diammonium oxytartratovanadate.[10] An equimolar amount of tartrate was added to the control flask. Following incubation of the flasks containing acetate substrate, 30 mg. HMG, 40 mg. BMC, 35 mg. squalene, and 2 mg. of cholesterol were added to each flask as carrier. After saponification in 70% ethanol and 5% potassium hydroxide under nitrogen for one hour, the non-saponifiable fraction was extracted with petroleum ether and from it squalene and cholesterol were isolated by means of an alumina column.[6] The radioactivity of squalene was determined as the hexahydrochloride and cholesterol as the digitonide. The saponifiable fraction was acidified to *p*H 2 with concentrated hydrochloric acid and extracted continuously with ether for 24 hours. The ether was evaporated to dryness and HMG[4] and BMC[5] isolated and their radioactivity determined. Derivatives of each compound retained the calculated amount of radioactivity.

The radioactivity (Table I) of BMC, squalene and cholesterol from acetate as substrate was depressed by vanadium in comparison to the control. The increased radioactivity of HMG in the vanadium inhibited reaction might be expected since it is known that inhibition at any step in a sequence will produce an accumulation of the intermediate just below the inhibition with increased trapping of the radioactive molecules. The radioactivity of cholesterol obtained with mevalonic acid as substrate was also depressed by vanadium. When biosynthetic C^{14}-labeled squalene was employed as

TWO-DIMENSIONAL TRANSITIONS IN ADSORBED MONOLAYERS

Sir:

Because of the obvious interest[1,2] in theoretically-simple adsorption systems which exhibit transitions, we are moved to make this preliminary report on our measurements for krypton adsorbed on sodium bromide, Fig. 1.

Localized adsorption with nearest-neighbor interactions which, in addition to their usual effects, alter the *lateral* frequency $\omega_{||}$ of the adsorbed molecule with increasing coverage θ according to

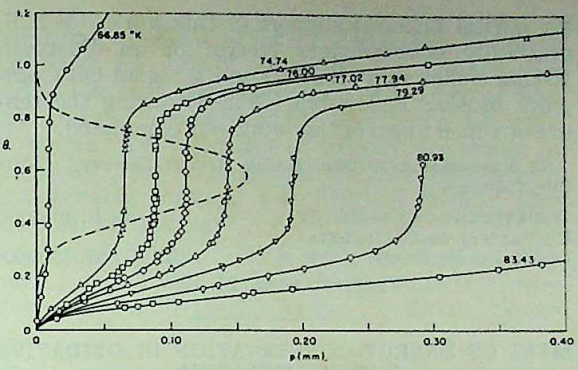

Fig. 1.—Adsorption isotherms of krypton on sodium bromide.

the prescription $\mathrm{d} \ln \omega_{||}^2 / \mathrm{d} \ln \theta = \gamma$ (= 1 for Kr) leads to the isotherm

$$\ln p(1-\theta)/\theta^{1+\gamma} = -\beta(\chi - 2w\theta) + \text{const.} \quad (1)$$

where $\beta = 1/kT$, and χ and w are the energies of adsorption and of lateral interaction as employed by Fowler and Guggenheim.[3] As a result of important but compensating differences, our equation with $\gamma = 1$ is similar to that of Rushbrooke.[4] With $\gamma = 0$ it reduces to the Fowler "crude" theory,[3] and with $w = 0$ in addition, to the Langmuir result.

In Fig. 2 we show how the data of Fig. 1 are rectilinearized according to the prescription of Eq. (1). Evidently the intercepts and slopes may be used

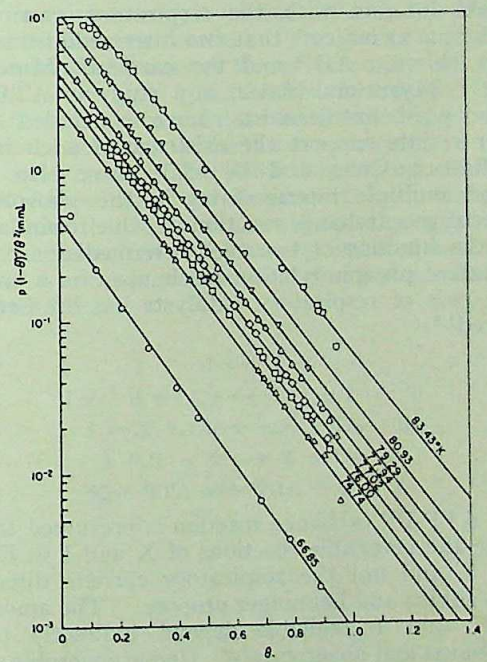

Fig. 2.—Adsorption isotherms of krypton on sodium bromide, plotted according to Eq. (1), $\gamma = 1$.

to evaluate χ and w, both of which are in reasonable agreement with independent theoretical calculations.

SITES OF ENERGY CONSERVATION IN OXIDATIVE PHOSPHORYLATION

Sir:

Direct spectroscopic and kinetic studies of respiratory carriers in mitochondria have led to the conclusion that the *reduced* forms of the carriers, especially DPNH, are involved in the "high energy" complexes which are intermediates in the phosphorylation of ADP.[1] Wadkins and Lehninger reached the opposite conclusion on the basis of an experiment on the effect of aerobiosis and anaerobiosis on the ATP-P_i^{32} exchange reaction.[2] We show here that their interpretation of their experimental result is not unique and actually affords support for the conclusion they seek to refute.

The reaction mechanism for oxidative phosphorylation on which Wadkins and Lehninger based their conclusions ignores spectroscopic studies of the rate with which ADP and uncoupling agents interact with the respiratory carriers.[1,3] Such studies indicate that two intermediates intervene between ADP and the carriers. More recently, Myers and Slater, in a study of ATP-ase activity of mitochondria, have concluded that their results support the existence of such intermediates.[4] Cohn and Drysdale have also proposed multiple intermediates in the phosphorus and oxygen exchange reactions.[5] One formulation for the function of two such intermediates in the oxidative phosphorylation mechanism for a particular pair of respiratory catalysts has been represented[1,6]

$$b^{\cdot\cdot\cdot} + I \longleftrightarrow b^{\cdot\cdot\cdot} \cdot I \quad (1)$$

$$b^{\cdot\cdot\cdot} \cdot I + c^{\cdot\cdot} \longrightarrow c^{\cdot\cdot\cdot} + b^{\cdot} \sim I \quad (2)$$

$$b^{\cdot} \sim I + X \longrightarrow b^{\cdot} + X \sim I \quad (3)$$

$$X \sim I + P \longleftrightarrow X \sim P + I \quad (4)$$

$$X \sim P + ADP \longleftrightarrow ATP + X \quad (5)$$

The ATP-P^{32} exchange reaction is presumed to involve the reversible reactions of X and I in Eq. 4 and 5, and not the respiratory carriers directly, as Wadkins and Lehninger propose. The amounts of X and I available depend indirectly upon aerobiosis and anaerobiosis. Under anaerobic conditions X and I can be bound as $X \sim I$ and $b^{\cdot\cdot} \sim I$, and the exchange will be slow. Under aerobic conditions in the absence of substrate, less binding occurs and the concentrations of X and I are higher, and the exchange will proceed at high ATP concentrations, just as has been found in Wadkins and Lehninger's Table I.[2] If, on the other hand, we assume, as Wadkins and Lehninger assume, that the oxidized form of the respiratory enzyme is the high-energy carrier, we find that binding of X and I as $X \sim I$ and $b^{\cdot\cdot\cdot} \sim I$ is maximal under aerobic conditions and minimal under anaerobic conditions. This leads to the conclusion that the exchange reaction should have gone more rapidly under anaerobic conditions than under aerobic conditions which it did not do.

It now may be concluded that Wadkins and Lehninger's data on the 10-fold acceleration of the ATP-P_i^{32} exchange reaction under aerobic conditions support our earlier conclusions: (a) that the reduced forms of the respiratory pigments represent the carriers of the "high-energy" complex and (b) that intermediates exist between the respiratory carriers and ADP.

The ATP-P_i^{32} exchange reaction is at present poorly understood and may not yet provide a substantial basis for proof of any further hypothesis; the reaction is slow in the digitonin preparation, requires high ATP concentrations, and is affected by added ADP at concentrations outside the range of that needed for maximal rate of electron transfer.[7] However, Wadkins and Lehninger's data appear to provide additional evidence that the "high-energy" complex involves the reduced carrier. In their Table I, they find that the incorporation of P_i^{32} into ADP to form ATP^{32} gives over 67 times as much incorporation when the carriers are reduced than when they are oxidized. Since the mitochondria are stated to be anaerobic, this phosphorylation is attributed to the presence of the "high-energy" complexes of the reduced carriers.

Thus the data of Wadkins and Lehninger support in two ways our conclusion[1] that the reduced form of the respiratory carrier serves as the site of the "high-energy" complex. The transition from oxidized to reduced carriers gives first a one-tenth as rapid catalysis of the ATP-P_i^{32} exchange reaction caused by a binding of the reaction intermediates X and I by the reduced carriers and, second, a 67-fold greater anaerobic phosphorylation of ADP caused by "high energy" compounds of the reduced carriers.

June 5, 1957

medium made of equal volumes of 0.2 *M* phosphate buffer *p*H 7.2 and 1.15% KCl. The homogenate was centrifuged in the Spinco ultracentrifuge at 60,000 × *g* for 30 minutes. The enzyme system contained in the supernatant fluid was salted out by the careful addition of solid ammonium sulfate at 0° (56 g. per 100 ml. initial volume) and was redissolved in 0.05 *M* phosphate buffer of *p*H 7.2. The assay for enzymatic activity was carried out in test tubes by incubating an aliquot of the enzyme solution with inositol. At the end of the incubation the tubes were heated for 2 minutes at 100° and the protein-free filtrate was assayed for glucuronic acid using the orcinol method of Mejbaum.[1] Table I summarizes a typical experiment. When inositol was omitted from the incubation mixture or when the enzyme solution was heat-

TABLE I

RATE OF FORMATION OF GLUCURONIC FROM INOSITOL

The reaction mixture contained 0.2 ml. of 1 *M* phosphate buffer *p*H 7.2, 0.2 ml. of 0.5 *M* inositol, 0.15 ml. of enzyme solution and distilled water to a final volume of 2 ml.; gas phase oxygen, incubation at 34°.

Time of incubation (minutes)	5	10	15	20	30	40
Glucuronic acid (γ)	50	75	101	118	147	160

inactivated prior to its use the amount of orcinol-reacting substances was 3–5% of that formed in the complete system.

In a large scale experiment in which 15 ml. of enzyme solution was used, 78.3 mg. of glucuronic acid was formed representing a 10% conversion of the added inositol. The glucuronic acid was isolated by column chromatography on Dowex-1 X10 (acetate form) using 0.4 *N* acetic acid as the eluting solvent and was identified by paper chromatography using the solvent systems: pyridine–ethyl acetate–acetic acid–water,[2] ethanol–water (88:12), acetone–water (80:20), *n*-butanol–acetic acid–water (100:21:50), and ethanol–acetic acid–water (80:10:10). The spots were revealed by spraying the paper with aniline oxalate and heating at 100° for 5 minutes. In all cases the isolated uronic acid migrated in a manner indistinguishable from authentic glucuronic acid and was resolved from guluronic, galacturonic, mannuronic, idur-onic, 2-ketogluconic, 5-ketogluconic, and ascorbic acid, as well as from the corresponding lactones of the above uronic acids.

The sodium salt of the isolated uronic acid was crystallized from ethanol (*Anal.* Calcd. for $C_6H_9O_7Na \cdot H_2O$: C, 30.77; H, 4.70. Found: C, 30.86; H, 4.74). The free acid has a m.p. of 162–163°, while the lactone had a m.p. of 176–178°. The brucine salt of the isolated uronic acid had a m.p. of 162–165°.

The isolated glucuronic acid as well as its lactone were optically inactive, indicating that it is a racemic mixture. *Escherichia coli* (Strain B) adapted on D-glucuronic acid utilized approximately half of a known amount of the isolated uronic acid. The remaining half was recovered from the culture medium and its specific rotation at equilibrium was found to be $[\alpha]^{24}D$ −33.3° (*c* 0.48 in H_2O, *1 l* dm.) compared to −36.0° expected for L-glucuronic acid. The enzymatic formation of glucuronic acid from inositol occurs with the simultaneous uptake of oxygen (1–1.2 μmoles of oxygen per μmole of glucuronic acid formed) and the disappearance of an equivalent amount (± 10%) of inositol (determined by bioassay[3]).

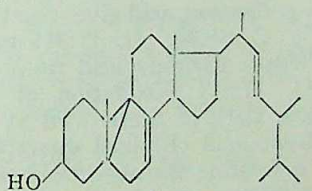
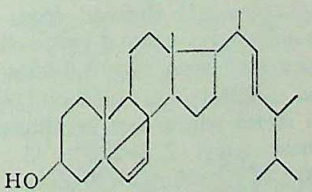
THE STRUCTURE OF PHOTOISOPYROCALCIFEROL[1]

Sir:

Recent studies by Velluz, Havinga and their associates[2] have established that the first step in the ultraviolet irradiation of ergosterol (9α-H, 10β-CH_3, 9,10-*anti*) is a bond cleavage reaction with the formation of a 9,10-*seco*-sterol type of intermediate. On the other hand, Dimroth and Windaus[3] have shown that a similar irradiation of the 9,10-*syn* epimer, isopyrocalciferol (9β-H, 10β-CH_3), is a bond forming reaction. The product, photoisopyrocalciferol, showed the presence of only two double bonds (on quantitative hydrogenation), showed no maximum in the ultraviolet spectrum and upon oxidation yielded a non-conjugated unsaturated ketone. The photo isomer, upon heating, was reconverted to the starting homoannular diene. On the basis of these data, the following two structures (I and II) were postulated and the present work has established the correctness of structure II.



I



II

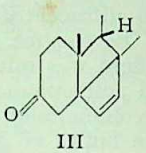
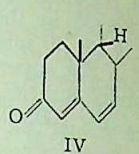
Photoisopyrocalciferol displays bands in the infrared at 970 and 748 cm.$^{-1}$, characteristic of *trans*- and *cis*-symmetrically disubstituted olefins, respectively, and the nuclear magnetic resonance spectrum shows vinyl proton bands at 0 and −1.0 (doublet) p.p.m.[4] The former band is characteristic of the 22-ene structure and thus the latter must be assigned to the remaining nuclear double bond. The large negative displacement is similar to that found for the vinyl proton in cyclobutene (−0.72 p.p.m.).[5] Upon oxidation, the photo compound is converted into a crystalline non-conjugated unsaturated ketone (m.p. 80–81°; C, 85.36; H, 10.62; $\lambda_{max.}$ 1705 cm.$^{-1}$; ϵ_{205} 2350, no. max. at higher wave length) which upon reduction by lithium aluminum hydride is converted to the starting alcohol. Upon ozonization of the acetate, there is obtained a tricarboxylic acid (m.p. 273–275°, C, 64.12; H, 7.51, neut. equiv. 157) which is readily transformed into a cyclic anhydride-carboxylic acid (m.p. 243–244°, C, 66.78; H, 7.62; $\lambda_{max.}$ 1770 and 1825 cm.$^{-1}$). The photo compound can be hydrogenated, stepwise, to yield a dihydro (m.p. 58–59°; C, 84.46; H, 11.58) and a tetrahydro alcohol (m.p. 51.0–52.5°; C, 84.02; H, 12.01); the nuclear double bond is attacked first. All of the foregoing compounds are stable to hydrogen chloride in chloroform solution.[6] These data clearly establish the presence of olefinic linkages at C_6,C_7 and C_{22},C_{23} and they also indicate the presence of a cyclobutene ring and the absence of a cyclopropane structure.

The tetrahydro alcohol upon oxidation with CrO_3 in acetic acid at 0° yields a ketone (m.p. 47.0–48.5°; C, 84.51; H, 11.47; $\lambda_{max.}$ 1705 cm.$^{-1}$; ϵ_{205} 680) whose infrared and ultraviolet spectra are normal for a saturated, isolated ketone. Either the tetrahydro alcohol or ketone upon oxidation with CrO_3 in acetic acid at 70°, followed by esterification with diazomethane, yields a diester (m.p. 65.0–66.5°; C, 77.68; H, 8.47; sapon. equiv., 229), showing the presence of at least one adjacent methylene group. The tetrahydro ketone upon reaction with perbenzoic acid gives rise to a lactone (m.p. 71–73°; C, 81.30; H, 11.31) which when saponified yields a hydroxy acid (m.p. 172–173°; C, 77.59; H, 11.01). Oxidation of the latter compound with CrO_3 in acetic acid at 60° forms the same dibasic acid obtained directly from the ketone, thus indicating the absence of substituents α to the carbonyl group.[7]

When the ketone III derived from the photo compound is allowed to stand with alcoholic alkali, it is converted into oily 4,6-dien-3-one, IV, ($\lambda_{max.}^{EtOH}$ 283 mμ, ϵ 21,00; $\lambda_{max.}$ 1650 cm.$^{-1}$) of the isopyrocalciferol series which can be characterized as a semicarbazone (m.p. 221–223°; C, 77.21; H, 10.12; N, 9.47; $\lambda_{max.}^{EtOH}$ 305 mμ, ϵ 38,500). The same compounds also can be prepared directly from isopyrocalciferol by oxidation followed by base and acid isomerization.



III



IV

Finally, the photo compound II upon heating to 160° in EtOD is reconverted into isopyrocalciferol which is devoid of deuterium. The above facts are only consistent with the valence tautomeric structure II for photoisopyrocalciferol.

Photopyrocalciferol also has been subjected to a similar sequence of reactions and shown to possess an analogous-type structure, different only in the stereochemistry at C_9-C_{10}. This formation of the valence tautomeric structures from 9,10-*syn* structures calls attention to the importance of stereochemistry in the irradiation of 5,7-dienes.

KINETIC ISOTOPE EFFECT IN THE IODINATION OF 2,4,6-TRIDEUTEROPHENOL

Sir:

The bromination of benzene and bromobenzene, and of their tritiated analogs as catalyzed by iodine proceeds without preferential displacement of hydrogen over tritium[1]; likewise bromination of benzene and hexadeuterobenzene by hypobromous acid with an acid catalyst proceeds at identical rates for these two compounds under similar reaction conditions.[2] Similarly no kinetic isotope effect has been found for nitration[1,3] of benzene, toluene, bromobenzene, naphthalene, or nitrobenzene containing tritium or deuterium nor for azo coupling with 1-naphthol-4-sulfonic acid.[4] The conclusion can be drawn that the breaking of the C–H bond has not made much progress in the transition state of the slow step of these electrophilic substitutions and, with less certainty,[5] that an intermediate[6] ArH·E, is formed during this slow step with electrophilic reagent E with loss of the proton occurring in a subsequent fast step.

While the above examples appear to be the only cases in which it has been proven that loss of the proton is kinetically insignificant during electrophilic aromatic substitution, it has been tempting to apply this generalization to other cases. In particular Painter and Soper[7] and Berliner[8] have implicitly or explicitly made this assumption in

their interpretation of the kinetics of the iodination of phenol by solutions of iodine-triiodide ion in water. They concluded that the mechanism of the reaction probably involved attack of I^+ (or H_2OI^+) and acyl hypoiodite (or catalysis of HOI by a general acid HA) upon phenoxide ion. Grovenstein and Henderson[9] have pointed out that the kinetic results available do not exclude a rapid and reversible attack of iodine molecule upon phenoxide ion followed by a slow loss of proton to the solvent or to a general base A^- conjugate to the buffer acid HA.

In order to elucidate further the mechanism of the iodination of phenol, 2,4,6-trideuterophenol was prepared after the general procedure of Ingold[10] and co-workers. After two equilibrations of phenol with heavy water, a product which is estimated to be at least 99% 2,4,6-trideuterophenol was obtained. This phenol undergoes iodination at one fourth the rate of ordinary phenol. Thus in a typical experiment at 25° at initial concentrations of 0.0080 M in phenol and 0.00196 M in iodine, in aqueous solvent which was 0.500 M in acetic acid, 0.050 M in sodium acetate, 0.230 M in sodium perchlorate, and 0.020 M in sodium iodide, the initial apparent second order rate constants (calculated in terms of stoichiometric concentrations of phenol and iodine) were 1.21×10^{-3} l. mole^{-1} sec.$^{-1}$ for ordinary phenol and 3.05×10^{-4} l. mole^{-1} sec.$^{-1}$ for 2,4,6-trideuterophenol. These data give k_H/k_D 3.97. In related runs but in dilute perchloric acid in place of the acetate buffer, isotope effects of similar magnitude were obtained.

The present case, as far as we are aware, constitutes the first example of a hydrogen isotope effect during electrophilic aromatic halogenation. The only other known cases of hydrogen isotope effects during electrophilic aromatic substitution seem to be sulfonation[1,11] (k_H/k_T = 1.8), cyclodehydration[12] of 2-anilino-pent-2-ene-4-one (k_H/k_D = 1.5), and the reactions[4] of some diazonium ions upon hindered 2-naphthol-6,8-disulfonic acid (k_H/k_D = 3.6–6.6). Our present example shows that a phenol need not necessarily be hindered to give an isotope effect. We think it is significant that for the four types of electrophilic substitution reactions for which hydrogen isotope effects are known, three, including the present, involve reactions of phenols or aromatic amines. These are just the types of compounds which would be expected to give the most stable reactive intermediates, thus (I) for iodination of phenol. Substances analogous to (I)

(I)

have indeed been isolated from reactions of 2,4,6-trisubstituted phenols.[13] General evidence, therefore, favors (I) as an intermediate in the iodination of phenol. On this basis, in order to account for both the kinetic evidence and isotope effect, intermediate (I) must, under the kinetic conditions which have been studied,[7,8] be transformed back to reactants considerably faster than into the final products, *i.e.*, (I) must be essentially at equilibrium with the reactants. From such kinetic data, therefore, the nature of the iodinating agent for phenol *cannot be specified.* We hope to be able to find conditions in which intermediates such as (I) from phenols are formed in the rate-determining step; only under such conditions, at best, can the nature of the iodinating agent be ascertained by reaction kinetics. Meanwhile we are investigating the generality of isotope effects during electrophilic halogenation of phenols and related compounds.

GEORGIA INSTITUTE OF TECHNOLOGY
ATLANTA, GEORGIA DONALD C. KILBY

RECEIVED APRIL 24, 1957

DETECTION OF FREE RADICAL INTERMEDIATES IN THE ACTION OF OXIDATION INHIBITORS

Sir:

Aromatic amines and phenolic compounds which inhibit oxidation have been presumed to act through the removal of hydrogen from the hydroxyl or amino group:

$$\mathrm{ArXH} + \mathrm{RO_2}\cdot \longrightarrow \mathrm{ArX}\cdot + \mathrm{RO_2H}$$
$$(\mathrm{ArX}\cdot \xrightarrow{k_1} \text{inactive products}) \qquad (1)$$

Recent investigations have brought alternative proposals for the terminating reaction involving these inhibitors. Kooyman and Bickel[1] now suggest two consecutive reactions, both of which terminate oxidation chains

$$\mathrm{ArXH} + \mathrm{RO_2}\cdot \longrightarrow \mathrm{ArX}\cdot + \mathrm{RO_2H}\ k_{1a} \qquad (1a)$$
$$\mathrm{ArX}\cdot + \mathrm{RO_2}\cdot \longrightarrow \text{Stable product}\ k'_{1a} \qquad (1'a)$$

In (1′a) the product is either an adduct or the result of a second hydrogen abstraction.

Boozer, Hammond, *et al.*,[2,3] suggest two consecutive reactions

$$\mathrm{RO_2}\cdot + \mathrm{ArXH} \rightleftharpoons (\mathrm{RO_2ArXH})\cdot K_{1b} \qquad (1b)$$
$$(\mathrm{RO_2ArXH})\cdot + \mathrm{RO_2}\cdot \longrightarrow \text{inactive products},\ k'_{1b} \qquad (1'b)$$

the first of which is reversible and leads to an equilibrium concentration of a radical complex.

Kinetic analysis of the course of an oxidation inhibition period, when the inhibitor acts by the Kooyman and Bickel processes, gives

$$[\mathrm{ArX}\cdot] = \frac{1}{k_c - 1}[\mathrm{ArXH}]\left\{1 - \left(\frac{[\mathrm{ArXH}]}{[\mathrm{ArXH}]_0}\right)^{k_c - 1}\right\} \qquad (2)$$

for the concentration of the intermediate radical, where $[\mathrm{ArXH}]_0$ is the concentration of inhibitor

at the beginning of the inhibition period and $k_c = k'_{1a}/k_{1a}$.[4]

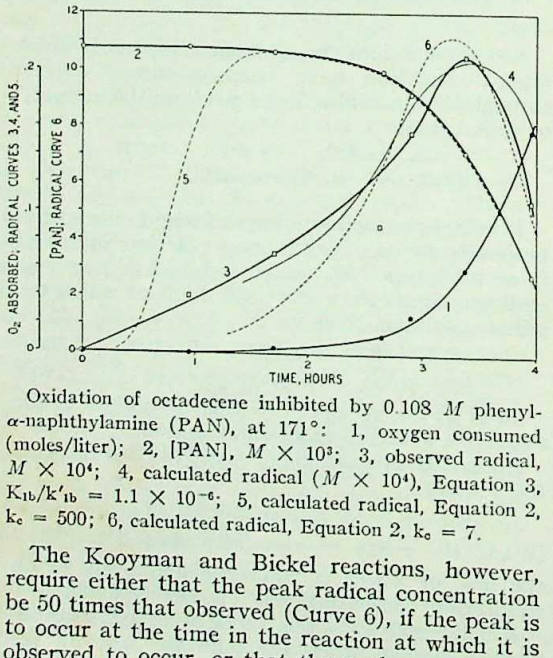
The Boozer and Hammond inhibition processes give

$$[(RO_2ArXH)\cdot] = \left(\frac{K_{1b}}{k'_{1b}}\right)^{1/2} [ArXH]^{1/2} (k_i + k_4[RO_2H])^{1/2} \quad (3)$$

during the inhibition period, where $(k_i + k_4[RO_2H]) = -d[ArXH]/dt$.

We have followed the concentration of a radical formed during the oxidation at 171° of octadecene, inhibited with phenyl-α-naphthylamine (PAN) at 0.0108 M initial concentration. The radical concentration was determined by electron paramagnetic resonance measurements[5] made upon samples withdrawn during the course of the oxidation reaction and immediately frozen in liquid nitrogen. The half-life of the radicals at 25° was estimated to be about 30 hours. No radicals were detected in the unoxidized sample, in the inhibitor by itself, or in octadecene oxidized in the absence of inhibitor.

The results of our measurements are shown in the accompanying figure. The radical concentrations observed during the course of the reaction agree approximately with those predicted by the Boozer and Hammond reactions (Equation 2) for $K_{1b}/k'_{1b} = 1.1 \times 10^{-6}$ hour.



Oxidation of octadecene inhibited by 0.108 M phenyl-α-naphthylamine (PAN), at 171°: 1, oxygen consumed (moles/liter); 2, [PAN], $M \times 10^3$; 3, observed radical, $M \times 10^4$; 4, calculated radical ($M \times 10^4$), Equation 3, $K_{1b}/k'_{1b} = 1.1 \times 10^{-6}$; 5, calculated radical, Equation 2, $k_c = 500$; 6, calculated radical, Equation 2, $k_c = 7$.

The Kooyman and Bickel reactions, however, require either that the peak radical concentration be 50 times that observed (Curve 6), if the peak is to occur at the time in the reaction at which it is observed to occur, or that the peak occurs much earlier in the reaction and that the shape of the curve (Curve 5) be quite different from that observed, if the observed peak radical concentration is to be matched.

The great stability of the radical at room temperature argues somewhat against the Boozer and Hammond mechanism, because if the radical is formed reversibly, radical decay by $RO_2\cdot + RO_2\cdot$ is possible.

The inhibitor decay curve measured by a fluorescence method and the oxygen absorption curve are acceptable by both mechanisms.

Reaction (1) can also provide the radical concentrations observed if it is assumed that the radical product is destroyed rapidly by some oxidation product, perhaps peroxide, which rises to high concentration near the end of the inhibition period.

Attempts were made to measure concentrations of radicals formed during inhibition periods in octadecene at 171° where the inhibitors were 4-amino-3-pentadecylphenol, di-*t*-butyl-*p*-cresol, and *t*-butylcatechol. No radicals were found. The experiments are being continued at lower temperatures in the hope that increased radical stability will permit detection.

We are indebted to Dr. R. H. Sands and to Varian Associates of Palo Alto, California, for the electron paramagnetic resonance measurements.

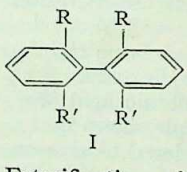
THE ABSOLUTE CONFIGURATION OF 6,6′-DINITRO-2,2′-DIPHENIC ACID AND 6,6′-DIMETHYL-2,2′-BIPHENYLDIAMINE

Sir:

Kuhn and Rometsch have assigned[1] the R-configuration to (−)-Ia as a result of calculations based on a theoretical model.[2] We have now obtained evidence directly at variance with the above conclusion.



I

Ia, R = CH_3, R′ = NH_2
b, R = COOH, R′ = NO_2
c, R = $COOCH_3$, R′ = NO_2
d, R = CH_2OH, R′ = NO_2
e, R = CH_2Br, R′ = NO_2
f, R = CH_3, R′ = NO_2

Esterification of (−)-Ib[3] (m.p. 230–233°, $[\alpha]^{23}D$ −125° (MeOH)) gave (−)-Ic (m.p. 141–142°, $[\alpha]^{28}D$ −113° (EtOAc)); found: C, 53.6; H, 3.2, N, 8.2), which was reduced to (−)-Id (m.p. 120–121°, $[\alpha]^{20}D$ −65° (EtOAc)); found: C, 55.5; H, 3.7; N, 9.1) with $LiAlH_4$–$AlCl_3$. Conversion to (−)-Ie (m.p. 172–173°, $[\alpha]^{32}D$ −8.9 (THF); found: C, 39.3; H, 2.1; N, 6.7) was followed by ring-closure to the iminonitrile (m.p. 295–300° dec., $[\alpha]^{28}D$ +837° (pyridine); found: C, 60.1; H, 3.7; N, 17.4). Hydrolysis gave DNDBCH-6-one[4] (m.p. 227–229°, $[\alpha]^{25}D$ +218° (EtOAc); found: C, 61.0; H, 3.8; N, 9.5). Since (+)-DNDBCH-6-one has the S-configuration,[4] the absolute configuration of (−)-Ib is thus established. Ib is of historical interest: it is the first compound[5] known to owe its optical activity to restricted rotation about a single bond.

June 5, 1957

Reduction of (−)-Ie with $NaBH_4$-$AlCl_3$ to (−)-If (m.p. 95–97°, $[\alpha]^{27}D$ −25° (EtOH); found: C, 62.0; H, 4.2; N, 10.3), followed by hydrogenation over Pd/C, afforded (−)-Ia (m.p. 153–158°, $[\alpha]^{25}D$ −49° (EtOH)). The melting point, 232–233°, of the diacetamide, $[\alpha]^{30}D$ +134° (EtOH), was undepressed by admixture of authentic[6] diacetamide, m.p. 233–235°, $[\alpha]^{26}D$ +128° (EtOH), prepared from authentic[6] (−)-Ia, m.p. 156–158°, $[\alpha]^{24}D$ −47° (EtOH), +34° (*N* HCl).[7]

(−)-Ia and (+)-DNDBCH-6-one have thus been correlated *via* (−)-Ie; (−)-Ia therefore[4] has the S-configuration. It would appear that the assumptions underlying the theoretical treatment[1,2] deserve re-examination.

The absolute configurations of the many common hindered biphenyls related[8] to Ia and Ib will be listed in future publications.

LEWIS ACID CHARACTER OF TELLURIUM HEXAFLUORIDE

Sir:

In a previous communication,[1] the formation of fluorotellurate salts from tellurium hexafluoride and certain alkali metal fluorides was described. We have now found that tellurium hexafluoride will react exothermally with tertiary amines to form stable adducts of the composition $TeF_6 \cdot 2R_3N$. Analysis of the n-m-r data suggests that geometrical isomers are present in solutions of the trimethylamine complex.

Trimethyl- and triethylamines were added to tellurium hexafluoride in a vacuum system. The trimethylamine adduct was a white solid, but the ethyl analog had a dark color that apparently was due to minor secondary reactions. The pressure–volume relationships indicated a stoichiometry of two molecules of amine for one of the hexafluoride and analysis of the trimethylamine complex confirmed the indicated composition (*Anal.* Calcd. for $TeF_6 \cdot 2N(CH_3)_3$: C, 20.0; H, 5.04; F, 31.7. Found: C, 19.56; H, 5.10; F, 29.14). Pyridine formed a complex that was highly dissociated at 25°, but amides, ethers and nitriles did not absorb tellurium hexafluoride at this temperature. This low acceptor strength and the previously cited[1] low stability of fluorotellurate salts indicate that tellurium hexafluoride is a relatively weak Lewis acid.

The F^{19} magnetic resonance spectrum of the molten trimethylamine adduct showed only one sharp peak; amine exchange through simple dissociation of the complex was therefore indicated. A dimethylformamide solution of the trimethylamine adduct gave a single broad resonance at 25°, and at higher temperatures, the peak sharpened and shifted in the direction of the tellurium hexafluoride resonance. The amide solution was cooled to a glass that at ∼ −180° displayed three broad resonances of approximate intensities 1:1:0.4. On warming above −180°, these three peaks broadened rapidly (but at different rates) and finally merged into a single peak. It should be noted that the weak doublet due to spin–spin coupling of fluorine with the Te^{125} isotope persisted at 25° (masked at low temperatures by the broad resonances), and therefore no fluorine exchange was taking place in this system.

The n-m-r data are consistent with the behavior of an octacovalent complex which has geometrical isomers and which undergoes amine exchange through simple dissociation of the complex. At ∼ −180°, the three fluorine resonances may be ascribed to the three possible isomers. On steric grounds, the two peaks of relative intensity 1 probably arise from the 1,8- and 1,3-isomers, and the peak of relative intensity 0.4 from the 1,2-isomer. Above ∼−180°, slight dissociation of the complexes leads to amine exchange and this occurs at different rates for the three isomers. At higher temperatures the three isomers are indistinguishable in the n-m-r spectrum because of fast amine exchange. At temperatures above 25°, the complex is highly dissociated in solution and the position of resonance is a measure of the equilibrium constant for the dissociation. Without supporting data, these conclusions cannot be considered rigorously established. Unfortunately, the rapid amine exchange will not permit isolation of the postulated isomers by conventional techniques.

A CRYSTALLIZABLE ORGANOMETALLIC COMPLEX CONTAINING TITANIUM AND ALUMINUM

Sir:

Following our previous researches[1] concerning the nature of the catalytic agent promoting the α-olefins polymerization, we have isolated a crystallizable compound containing titanium, aluminum and organometallic bonds, which causes the polymerization of ethylene.

By treating 0.01 mole of bis-(cyclopentadienyl)-titanium dichloride[2] suspended in 50 ml. of *n*-heptane with 0.025 mole of triethylaluminum at 70°, in the absence of air and of moisture, a slow gas evolution takes place, the titanium compound is dissolved and the solution becomes dark blue. By cooling the solution at −50°, a blue crystalline solid has been obtained in good yield.

The macroscopic blue needles of the compound, recrystallized four times from *n*-heptane, melt at 126–130° without appreciable decomposition.

Digitized by Arya Samaj Foundation Chennai and eGangotri

The blue compound contains titanium, aluminum, chlorine and organic groups; from the elementary quantitative analysis a ratio Ti:Al:Cl = 1:1:2 has been found.

The values 331 and 339 have been calculated for the molecular weight of the blue compound from two different cryoscopic measurements in benzene.

By treating the blue product with 2-ethylhexanol, ethane is evolved; a quantitative gas volumetric determination shows that two moles of ethane are evolved per mole of compound.

By treating the product with anhydrous hydrochloric acid in ether solution bis-(cyclopentadienyl)-titanium dichloride is formed in almost quantitative yield (more than 90%).

The analytical data and the chemical behavior agree very well with a formula $(C_5H_5)_2TiCl_2Al(C_2H_5)_2$, as shown in the table for $(C_5H_5)_2TiCl_2Al(C_2H_5)_2$

	Calcd.	Found	
Cl, %	21.22	21.02[3]	20.78[4]
Al, %	8.073	7.92	7.90[3]
Ti, %	14.33	14.34	14.55[3]
$-C_2H_5$, %	17.40	16.07	17.67[5]
Mol. weight	334	331	339[6]

It seems probable that, in the complex, both C_5H_5- groups are bound to the titanium atom and that both C_2H_5- groups are bound to the aluminum atom.

By polymerizing ethylene in heptane solution in the presence of 0.6 g. of the Ti–Al complex at 40 atm. and 95° after a reaction time of 20 hours, 8.4 g. of white polymer has been obtained, which has been fractionated by boiling solvent extraction (acetone extractable fraction 10.1%; ether extractable fraction 1.8%, carbon tetrachloride extractable fraction 17.20%, residue 70.9% having intrinsic viscosity in tetralin at 135° = 1.55 × 100 ml./g.).

As it is reported in the next table, $(C_5H_5)_2TiCl_2$ alone is completely inactive for the ethylene polymerization; $Al(C_2H_5)_3$, accordingly with previously published data,[7] does not give solid polyethylene in the reaction conditions, but only low molecular weight oily polymers. Comparative experiments were carried out at 95° and 40 atm.

Soluble catalyst Type	Moles	Solvent Type	Cc.	Reaction time, hours	Crystalline polyethylene, g.	Oily polymers, g.
$(C_5H_5)_2TiCl_2$	0.005	Benzene	100	20	0	0
$Al(C_2H_5)_3$	.05	*n*-Heptane	300	8	0	11.07[a]
$(C_5H_5)_2TiCl_2$-$Al(C_2H_5)_2$	.003	*n*-Heptane	40	8	7	0.4

[a] 66% of the product consists of hydrocarbons lower than decane.

(3) Decomposition of the complex by H_2SO_4 5%; titanium has been determined as titanium cupferrate, aluminum as 8-oxyquinolinate, chlorine by gravimetric determination (I. Ubaldini and F. Capizzi, *Chimica e Industria*, **37**, 779 (1955)).

(4 Decomposition of the complex by Na_2O_2; chlorine has been determined by the Volhard titration.

(5) By gas volumetric determination.

(6) By cryoscopic determination in benzene solution.

(7) G. Natta, P. Pino, and M. Farina, *Supplemento Ric. Scient.*, **25**, 120 (1955).

Although the complex is a catalyst for the ethylene polymerization, less active than the catalyst prepared from $TiCl_4$ and $Al(C_2H_5)_3$, the composition of the complex strongly supports the hypothesis that the Ziegler type catalysts[8] for the polymerization of ethylene are, generally, bimetallic complexes containing organometallic bonds.

A NOVEL REARRANGEMENT IN THE 5-NITRONORBORNENE SERIES

Sir:

The failure of salts of 5-nitronorbornenes (Ia, R = H[1]; Ib, R = CH_3[2]; Ic, R = C_6H_5[3,4]; shown in the aci form) to undergo the Nef reaction[5] has been attributed[6] to homoallylic[7] resonance stabilization (I ⟷ II) of the aci forms. We find, however, that, although a ketone is not obtained, Ia does yield a nitrogen-containing transformation product under Nef reaction conditions.

Addition of an ice-cold aqueous methanolic slurry of the sodium salt of Ia to 8.5% (by wt.) hydrochloric acid at −20 to −10° gave in 30–37% yields a rearrangement product (VI), m.p. 104.5–106.5°, isomeric with 5-nitronorbornene. *Anal.* Calcd. for $C_7H_9NO_2$ (139.15): C, 60.42; H, 6.52; N, 10.07. Found: C, 60.71; H, 6.63; N, 10.04; mol. wt. (Rast) 150. γ_{NH} 3380, 3150; $\gamma_{C=O}$ 1667; $\gamma_{C=C-H}$ 3040; $\gamma_{C=C}$ 1616 (shoulder) cm.$^{-1}$ in $CHCl_3$. As is true with hydroxamic esters,[8] VI and VII do not give a color test with ferric chloride and are weakly acidic; they can be extracted with ether from 10% sodium bicarbonate solution but not from 20% sodium hydroxide; they are regenerated upon acidification.

Hydrogenation of pure VI over platinic oxide at 2 atm. consumed 1.00 mole of hydrogen and gave in 96% yield a dihydro derivative (VII), m.p. 43–46°, $n^{25}D$ 1.5065 (on the supercooled liquid). *Anal.* Calcd. for $C_7H_{11}NO_2$: C, 59.55; H, 7.85; N, 9.93. Found: C, 59.41; H, 7.79; N, 9.68. γ_{NH} 3180; $\gamma_{C=O}$ 1668 cm.$^{-1}$. Dichromate oxidation of VII and VIII gave glutaric acid.

Hydrogenation of VI over Raney nickel catalyst at 2 atm. (92% yield) or reduction of VII with iron powder and aqueous ethanolic ammonium chloride solution[9] yielded a tetrahydro derivative

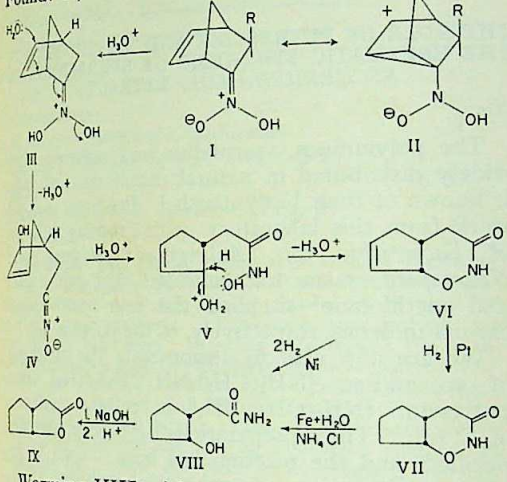
(VIII) of VI, m.p. 95.5–96°. *Anal.* Calcd. for $C_7H_{13}NO_2$ (143.18): C, 58.72; H, 9.15; N, 9.78. Found: C, 58.79; H, 8.98; N, 9.86; mol. wt. (Rast) 139; γ_{OH} 3500; γ_{NH} 3390, 1589; $\gamma_{C=O}$ 1668 in $CHCl_3$. VIII evolved a gas on treatment with nitrous acid. When warmed with 20% sodium hydroxide solution VIII evolved ammonia; under Schotten–Baumann conditions it yielded benzamide. Phenylurethan of VIII, m.p. 151.5–153.5°. *Anal.* Calcd. for $C_{14}H_{18}N_2O_3$: N, 10.68. Found: N, 10.67.



Warming VIII with 10–20% sodium hydroxide solution, followed by acidification, gave the known[10–13] lactone IX, b.p. 69° (0.5 mm.), $n^{25}D$ 1.4727, m.p. −13.5° to −12°. *Anal.* Calcd. for $C_7H_{10}O_2$ (126.15): C, 66.64; H, 7.99. Found: C, 66.54; H, 7.67; mol. wt. (Rast) 144; $\gamma_{C=O}$ 1759, 3520 (overtone; sample was shown to be pure by vapor phase chromatography). The infrared spectrum of our sample was identical with an authentic sample of IX,[11] and there was no depression in mixed m.p. Alkaline permanganate oxidation of our sample of IX gave glutaric acid; nitric acid oxidation of IX has been reported to give glutaric acid.[10]

The location of the double bond in VI has not been determined through chemical evidence; it is assigned tentatively on the basis of the mechanism (Ia → III → IV → V → VI) proposed to account for this novel fission of the norbornene ring system: Hydrolysis at C_2 of protonated Ia (III, or a more highly protonated version), with concerted shift of the double bond to C_3–C_4, fission of the C_1–C_5 bond, and elimination of hydroxyl to form the nitrile oxide IV. Hydrolysis of the nitrile oxide[14] to the hydroxamic acid followed by displacement, with inversion and ring closure, of the conjugate acid of the latter (possibly concerted as shown in V) would complete the *cis*-ring fusion of VI.

SOLVENT EFFECTS IN THE REACTIONS OF FREE RADICALS AND ATOMS[1]

Sir:

Complexes between free radicals and aromatic hydrocarbons have been suggested,[2–5] but conclusive evidence supporting their existence is lacking. We have found that various aromatic solvents can drastically alter the position of attack of a chlorine atom on a branched-chain hydrocarbon and believe that this effect is connected with the ability of the aromatic hydrocarbon to form a complex with chlorine atoms. The data indicate that the complexed chlorine atom is much more selective than the free chlorine atom.

This effect was observed in the photochlorination of 2,3-dimethylbutane, analysis being performed by vapor phase chromatography. The 1- and 2-chloro-2,3-dimethylbutanes have retention times at 80° of 33 and 22 minutes, respectively, in a 2-m. B-column of a Perkin–Elmer model 154B Vapor Fractometer. Since we have previously demonstrated that the products of photochlorination are a true measure of the point of attack of the chlorine atom,[6] the relative reactivities of the tertiary and primary-hydrogen atoms were calculated by the equation

$$\text{Re. react. } (tert./prim.) = \frac{\text{moles } tert.\text{-chloride} \quad (12)}{\text{moles } prim.\text{-chloride} \quad (2)}$$

TABLE I

Table I shows that most aliphatic solvents have little effect upon the position of attack of a chlorine atom on 2,3-dimethylbutane. However, in the presence of aromatic solvents the chlorine atom is directed toward the tertiary hydrogen atoms, the effect increasing with the basicity of the aromatic hydrocarbon[7] and with a decrease in temperature.

Figure 1 demonstrates the effects of *t*-butylbenzene, benzene, and chlorobenzene on the relative reactivities of the tertiary and primary-hydrogen atoms of 2,3-dimethylbutane. Qualitatively, it is

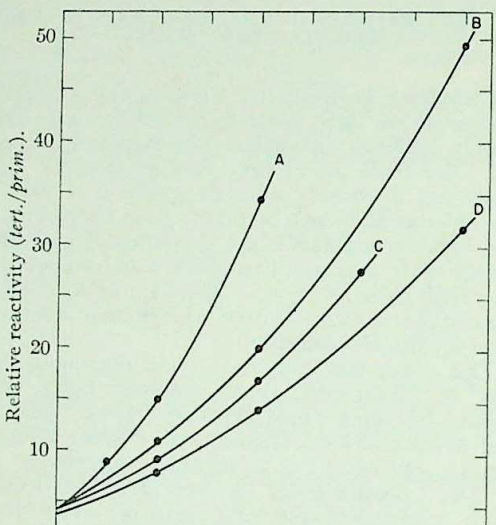

Fig. 1.—Relative reactivities of hydrogen atoms of 2,3-dimethylbutane in the presence of aromatic hydrocarbons: A, *t*-butylbenzene, 25°; B, benzene, 25°; C, chlorobenzene, 25°; D, benzene, 55°.

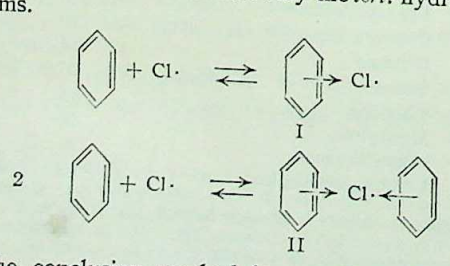
obvious that the attacking species is very selective at high concentrations of aromatic hydrocarbon. Quantitatively, the curves in Figure 1 fit the expression

$$\text{Rel. react. } (tert./prim.) = k + k'[\text{Ar}] + k''[\text{Ar}]^2$$

where Ar represents the aromatic hydrocarbon. An expression of this type can be derived if it is assumed that there are three types of chlorine atoms in an aromatic solvent, a free chlorine atom, I and II, and if I and II can attack only the *tert.*-hydrogen atoms.



The conclusion reached in regard to the complexing of free radicals by aromatic solvents calls for reappraisal of many homolytic substitutions, particularly those involving competition reactions. Complexing may also be important in other homolytic reactions, such as vinyl polymerization.[3,8] The study of solvent effects in free radical reactions is being extended to other solvents, substrates and free radicals.

GENERAL ELECTRIC RESEARCH LABORATORY
SCHENECTADY, NEW YORK GLEN A. RUSSELL

RECEIVED APRIL 3, 1957

THE ROLE OF PUTRESCINE AND METHIONINE IN THE ENZYMATIC SYNTHESIS OF SPERMIDINE IN *ESCHERICHIA COLI* EXTRACTS

Sir:

The polyamines, spermidine and spermine, are widely distributed in natural materials, but little is known of their biosynthesis.[1] Previous isotopic work from this laboratory, with growing cultures of *Escherichia coli*, *Aspergillus nidulans*, and *Neurospora crassa*, has indicated that putrescine[2] and methionine[3] supplied the four- and three-carbon moieties, respectively, of the polyamines.

We are now able to demonstrate the synthesis of spermidine $[NH_2(CH_2)_3NH(CH_2)_4NH_2]$ from putrescine $[NH_2(CH_2)_4NH_2]$ in cell-free extracts of *E. coli*. These preparations have been partially purified, and the reaction has been shown to require L-methionine, adenosine triphosphate (ATP), and Mg^{++} (Table I). The isotope of 1,4-C^{14}-putrescine and of 2-C^{14}-methionine, but not of $C^{14}H_3$-methionine or of $C^{14}OOH$-methionine, was incorporated into spermidine.

Preliminary data indicate that three steps are involved in this reaction

$$\text{ATP} + \text{L-methionine} \xrightarrow{Mg^{++}} \text{compound I} \xrightarrow[-CO_2]{Mg^{++}}$$

$$\text{compound II} \xrightarrow{\text{putrescine}} \text{spermidine}$$

(1) In the first step ATP and methionine form compound I. In the presence of 0.01 *M* NaCN this accumulates, and can be purified by chromatography. On the basis of preliminary data, compound I is believed to be adenosylmethionine.[4] It contains approximately one equivalent of methionine (as shown by the incorporation, in separate experiments, of the isotope from 2-C^{14}-methionine, $C^{14}H_3$-methionine, and $C^{14}OOH$-methionine), one equivalent of adenine (absorption maximum at 260 mμ) and no phosphorus. The R_f of compound I is very similar to that reported[4] for adenosylmethionine [0.12 in ethanol 80, HAc 5, H_2O 15; 0.07 in butanol–acetic acid–H_2O]. Compound I can serve as a methyl donor with nicotinamide methylpherase[4] [60% yield], in the absence of ATP, Mg^{++}, and methionine.

TABLE I

ENZYMATIC SYNTHESIS OF SPERMIDINE FROM 1,4-C^{14}-PUTRESCINE

The complete system contained C^{14}-putrescine dihydrochloride[a] (0.12 μmole, 8,000 c.p.m.), L-methionine (1 μmole), ATP (2.5 μmoles), $MgSO_4$ (30 μmoles), *E. coli* enzyme (10 mg. of an ammonium sulfate fraction), and triethanolamine buffer (*p*H 8.1) in a final volume of 0.3 ml. Incubation time was 3 hr. at 37°. Spermidine was isolated by Dowex 50 (H) and Amberlite XE-64 (H) chromatography by a modification of the methods previously reported (ref. 1).

	Spermidine,[b] c.p.m.
Complete system (C^{14}-putrescine, ATP, Mg^{++}, L-methionine, enzyme)	5070
No ATP	140
No Mg^{++}	220
No L-methionine	160
D-Methionine[c] instead of L-methionine	120
Compound I instead of ATP and L-methionine[d]	5700
Adenosyl-L-methionine instead of ATP and L-methionine[d]	6460

[a] Synthesized by catalytic reduction (in ethanol–H_2SO_4) of C^{14}-succinonitrile, formed from $NaC^{14}N$ and bromopropionitrile. We wish to thank Drs. H. Bauer and E. May for help with these syntheses. [b] For convenience isotopic assays usually were used. In other experiments the spermidine formed was assayed with dinitrofluorobenzene, demonstrating net synthesis. Further identification of the spermidine formed was attained by rechromatography and by recrystallization, with carrier, to constant specific activity. [c] 1 μmole of D-methionine. [d] The incubation mixtures in these two experiments contained buffer, $MgSO_4$, and enzyme (as indicated above), 0.12 μmole of C^{14}-putrescine (8,000 c.p.m.), and 0.17 μmole of compound I or adenosyl-L-methionine in a final volume of 0.3 ml. Control incubation mixtures without enzyme showed no synthesis of spermidine.

TABLE II

DECARBOXYLATION OF C^{14}OOH-DL-METHIONINE AND OF C^{14}OOH-COMPOUND I

The complete system in experiment A contained putrescine (0.12 μmole), $MgSO_4$ (30 μmoles), *E. coli* enzyme (5 mg. of an ammonium sulfate fraction), ATP (2.5 μmoles), triethanolamine buffer (*p*H 8.1), and C^{14}OOH-DL-methionine in a final volume of 0.3 ml. The complete system in experiment B contained the same additions of $MgSO_4$, enzyme and buffer plus C^{14}OOH-compound I in a final volume of 0.3 ml. Incubation time was 45 minutes at 37°.

	$C^{14}O_2$, c.p.m.
A. With C^{14}OOH-DL-methionine[a] (0.13 μmole, 40,000 c.p.m.)	
Complete system (putrescine, ATP, Mg^{++}, C^{14}OOH-methionine, enzyme)	1044
No putrescine	1146
No ATP	30
No Mg^{++}	24
Complete system + NaCN (3 μmoles)[b]	54
B. With C^{14}OOH-compound I (0.003 μmole, 800 c.p.m.)	
Complete system (Mg^{++}, C^{14}OOH-compound I, enzyme)	378
No Mg^{++}	98

[a] C^{14}OOH-DL-methionine was prepared by a modification of the non-isotopic synthesis of R. Gaudry and G. Nadeau, *Can. J. Research* 26B, 226 (1948). [b] In the presence of NaCN, compound I accumulated. Larger amounts of compound I were made with 2.6 μmoles of C^{14}OOH-DL-methionine (700,000 c.p.m.), 50 μmoles of ATP, 600 μmoles of $MgSO_4$, 60 moles of NaCN, *E. coli* enzyme (100 mg. of ammonium sulfate fraction) in a volume of 6 ml. Compound I was purified by Dowex 50 (H) or XE 64 (H) chromatography, or by paper chromatography.

(2) In the second step compound I undergoes enzymatic decarboxylation (Table II) in the presence of Mg^{++}. ATP is not necessary for this reaction, although, for the formation of $C^{14}O_2$ from C^{14}OOH-labeled methionine, both ATP and Mg^{++} are essential. 0.01 *M* NaCN markedly inhibits decarboxylation; putrescine is not required. Compound II has been partially purified by chromatography, but has not been separated from compound I.

(3) Either compound I or adenosylmethionine,[5] in the presence of putrescine and the enzyme, forms spermidine in the absence of ATP or methionine (Table I). The remainder of the molecule would be expected to form thiomethyladenosine[6]; some preliminary evidence for a product of this type has been obtained.

Experiments with intact *E. coli* demonstrate that the synthesis of spermidine represents an important pathway for the metabolism of methionine. A three-carbon transfer is involved, comparable to the methyl-transfer of Cantoni. Further work is in progress on the purification of the respective enzymes and products, and on the role of other substrates as three-carbon donors and acceptors.

(5) S-Adenosyl-L-methionine was prepared according to the method of Cantoni (ref. 4), using ATP, L-methionine, and a rabbit liver enzyme.

THE CRYSTAL STRUCTURE OF SODIUM PEROXIDE

Sir:

From single-crystal X-ray diffraction work on sodium peroxide, a unit cell has been deduced which indexes the powder pattern more satisfactorily than does the unit cell reported in the literature.[1] A single crystal of Na_2O_2 was found among the fragments from a cooled melt of high purity Na_2O_2 contained in a crystalline MgO crucible. From the Laue patterns taken it can be shown that sodium peroxide is hexagonal, belonging to Laue group 6/mmm. Single crystal rotation patterns and powder patterns taken with Cu Kα X-radiation yield the repeat distances $a = 6.22 \pm 0.01$ Å. and $c = 4.47 \pm 0.01$ Å. Interplanar spacings calculated from these dimensions agree well with those observed on a powder pattern taken with a camera of 114.6 mm. radius.

Since no systematic absences are found in the reflections, the space groups P622, P6mm, P$\bar{6}$2m, P$\bar{6}$m2 and P6/mmm remain as possibilities, from those having Laue symmetry 6/mmm. Density measurements on Na_2O_2(2.2 to 2.8 g./cc.) favor a unit cell containing three formula units (Na_2O_2), which gives a calculated density of 2.60 g./cc. Spatial considerations favor only the structure (of

symmetry P$\bar{6}$2m) with the following approximate positions: Oxygen: 0,0,p; 0,0, $-p$; $^1/_3$, $^2/_3$,q; $^2/_3$, $^1/_3$,q; $^2/_3$,$^1/_3$,$-q$; Sodium: r,0,$^1/_2$; 0,r,$^1/_2$; $-r$,$-r$, $^1/_2$; s,0,0; 0,s,0; $-s$,$-s$, 0; where p = 0.167, q = 0.333, r = 0.724, s = 0.366. Intensities calculated from these parameters are consistent with estimated powder and rotation intensities.

This structure has been deduced independently by Klemm and Foppl.[2]

In this structure, the peroxide ions lie parallel to the c-direction, one at the corner and two within the unit cell. Each peroxide ion is in contact with nine sodium ions, three about the middle and three about each end. A sodium ion of 0.98 Å. radius, and a peroxide ion regarded as a cylinder of radius 1.29 Å. and length 1.49 Å. with caps of radius 1.29 Å. are consistent with this structure and with other crystallographic data.[3,4]

There appears to be no direct correlation between this hexagonal unit cell and the tetragonal unit cell reported by Feher[1] with dimensions a = 6.65 Å., c = 9.91 Å., and Z = 8. The fact that the ASTM Index lists for Na_2O_2 at least 15 powder lines (of the 29 listed) either not observed or of significantly greater intensity than observed for pure Na_2O_2 is readily explained as due to the presence of impurities, principally NaOH, in the material which gave the ASTM pattern.

We wish to acknowledge the support of a du Pont Summer Fellowship (R.L.T.) and of funds from the Wisconsin Alumni Research Foundation in this work.

ACETOLACTATE, AN EARLY INTERMEDIATE IN VALINE BIOSYNTHESIS[1]

Sir:

Strassman, *et al.*,[2,3] and Adelberg[4] have proposed schemes for the conversion of pyruvate to L-valine and of α-ketobutyrate to L-isoleucine. Each scheme involved a condensation of acetaldehyde and the appropriate keto acid followed by a pinacol rearrangement to account for the distribution of C^{14} in tracer studies. As pointed out by Adelberg,[4] the first step in L-valine biosynthesis might be a ketol (as first proposed by Strassman, *et al.*[2]) or an aldol condensation, since either reaction would be consistent with the data. Evidence that the initial step is acetolactate formation (ketol condensation) is presented here.

A valineless mutant of *Escherichia coli*, strain M4862,[5] accumulates α-acetolactic acid when grown in media supplemented with limiting amounts of L-valine. Extracts prepared by sonic oscillation of cells of this mutant, harvested when acetolactate accumulation was marked, were observed to produce at least ten times as much α-acetolactate from pyruvate as did an extract of the parent *E. coli* strain W (Table I, Expt. 1). The formation of acetolactate was inhibited by L-valine.

A similar valine sensitive system was also formed by a wild type *Aerobacter aerogenes*, strain 1033, when grown in minimal medium containing L-histidine as the sole carbon source (chosen so as to assure absence of the classical carboligase[6] system). The same strain grown in nutrient broth with 1% glucose exhibits virtually no carboligase activity at pH 8 but is extremely active when tested at pH 6 (Table I, Expt. 2). L-Valine does not inhibit this enzyme.

TABLE I

Assay system contained 10^{-2} M pyruvate, 20 μg. cocarboxylase, 2×10^{-3} M Mg^{++} and cell-free extract equivalent to 25 mg. wet weight of cells in one ml. 0.1 M phosphate buffer. Ten minutes incubation at 37° in air. Reaction stopped with $Zn(OH)_2$. Acetoin and acetolactate determined by method of Westerfeld[7] before and after decarboxylation[6] of β-ketoacids with 1.8 N H_2SO_4. In a separate experiment the acetolactate was isolated and converted to the bis-phenylhydrazone of diacetyl. The melting point was 258–259° (uncorrected) and there was no depression upon mixing with the same derivative prepared from synthetic α-acetolactic acid.

If acetolactate is an intermediate in L-valine biosynthesis, the inhibition of its formation by L-valine could be the feedback loop by which L-valine controls its own biosynthesis.[8] That acetolactate is very likely on the pathway in question is indicated by the following observations: (1) acetolactate labeled in the β-methyl position was incorporated into L-valine and L-leucine of *E. coli* pro-

BOOK REVIEWS

Chemistry of Carbon Compounds. Volume III, Part B. Aromatic Compounds. Edited by E. H. RODD, D.Sc., F.C.G.I., F.R.I.C., D. Van Nostrand Company, Inc., 126 Alexander Street, Princeton, New Jersey. 1956. xx + pp. 687–1670. 16.5 × 23 cm. Price, $25.00.

This volume continues the excellent treatise on organic chemistry which began appearing in 1951, and which seems destined to be the standard reference on the subject for the next decade or two.

It completes the treatment of aromatic compounds begun in Volume IIIA and is largely devoted to polyfunctional benzene derivatives (some of which were treated in Volume IIIA) and polycyclic aromatic substances. A major share of the preparation of this volume has fallen to W. J. Hickinbottom who has prepared six of the twelve chapters. Other contributors are Z. E. Jolles, R. F. Garwood, M. F. Ansell, S. H. Harper, G. L. Buchanan, R. A. Raphael, E. H. Rodd, J. van Alphen, S. Coffey, G. M. Badger and J. W. Cook. It is highly recommended.

Perspectives in Organic Chemistry. A volume dedicated to Sir Robert Robinson, prepared by friends, colleagues and former pupils under the editorship of SIR ALEXANDER TODD. Interscience Publishers, Inc., 250 Fifth Avenue, New York 1, N. Y. 1956. x + 527 pp. 16 x 23.5 cm. Price, $7.50.

Sir Robert Robinson has been one of the giants of the art and science of organic chemistry, and it is altogether fitting that a distinguished group of leaders in the practice of this art and science have been banded together under the leadership of Sir Alexander Todd to honor Sir Robert on his 70th birthday by the publication of this series of essays.

One of the most pleasant characteristics of the book is the frankly speculative nature of some of the chapters. Others are masterful syntheses of the state of knowledge in particular fields. These characteristics seem peculiarly appropriate in a book dedicated to Robinson, who has always been at his best and most forceful when advancing inspired speculation and when assembling and interpreting the widely divergent and often conflicting evidence applicable to problems falling within his interest. Likewise, the very breadth of the fields covered reflect Robinson's own catholic tastes.

Chapters have been contributed by Linus Pauling, Paul D. Bartlett, Wilson Baker, D. H. R. Barton, V. Prelog, A. J. Birch, R. B. Woodward, Karl Ziegler, E. L. Hirst, Sir Alexander Todd, L. Ruzicka, C. W. Shoppee, E. Schlittler, J. W. Cornforth, Karl Folkers, James Walker, Holger Erdtman and A. Butenandt.

The book is stimulating and entertaining.

Photoconductivity Conference. Held at Atlantic City November 4–6, 1954. Editorial Committee: R. G. BRECKENRIDGE, Chairman, B. R. RUSSELL and the late E. E. HAHN. Sponsored by University of Pennsylvania, Radio Corporation of America, Office of Naval Research. John Wiley and Sons, Inc., 440 Fourth Avenue, New York 16, N. Y. 1956. xiii + 653 pp. 16 × 23 cm. Price, $13.50.

This large volume is a compilation of thirty papers which were presented at a conference in Atlantic City a little more than two years ago. As stated in the forward, "The purpose of this conference was to advance the science of photoconductivity through plenary discussion among the leading workers in the field. . . . Sensing keenly a gap in the literature, the sponsors considered it particularly desirable to publish the papers presented, together with pertinent discussions, as a comprehensive treatise on photoconductivity." There can be little doubt that the papers in this book span the science of photoconductivity no matter what definition of this field one chooses to use, and that there is at present no other source which can give one such a complete view of all of the avenues of research leading to an understanding of this complex phenomenon. However, it would be nearly miraculous if any collection of separately conceived papers in a new and controversial field could be arranged in such a manner as to give the reader a systematic exposition of all of the facts and principles involved, *i.e.*, a treatise. This is not the sort of book one starts at the front cover and finishes at the back cover. Any worker in this field will find some papers of immediate interest, other papers useful in gaining perspective for his own field, and still others of rather negligible interest. In many cases, the table of contents is not a sufficiently reliable guide to the selection of those papers in which one is most interested. Fortunately, almost all of the papers are concluded with brief summary paragraphs, and many of them have introductory paragraphs which are nearly abstracts.

The book has been divided into five sections: I. Phenomenological Theory of Photoconductivity (2 papers); II. Photon Absorption Process (6 papers); III. Electron Processes (6 papers); IV. Photoconducting Materials (7 papers); and V. Current Topics (9 papers). The first paper in Section I, by Rose, comes about as close as anything in the book to being a general introduction to photoconductive phenomena, and also gives sufficient warning that the subject is one of great complexity. The second paper in this section, by Petritz, is considerably more specialized, treating signal-to-noise problems in the use of photoconductors as signal detectors. The second section is the domain of the solid-state theoretical physicist, being an account of the quantum-mechanics of the interaction of photons with semiconductors and insulators and their imperfections (including phonons). The first article, by Herring, is fairly readable for the non-theoretician and gives one at least a feeling for theories of centers. Section III is largely concerned with the application of transistor physics to photoconduction and is of primary interest to the experimentalist. There does not appear to be much of a

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

as both sections deal with the properties of particular photoconductive materials. Here one can perhaps better distinguish between groups of materials: the elemental semiconductors, germanium and silicon; the III-V compounds; lead sulfide, selenide and telluride; and ionic compounds such as zinc oxide. The degree to which the photoconductive phenomena can be discussed in terms of a detailed physical model is, not surprisingly, in direct proportion to the state of advancement of semiconductor technology for the material under discussion. At one end of the scale one finds the finely detailed study of minority carrier trapping in silicon by Haynes and Hornbeck and at the other the necessarily more speculative interpretation of experiments on zinc oxide by Mollwo and by Miller. In most of the papers, photoconductivity is treated as a bulk process, however for thin-film detectors of the lead sulfide group, and for sintered powders of zinc oxide it is pointed out that the important processes are localized at the inter-crystallite surfaces.

The art of actually making a useful photoconductor for a particular purpose is really never explicitly discussed, but this is probably a subject for another book.

BELL TELEPHONE LABORATORIES
MURRAY HILL, N. J. A. R. HUTSON

Technique of Organic Chemistry. Volume III. Second Completely Revised and Augmented Edition. Part I. Separation and Purification. Editor, ARNOLD WEISSBERGER, Research Laboratories, Eastman Kodak Co., Rochester, New York. Interscience Publishers, Inc., 250 Fifth Avenue, New York 1, N. Y. 1956. ix + 873 pp. 16.5 x 23.5 cm. Price, $17.50.

The former Volume III of this series has been divided into two parts in order to permit addition of new chapters and more intensive treatment. Part I concerns Separation and Purification Methods, and Part II, which will appear later, deals with Laboratory Engineering techniques. Chapter I of the present book concerns Diffusion Methods. Four topics are included, three of them new. A. Letcher Jones describes the techniques of Thermal Diffusion of Organic Liquids; Karl Kammermeyer, Barrier Separations; R. Eliot Stauffer, Dialysis and Electrodialysis; and E. MacWilliam, Zone Electrophoresis. Chapter II is an expanded treatment of Laboratory Extraction and Countercurrent Distribution by Lyman C. Craig and David Craig. A new part (61 pp.) has been added to this topic by Edward G. Scheibel who discusses Liquid–Liquid Extraction for Increased Quantities. Chapter III, Crystallization and Recrystallization by R. Stuart Tipson has been expanded from 122 to 167 pp. Two new authors, C. M. Ambler and F. W. Keith, Jr., have revised and expanded Chapter IV on Centrifuging. The treatment of Filtration (Chapter V) also has been expanded by A. B. Cummins and F. B. Hutto, Jr. The last chapter (VI) concerning Solvent Removal, Evaporation and Drying by G. Broughton has been revised and increased from 30 pp. to 52 pp.

This second edition brings up-to-date the information, data and references on these useful techniques. The book is especially valuable for the excellent coverage of the literature by each of the authors. The revision has been well done and well edited. The discussions are good and the diagrams and illustrations are excellent. A good index to this volume is provided followed by Cumulative indices to Volumes I through IX, both Author and Subject. Although the material is primarily slanted to Organic Chemistry, the techniques of Separation and Purification and the discussions will be useful to inorganic and physical chemists also. This is a valuable reference volume for all research chemists.

Mechanism Studies of the Fischer–Tropsch Synthesis. The Addition of Radioactive Methanol, Carbon Dioxide and Gaseous Formaldehyde

BY W. KEITH HALL, R. J. KOKES AND P. H. EMMETT

RECEIVED JANUARY 26, 1957

When a gas mixture containing 1.4% radioactive carbon dioxide in a 50:50 H_2:CO synthesis gas is passed over an iron catalyst at 240°, very little carbon dioxide is converted to carbon monoxide or to hydrocarbons. Apparently the water gas conversion reaction under these conditions is very slow. Methanol can act as a chain initiator in hydrocarbon synthesis and to a slight extent can build into the chain to form higher hydrocarbons. It also forms considerable carbon dioxide by direct decomposition on the catalyst. Similar results were obtained with gaseous formaldehyde, except that it decomposes rapidly on the iron catalyst in the presence of synthesis gas to form carbon monoxide and carbon dioxide having activities almost as great as for complete equilibration between these two gases and the formaldehyde. Hence, in this instance, the slope of the activity *vs.* carbon number plot for the hydrocarbons formed can be accounted for by the radioactivity of the carbon monoxide. Apparently neither formaldehyde nor methanol forms on adsorption the type of C_1 complex identical to that occurring in actual synthesis.

Tracer studies reported in two previous communications[1,2] from this Laboratory have shown that when small amounts of radioactive primary alcohols are added to a 1:1 carbon monoxide–hydrogen synthesis gas mixture which is being passed over a reduced iron catalyst at about 235°, the hydrocarbon synthesis products of carbon number greater than that of the added alcohol have an approximately constant radioactivity per cc. This has been interpreted as indicating that the complex formed by the adsorption of the alcohol on the iron catalyst is capable of acting as an intermediate (a chain initiator) in the synthesis of higher hydrocarbons.

Of all the primary alcohols studied only radioactive methanol yielded hydrocarbon products, the radioactivity of which per cc. increased appreciably with increasing carbon number. Apparently the complex formed on addition of methanol not only initiates chains but also enters into chain building. With a view to investigating further the behavior of radioactive complexes containing a single carbon atom, the methanol experiments have now been extended into the higher pressure range of commercial synthesis. These are reported in the present paper together with experiments at one atmosphere pressure in which radioactive formaldehyde and radioactive carbon dioxide were used as tracers. Gaseous formaldehyde was used with a view to testing it as a possible source of a single carbon complex both for chain building and chain initiation.

Several other facts, pertinent to the discussion of the present paper, had also been established in the earlier work. Pyrolysis of the propane formed in experiments,[1] where methyl-labeled and methylene-labeled ethanol were added to the synthesis gas, showed that carbon atoms attach themselves preferentially to the methylene carbon atom of the alcohol complex. Further, all results obtained were in agreement with the pattern of build-up of hydrocarbon on the surface of the catalyst suggested by Weller and Friedel,[3] by Anderson, Friedel and Storch,[4] and by Weitkamp, *et al.*[5] In addition, it was possible to suggest[2] a modification of one of these reaction schemes[4] to allow for the enhanced reactivity of the carbon attached to the hydroxyl group; the result was a somewhat more descriptive picture of these surface processes than had previously been available.

The experiments with carbon dioxide were designed to ascertain whether or not the slope of the curves representing plots of radioactivity of the products as a function of carbon number obtained in the methanol and formaldehyde tracer runs could be explained as due to the incorporation of the moderately active carbon dioxide obtained as a reaction product.

Experimental

Most of the techniques involved in the radioactive analysis of the products had previously been standardized.[1,2] A description of these will not be repeated here. A few remarks are in order, however, relative to the analysis of the carbon monoxide and carbon dioxide in the tail gas for radioactivity. For measurements on the carbon monoxide, the tail gas was passed through a liquid nitrogen trap and over copper oxide heated to 360°. The exit gas containing water vapor, CH_4 and CO_2 was passed into a second trap where the CO_2 and water vapor were condensed and the methane was removed by pumping. The carbon dioxide was then evaporated from the trap at −78° and counted. Carbon dioxide in the tail gas was collected by passing a portion of the tail gas through barium hydroxide for about five minutes. Such pairs of samples were obtained from two to three times during a run.

In the methanol run, it was thought to be important to establish whether or not the activity of the olefin and paraffin fractions behaved similarly as a function of carbon number. Since the activity of the gaseous olefins and paraffins alone could not decide this point, an attempt was made to extend these measurements to the liquid product. This entailed a separation of the olefins and paraffins. To this end the liquids were passed through a chromatographic column packed with Davison code 923 silica gel (inactive toward the polymerization of olefins); ethanol was used as the eluting developer. The oil product was thus cut into 13 approximately equal cuts of about 2 cc. each. Refractive index measurements showed a sharp rise after the fourth cut and another after the twelfth cut. In the region between these points, there was a gradual decrease in refractive index with an increase in cut number indicating a small fractionation according to molecular weight. The thirteenth cut contained the entire colored band and was presumed to contain most of the oxygenated product obtained in synthesis. Beyond cut 13, the refractive index fell rapidly to that of the eluting ethanol. On the basis of these results, it could be inferred that the liquid had been at least partially fractionated into olefins and paraffins.

Since preliminary examination of the infrared spectrum of these fractions indicated that a major portion of the olefins present consisted of α-olefins, a group type analysis was set up for this species. The results of this analysis are contained in Table I, where the concentration of the $-HC{=}CH_2$ radical is expressed in moles per liter of liquid.

TABLE I

Fraction no.	Concn. α-olefin, moles/l. of liq.	Fraction no.	Concn. α-olefin, moles/l. of liq.
1	0.31	8	3.3
2	.23	9	3.4
3	.18	10	3.5
4	.16	11	3.7
5	1.9	12	3.5
6	2.8	13	1.1
7	3.1		

These data indicated that at least a semi-quantitative separation of olefins and paraffins occurred between cuts four and five. None of the fractions was found to be completely free of olefin, but since the concentration of α-olefin in fraction 10 was nearly 20 times that of fraction 3, an upper limit of about 5% α-olefin could be put on the latter fraction. The other question of interest is the purity of the olefin fractions with respect to paraffins; this may be defined as C/C_0, where C is the observed olefin concentration and C_0 is the concentration in moles per liter of the pure olefin of the same molecular weight. A minimum average molecular weight could be determined from the data, if it turned out to be greater than octane, the uncertainty existing because it was not possible to distil a small residual portion of the material in high vacuum at room temperature. On this basis, the purity of the predominant α-olefin turns out to be 55%. The spectra, however, showed also the presence of both *cis*- and *trans*-olefins of the type $R_1CH{=}CHR_2$. There is some uncertainty in treating the spectral data for these species, because the 965 cm.$^{-1}$ band of the *trans*-olefin overlaps the 990 cm.$^{-1}$ band of the α-olefin. In fraction 10, however, it was possible to establish that these species amounted to a total of 2.4 ± 0.3 mole/liter. Making this correction leads to a purity value for the olefin in this cut of 92%. Cuts 3 and 10 were used for the analysis of the radioactivity of the liquid paraffins and olefins, respectively. It is apparent from the above that these cuts were 90+% pure paraffin and olefin, respectively.

The runs with the gaseous formaldehyde and the carbon dioxide additions were made in our one atmosphere all-glass reactor previously described;[1,2] the run in which the radioactive methanol was added to the synthesis at 100 p.s.i.g. was made in the bench scale reactors[6] of the catalyst testing laboratories of the U. S. Bureau of Mines, Bruceton, Pennsylvania.

In the glass reactor several thermocouples were buried in the catalyst bed. The reduced catalyst was brought into synthesis at about 200° the gradual addition of carbon monoxide to the gas stream so as not to locally overheat the catalyst. Then, the temperature was slowly increased until a contraction of from 20 to 35% was reached. When these steady state conditions were attained, traps were put on and the run commenced. After a period comparable to that to be used in the radioactive run, the products were collected for analysis, and the synthesis was continued with the radioactive additive in the gas stream. Similarly, after the collection of the radioactive products, another non-radioactive test run was made. In the run in the pressure reactor, a similar procedure was followed, except that the catalyst was put on stream using the Bureau's standard test procedure,[7] and the radioactive run was started in the fourth week of operation. In all instances, the presence of the radioactive additive in the synthesis gas appeared to have no large effect on the catalytic activity or on the product distribution. Therefore, the data collected in Table II are representative not only of the tracer runs but also the control runs.

The catalysts used in the individual runs are noted in Table II. All were reduced fused iron oxides. Catalyst number 955 contained 7.95% Al_2O_3 and number 614, 2.0% ZrO_2 and 0.64% Al_2O_3 in addition to Fe_3O_4. Catalyst D-3001 is the standard doubly promoted catalyst of the Bureau of Mines; it contains 0.6% SiO_2, 0.6% Cr_2O_3, 4.6% MgO and 0.6% K_2O; its properties and behavior have been extensively described elsewhere.[8-11] It should be noted that catalyst 955 was used in the earlier[2] methanol run, so that the carbon dioxide addition experiment reported herein pertains more directly to the earlier than to the present methanol experiment. Since, however, the behavior of the methanol in both experiments is qualitatively similar, this makes little difference.

One millicurie lots each of carbon dioxide (as $BaCO_3$) and formaldehyde (as a dilute aqueous solution) were secured from the Atomic Energy Commission's laboratory at Oak Ridge, and two millicuries of methanol were obtained from Tracerlab, Inc., Boston.

The methanol was appropriately diluted with non-radioactive methanol to a volume of 35 cc. The carbon dioxide was liberated from the $BaCO_3$ with concentrated H_2SO_4 in a vacuum system and subsequently diluted to about 7.5 liters. This was transferred into a small (approximately 12 l.) steel cylinder where it was blended with

C_5H_{12}	0.5	0.4	1.0

[a] In all runs herein reported a 1:1 H_2:CO synthesis gas was used. [b] Space velocity is here defined as volume of entering gas per volume of catalyst space per hour; the catalyst volume was 100 cc. in the radioactive methanol addition experiment and 50 cc. in all others. [c] Contains an estimated 15% CO_2; exact figures are not available.

enough carbon monoxide to bring the final pressure up to about 285 p.s.i. Under these conditions, the tank was found to contain 2.6% radioactive CO_2. This gas, after passing through a Dry Ice trap, was blended with a separate stream of pure dry hydrogen to obtain a 1:1 H_2:CO synthesis gas.

The radioactive formaldehyde was mixed with an appropriate amount of a concentrated (40%) solution of formaldehyde. From this, paraformaldehyde was prepared by vacuum distillation of the water from the solution. This polymer was thoroughly dried over anhydrous magnesium perchlorate in a vacuum desiccator. Production of the formaldehyde gas was carried out in a vacuum system, which prior to the actual synthesis was baked out with a torch under vacuum to remove adsorbed water from the glass. The gas was generated when the paraformaldehyde was heated to 120° *in vacuo* and was passed through a line heated to the same temperature followed by a five-stage trap, the top stages of which were kept at 120° and the bottom stages at −78°; it was then collected in a receiver at liquid nitrogen temperature. This procedure is similar to that used by Spence and Wild.[12] Further purification was achieved by several distillations. The over-all yield of purified formaldehyde was better than 80%. A stream of hydrogen was passed through the liquid formaldehyde at −78° where it picked up approximately 2.8% gaseous formaldehyde. This was blended with an equal amount of CO to yield about 1.4% formaldehyde in the 1:1 synthesis gas. The concentration of formaldehyde in the synthesis stream was continuously monitored with a thermal conductivity gage. In spite of all the precautions taken in drying the hydrogen, after two to three hours the clear formaldehyde would become a stiff gel. It was discovered, however, that this gel would maintain the vapor pressure of pure formaldehyde for periods up to 20 hours; at the end of this period the vapor pressure would fall suddenly. It was found, furthermore, that a good percentage of the original liquid could be regenerated by a simple distillation. For these reasons, the addition to the synthesis was interrupted after about 18 hours for a few minutes to heat up the gel and regenerate the formaldehyde.

In the methanol experiment, the liquid was injected into the top of the reactor under pressure by a small single-stroke pump run by a synchronous motor. This pump, which operated much like a hypodermic syringe, was developed by the Bureau of Mines engineers and was found capable of delivering as little as 1/4 cc. per hour, accurately and reproducibly, under pressure up to 300 p.s.i. Under the conditions of the present experiment, this amounted to 1% of the synthesis gas.

Results

(a) **Methanol.**—The data collected from the hydrocarbon products of the methanol run are plotted in Fig. 1, where they are compared to those obtained earlier at lower pressure by Kummer and Emmett.[2] In the earlier run, the olefins and paraffins were determined separately only on the gaseous products (C_2 to C_4); the liquid products were fractionated by distillation and the activities of the individual cuts, which contained both olefins and paraffins, were determined. These data fall on a straight line indicating the "build-in" of at least enough of the complex formed on the adsorption of methanol to account for the difference between the observed slope of 70 counts/min./cc./carbon number and the activity increment due to the radioactivity of the carbon monoxide (32 counts/min./cc. in the exit gas). In the new runs, on catalyst D-300 under pressure, the data do not fall on a straight line, although the over-all trend indicates a similar "build-in" corresponding to about 38 counts/min./cc./carbon number, of which at most 23 counts/min./cc./carbon number may be attributed to the radioactivity contained in the carbon monoxide. These newer data were obtained with nearly pure fractions of olefins and paraffins; it should be noted that the olefin curve more or less parallels that of the paraffins, though it falls slightly

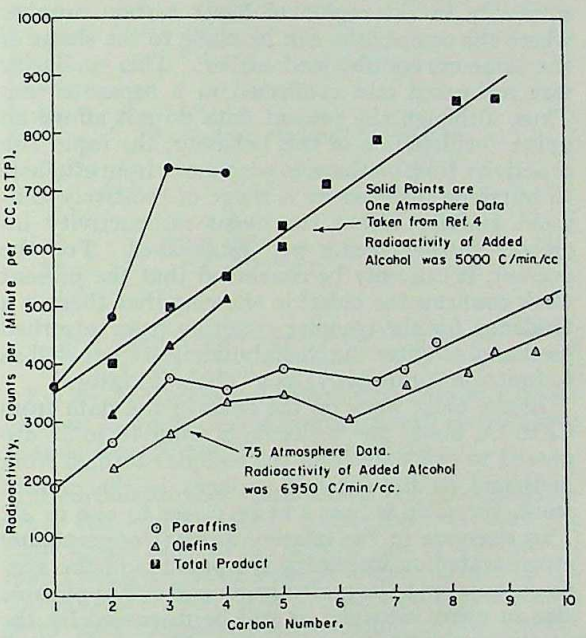

Fig. 1.—Radioactivity of hydrocarbons obtained in the experiment in which 1% radioactive methanol was added to the synthesis at 7.5 atmospheres. These data are compared to the earlier one atmosphere results of ref. 4.

[a] Taken from data of ref. 2; radioactivity of added alcohol was 5000 counts/min./cc. [b] Radioactivity of added alcohol was 6950 counts/min./cc [c] Radioactivity of added formaldehyde was 5010 counts/min./cc.

below it. Further, both curves show an amazing similarity in the region of lower carbon number where the comparison can be made to the shape of the same curves obtained earlier. This similarity was rechecked and confirmed in a separate run. Thus, although the present data do not afford an unique explanation of this behavior, the rapid rise in activity from methane to propane or from ethylene to butylene followed by a range of relatively constant activity before the molar radioactivity increases further seems well established. For the present, it can only be concluded that the present work confirms the older[2] in showing that there is a tendency for the complex resulting from adsorbed methanol to enter the chain building step as well as to function (principally) as a "chain initiator."

In the older work on the basis of the data from C_2 to C_3, about one molecule in from 10 to 15 appeared to originate from the complex formed from methanol on the catalyst surface; in the present work, the ratio is found to be closer to one in 35. This decrease in the relative amount of methanol incorporated on increasing the pressure of the synthesis appears to be perfectly general and applicable also to other alcohols; it will be discussed by the present authors in a paper to be published shortly.[13] It will suffice here to point out that it may be explained by the simple assumption that methanol must compete for adsorption sites with the complex formed from carbon monoxide and hydrogen, and that the fraction of the adsorbed layer consisting of radioactive methanol is smaller at 7.5 atmospheres than at one atmosphere pressure.

Further data of interest are collected in Table III. The activity of the carbon monoxide is low in both methanol runs, indicating that the amount of methanol which decomposes to carbon monoxide is a small but definite amount.

Had all the methanol entering the pressure reactor been decomposed at the entrance, the radioactivity of the emerging carbon monoxide would have been some six times higher (*i.e.*, 138 counts/min./cc). In the present instance in which 1% methanol was added, the activity is about $^2/_3$ that found in the earlier one atmosphere run in which 1.5% methanol was added.

The presence of the high activity carbon dioxide observed earlier[2] was confirmed by the present work; as before, the activity indicates that at least part of the radioactive CO_2 was not formed *via* CO. It is of interest to note that the radioactivity observed in the pressure run (83.5 c./min./cc.) has decreased with an increase in total pressure in almost exactly the same ratio as the fractional incorporation into hydrocarbons, suggesting that the reaction responsible is one involving a common intermediate on the catalyst surface.

(b) **Carbon Dioxide.**—The general trend of increasing radioactivity per cc. of hydrocarbon as a function of increase in carbon number observed in the methanol runs, might conceivably be attributed to the radioactive carbon dioxide formed in these runs. Thus, for example, the slope of 70 counts/minute/cc/carbon number observed by Kummer and Emmett[2] could easily be accounted for if a sufficient amount of the radioactive carbon dioxide (175 counts/min./cc.) were to enter into the chain building reaction. The present data appear to rule out this possibility.

In this experiment, a blend of 97.4% non-radioactive CO +2.6% radioactive CO_2 (9,450 counts/min./cc. of CO_2) was metered into the reactor along with an equal amount of hydrogen. The data collected are listed in Table IV. Since background on our tube ran from 40 to 46 counts/min., and since many observations (obtained by subtracting the background reading from the total reading) were only a fraction of this, the data obtained are admittedly crude; they are, however, adequate to show that the amount of carbon dioxide incorporated into the product (corresponding to about 2 atoms of carbon incorporated per 1000 carbon atoms) is much too small to account for the increasing activity as a function of carbon number found in the methanol runs. The activity of the carbon monoxide in the tail gas is found to be about 14 counts per minute per cc. This level of activity is high enough within our experimental error (probably ± 6 counts/min./cc.) to account for all of the activity found in the products. Thus the major portion of the entering carbon dioxide passes through the bed unchanged, but diluted with that formed in synthesis.

The low but detectable activity observed in the carbon monoxide could arise from either an exchange of an oxygen atom with the carbon monoxide, *viz.*

$$C^{14}O_2 + CO \rightleftharpoons CO_2 + C^{14}O \quad (1)$$

or by a reversal of the water gas shift reaction on the catalyst surface

$$C^{14}O_2 + H_2 \rightleftharpoons C^{14}O + H_2O \quad (2)$$

	8.28	120	15
Av. of hydrocarbons = 16			

[a] Radioactivity of the 1.3% carbon dioxide in synthesis gas was 9450 counts/min./cc. STP of gas. [b] Sample taken at ~38% contraction. [c] Sample taken at about 32% contraction.

Had complete radioactive equilibrium been reached by either of these reactions, the observed level of activity in the exit carbon monoxide would have been raised to 246 counts/min./cc. It is particularly interesting to note that reaction 2 is shown by these data to be quite sluggish over a Fischer–Tropsch synthesis catalyst operating under the conditions used. It is equally true, however, that these results do not preclude the possibility that such a reversal may be less sluggish with the higher contractions and the somewhat higher temperatures usually employed in a commercial synthesis.

(c) **Formaldehyde.**—As noted in an earlier communication,[1] if it were possible to add to the synthesis a radioactive organic compound which on adsorption became identical with the C_1 complex formed from carbon monoxide and hydrogen on the surface and responsible for building into the hydrocarbon chains, the molar activity *vs.* carbon number curve would necessarily be a straight line passing through the origin (at zero carbon number). Since current theories[2,4,5] of the mechanism of the synthesis lead to the inference that this "chain-building" complex contains oxygen, the number of possibilities of radioactive additives is severely limited. It was for this reason that formaldehyde addition was studied.

The data obtained from the hydrocarbon product of the synthesis are plotted in Fig. 2. The solid line shows that a reasonably good linear relation exists between the molar radioactivity and the carbon number of the total product (our most accurate data). These data, like those for methanol, cannot conceivably be interpreted as being due to the formation of a single complex identical with that obtained from carbon monoxide and hydrogen. If such a complex were formed, the data would fall on a straight line passing through the origin. Since the left hand margin of Fig. 2 corresponds to

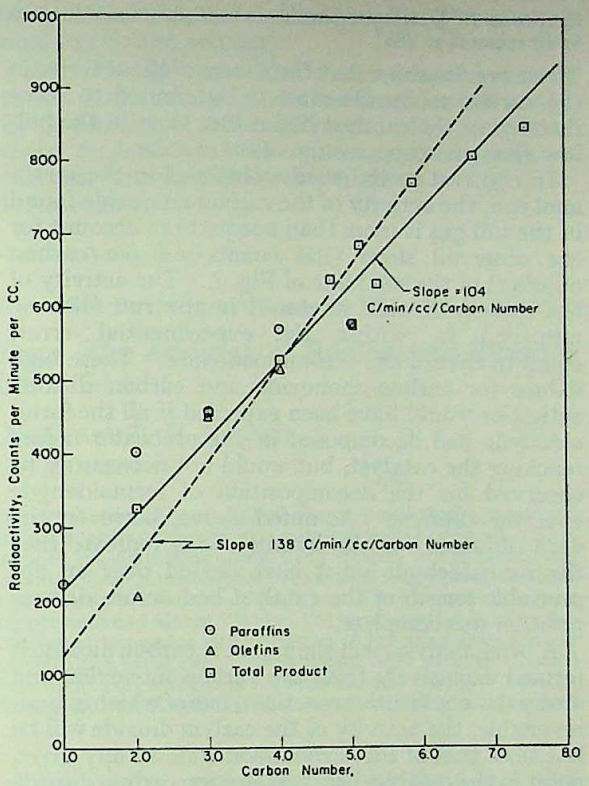

Fig. 2.—Radioactivity of hydrocarbons obtained in the experiment in which 1.4% radioactive gaseous formaldehyde was added to the synthesis at 1 atmosphere.

unit carbon number (rather than zero carbon number), the corresponding requirement is that the data would have to fall around one of a family of lines having the same slope as intercept, such as the dashed line shown. For the same reason, the data show that complete decomposition of the formaldehyde could not have taken place before an appreciable fraction of the bed length had been passed. Otherwise, all hydrocarbon activities would be the same per C atom as for CO, namely, 138 counts/min./cc. The data do not preclude but are actually consistent with the formation by the formaldehyde of a chain-initiating complex with or without a chain-building complex.

Data obtained for the pairs of carbon monoxide and carbon dioxide samples of the tail gases from the converter are shown in Table III. The average activity of 138 counts/min./cc. found for the carbon monoxide together with the observed activities for CO_2 and for the C_1—C_8 hydrocarbons show that the formaldehyde, in contrast to methanol, must have been nearly completely decomposed before the gases emerged from the reactor. (For complete decomposition outside the reactor, the activity of the carbon monoxide would have reached only 140 counts/min./cc.) In separate experiments, it was shown that

a. The expected amount of formaldehyde was delivered to the top of the reactor, undecomposed and unhydrogenated by the hydrogen carrying gas.

b. No appreciable decomposition of pure formaldehyde gas occurs in glass at temperatures up to 285° for periods of several hours up to 60 minutes.

c. Exchange between or decomposition of 27% formal-

dehyde in 73% carbon monoxide is negligibly small in glass in 45 minutes at 285°.

These results show that the source of the activity in the carbon monoxide must be attributed to some reaction in the catalyst bed rather than in the hollow glass preheater section of the reactor.

In contrast to the results obtained in the methanol run, the activity of the carbon monoxide found in the tail gas is more than adequate to account for the observed slope (104 counts/min./cc./carbon number) of the solid line of Fig. 2. The activity of the carbon dioxide produced in the run (132 c./min./cc.) is, within the experimental error, equal to that of the carbon monoxide. These high values for carbon monoxide and carbon dioxide activities would have been expected if all the formaldehyde had decomposed in the preheater before reaching the catalyst, but would not necessarily be observed for the decomposition of formaldehyde over the catalyst. As noted above, however, the data obtained for the hydrocarbons indicate that the formaldehyde must have passed over an appreciable length of the catalyst bed before decomposition was complete.

A brief analysis will show that if carbon dioxide is formed exclusively from the carbon monoxide and always by consecutive reactions, one of which is nonreversible, the activity of the carbon dioxide will be less than that of the carbon monoxide at any given point in the catalyst bed. However, carbon dioxide *produced* in any increment of the catalyst bed will, of course, have the same molar activity as the carbon monoxide in the same increment.

If x is the distance along a catalyst bed, and l is the total bed length

$$A_{CO_2}(l) = \frac{\int_0^l A_{CO} \frac{d V_{CO_2}}{dx} dx}{V_{CO_2}(l)} \qquad (3a)$$

where A_{CO} is the activity of CO (counts/min./cc.) at point x in the bed, l is the length of the bed, $A_{CO_2}(l)$ is the activity of CO_2 in the tail gas and V_{CO_2} is the total amount of CO_2 present at x. Integration by parts yields

$$A_{CO_2}(l) = A_{CO}(l) - \frac{1}{V_{CO_2}(l)} \int_0^l V_{CO_2} \frac{d A_{CO}}{dx} dx \qquad (3b)$$

Thus, it is apparent that $A_{CO_2}(l)$ can approach $A_{CO}(l)$ only if the integral term in 3b is small compared with $A_{CO}(l)$. This could most reasonably be realized if the activity of the CO increases rapidly at first (and in this region $V_{CO_2}/V_{CO_2}(l)$ is very small) and rapidly attains its final value. This would mean that the integrand is essentially zero over most of the bed length. Thus, A_{CO} would have to reach its final value much faster than V_{CO_2} if the second term in eq. 3b is to be small.

The above analysis would require that the decomposition of formaldehyde to CO occurs before appreciable synthesis and concomitant production of CO_2 can take place. The data in Fig. 2 show that synthesis is occurring before the decomposition of formaldehyde is complete. Thus, it would be closer to the truth to assume that the production of radioactive CO from formaldehyde follows the same functional dependence on x as the formation of CO_2 from CO. In this case, according to eq. 3, the activity of the CO_2 would be only one-half as great at the exit as the activity of the carbon monoxide. Since the activity of the CO_2 in the exit gas is roughly the same as the activity of the CO, it appears that at least some of the CO_2 is formed *directly* from the adsorbed formaldehyde. Similar conclusions were reached regarding the CO_2 produced in methanol tracer experiments.

The calculations that are made on the basis of eq. 3a and 3b for the increase in the radioactivity of carbon dioxide with bed length are equally applicable to the consideration of the slope of the line in Fig. 2 for the activity of the hydrocarbon products as a function of carbon number. A nonreversible transformation of CO into hydrocarbons along the bed would, on the basis of the arguments given in connection with eq. 3a and 3b, result in the activity increment per added carbon in the hydrocarbon being always less than the activity of the CO. The exit values of 138 counts/min./cc. for the carbon monoxide and a slope of 104 counts/min./added carbon for the plot in Fig. 2 conform to expectation if the build-in step in forming the hydrocarbons is mostly from a complex formed from carbon monoxide but not directly from formaldehyde.

Discussion

A detailed evaluation of the present data in terms of an over-all synthesis picture will be deferred until data are presented relative to the incorporation of propionaldehyde and ethylene in experiments at one atmosphere[14] and ethanol in high pressure experiments.[13] It will suffice, therefore, to summarize here the firm conclusions that can be drawn from these data without reference to subsequent runs. The conclusions to which the present experiments lead may be summarized as follows.

(1) Carbon dioxide does not build into hydrocarbons appreciably during their synthesis from carbon monoxide and hydrogen over a singly promoted iron catalyst at one atmosphere pressure and 240°.

(2) The water–gas conversion reaction is extremely sluggish over a singly promoted iron catalyst at 240° at one atmosphere, as judged by the very small conversion of radioactive CO_2 to carbon monoxide.

(3) Methanol adsorbs on iron catalysts to form a complex capable of initiating hydrocarbon synthesis chains on the catalyst surface, though as a chain initiator it is only about $^1/_5$ as effective as ethanol; furthermore, its effectiveness decreases by a factor of two when the pressure is raised from one to 7.8 atm. This or a different complex formed by methanol builds into the hydrocarbon chain and also forms CO_2, as evidenced by the fact that the slope of the activity *vs.* carbon number curve and the absolute activity of the carbon dioxide are both too high to be accounted for by the radioactivity of the carbon monoxide.

(4) Formaldehyde appears to decompose almost completely into carbon monoxide and hydrogen, though a portion of the decomposition must be

(14) W. K. Hall, R. J. Kokes and P. H. Emmett, to be published.

directly to CO_2. To a small but finite extent formaldehyde forms a complex capable of initiating hydrocarbon chains. The mechanism by which formaldehyde builds into the hydrocarbon chain involves either the carbon monoxide formed by decomposition or a second complex. The carbon monoxide at the exit has ample radioactivity (138 counts/min./cc.) to account for the observed slope of the activity *vs.* carbon number plot (104 counts/min./cc/carbon number).

Fischer–Tropsch Synthesis Mechanism Studies. The Addition of Radioactive Ethanol to the Synthesis Gas

BY R. J. KOKES, W. KEITH HALL AND P. H. EMMETT

RECEIVED JANUARY 26, 1957

The incorporation of radioactive ethanol in the Fischer–Tropsch synthesis has been studied over reduced singly promoted iron catalysts, a reduced doubly promoted iron catalyst, a nitrided doubly promoted iron catalyst and a reduced cobalt catalyst. Most of the experiments were carried out with the synthesis gas containing about 1.5% ethanol, but in some runs the concentration was as low as 0.04%. At one atmosphere the incorporation is greatest for the reduced singly promoted iron catalyst, less for the reduced doubly promoted iron catalyst, and least by far for the cobalt catalyst. The incorporation over the reduced doubly promoted iron catalyst falls off with increasing pressure and also at 7.5 atm. the incorporation is lower for the nitrided catalyst than it is for the reduced catalyst. The average of the molar radioactivities of the alcohols produced over the nitrided catalyst is the same as for the hydrocarbons from the same run. Experiments with varying ethanol concentrations indicate that the ethanol adsorption is medium strong at concentrations between 1.5 and 0.04%. The results are discussed on the basis of Langmuir adsorption and stepwise growth of hydrocarbon chains involving an adsorbed alcohol as the principal intermediate.

It has been shown that when small amounts of C^{14}-labeled primary alcohols containing 2, 3 or 4 carbon atoms are added to a 1:1 H_2:CO synthesis gas at one atmosphere and passed over a singly promoted iron catalyst at about 235°, the resulting Fischer–Tropsch hydrocarbon products (at least up to C_{10}) have an approximately constant radioactivity per mole.[1,2,3] Thus it appears that these alcohols are acting as chain initiators. In the experiments involving ethanol, moreover, it has been shown[2] that the chain initiation occurred preferentially (90% of the time) at the methylene carbon atom. These results, together with the fact that $^1/_2$ to $^1/_2$ of the synthesis products originate from the added alcohols, which constitute only 1.5% by volume of the synthesis gas, clearly suggest that the complex formed from the adsorbed alcohol may well be an intermediate in the normal synthesis.

According to the picture put forward by Storch, Golumbic and Anderson,[3] the formation of hydrocarbons from CO and H_2 occurs in a stepwise fashion. Various schemes have been advanced on the basis of such a mechanism, several of which predict both the isomer and carbon number distributions in the products.[4–6] The best agreement with the experimental data is obtained using scheme A of ref. 5. This scheme is similar but not identical to the one which would be obtained if the single carbon chain building unit, as well as the chain initiation units, were adsorbed alcohols with a carbon–hydrogen bond of the carbinol carbon atom replaced by a carbon–metal bond.[1–3,7]

Tracer experiments[1,2] over singly promoted iron catalysts at one atmosphere are, by and large, consistent with this picture. Perhaps its most significant shortcoming is the suggestion that the single carbon chain building complex is an adsorbed alcohol. This, of course, suggests that the C_1 complex should be derivable from either adsorbed methanol or adsorbed formaldehyde (enol form). The present authors[8] have shown that neither of these acts as the primary build-in unit although they both function as chain initiators. In spite of the difficulty, the over-all success of the mechanism justifies additional tracer experiments to further test its applicability.

The alcohol tracer experiments reported previously[1,2,8] with the exception of one of the methanol experiments,[8] have all been carried out at atmospheric pressure on reduced, singly promoted, iron catalysts. Of these experiments, those in which primary alcohols having 2, 3 or 4 carbon atoms were used yielded results which lend themselves most easily to interpretation in terms of a simple chain building scheme. In order to test more completely this simple picture, some additional ethanol tracer experiments were made. These were carried out over a reduced, doubly promoted, iron catalyst at 1, 7.5 and 21 atmospheres; over a nitrided, doubly promoted, iron catalyst at 7.5 atmospheres; and over a cobalt catalyst at 1 atmosphere. The synthesis gas for these experi-

[a] The symbols [R] and [N] mean reduced and nitrided. [b] The temperature was continuously raised during the run to maintain the same contraction. [c] In this run the methyl carbon atom was radioactive. [d] In this run the methylene carbon atom was radioactive.

ments contained about 1–1.5% radioactive ethanol. Also made were two experiments in which the synthesis gas contained about 0.05% strongly radioactive ethanol in the synthesis gas. These two runs, both at atmospheric pressure, were carried out over a singly promoted iron catalyst and over a cobalt catalyst.

Experimental

The experimental procedures are only outlined below, since detailed accounts of the equipment and the procedures used have been given in earlier publications.[1,2,8,9]

Syntheses at one atmosphere were performed in the fixed bed Fischer–Tropsch unit described in the first paper of this series. The runs at higher pressures were carried out in cooperation with the U. S. Bureau of Mines at Bruceton, Pennsylvania.

Gaseous synthesis products were separated into C_1, C_2, C_3, C_4 and C_5 cuts in a Podbielniak column. The individual cuts were analyzed for radioactivity, after which the olefins were removed in a scrubber and the residual gas was again analyzed for radioactivity. Subsequent mass spectrographic analysis made it possible to calculate the activity of olefins and paraffins as a function of carbon number.

Except for one instance, the liquid products were first washed with water, separated and then distilled from sodium hydride to remove the residual water, unreacted alcohol and other products containing oxygen. The liquids were then fractionated by low temperature distillation in high vacuum and burned to CO_2. From the volumes of the gaseous cut and the CO_2 produced, and the activity of the CO_2, the radioactivity of the cut could be calculated on a molar basis.

In run no. K10 over the nitrided catalyst, the procedure for handling the liquids was modified to permit separation of the alcohols from the hydrocarbons. The liquid products were first distilled to remove the waxes, and then refluxed with alkali to remove the acids and to saponify the esters. This step probably also removed aldehydes and/or ketones. The oil layer was then chromatographed using Davison silica gel No. 923 (inactive to olefins) as an adsorbent and methanol as a displacement agent. The alcoholic fraction obtained was then cut on a spinning band column into eight fractions, the last four of which were found to be substantially free of ethanol and methanol by mass spectrographic analysis. Except in the one case in which appreciable water was present, the carbon number was determined by a vaporometric method. From these data and the activity of the CO_2 formed on combustion, the radioactivity of the cuts could be calculated on a molar basis. Results of infrared analyses on these cuts showed that in spite of appreciable losses in the separation procedures, the cuts were substantially free of non-alcoholic organic contaminants and were 97 ± 2% pure on a molar basis. The hydrocarbon fraction from this run was analyzed in the standard fashion.

Three catalysts were used in this study. The singly promoted iron catalyst, no. 614, contained 0.64% Al_2O_3 and 2.00% ZrO_2 in addition to iron oxide. The doubly promoted iron catalyst, D3001, and the cobalt catalyst, 108B, are standard catalysts used by the U. S. Bureau of Mines at Bruceton, Pennsylvania.[3] Catalyst D3001 contains Fe_3O_4 + 4.6% MgO, 0.6% K_2O, 0.6% SiO_2 and 0.6% Cr_2O_3. The cobalt catalyst, 108B, has the composition Co:ThO_2: kieselguhr, 100:18:100. For the sake of completeness, the catalyst used by Kummer, *et al.*,[2] in run J4 was No. 333; in addition to iron oxide, it contained 2.82% Al_2O_3 and 1.39% ThO_2.

Results

The experimental conditions are summarized in Table I along with the product distributions for the various tracer runs. In Table II, the radioactivities per cc. are listed for the products of each of these runs. Previous[1,2] data have shown that a complete balance of inlet and exit radioactivity is not feasible owing to carbiding and wax retention on the catalyst; hence no attempts were made to effect a radioactive material balance.

In synthesis over the doubly promoted iron catalyst D3001, the gaseous product distribution is not strongly affected by increasing the pressure. The product distribution for a singly promoted catalyst was different from that for a doubly promoted catalyst. In the *control* runs at one atmosphere (not shown in Table I), it was found that the singly promoted iron catalyst was about 85% paraffinic, whereas for the doubly

[a] The precision of these data is about ±7 c./m./cc. *hydrocarbon*. [b] In this run the activities of the olefins and paraffins of a given cut were calculated on the basis of the amount absorbed by an olefin scrubber rather than by a subsequent mass spectrographic analysis. [c] In these two runs the yield of C_5 products was so low only the activity of the total C_5 cut could be determined. The yield of ethylene was also quite low (~1% of the C_2 cut); hence, the activity of the ethylene could not be determined. [d] Activity in c./min./cc.

promoted catalyst it was 85% olefinic. This may be a consequence of the known lower hydrogenation activity of the doubly promoted iron catalyst compared to those containing no alkali.[10] Furthermore, although it had been previously noted[2] that ethanol addition definitely retarded the synthesis reaction over singly promoted catalysts at one atmosphere, this effect was not found in the present studies.

The gross results of these experiments are summarized in Table III, which gives the fraction of the products formed from the alcohol (per cent. incorporation) *vs.* synthesis variables for all the experiments herein reported. For the sake of comparison, a representative run reported by Kummer, *et al.*,[2] has been included. Runs H7, H19 and H15 yielded data for the same catalyst under different synthesis conditions. In these runs, the temperature, contraction and synthesis pressure vary. There does not appear to be a clear relation between the per cent. incorporation and either the temperature or the contraction; on the other hand, it does appear that the per cent. incorporation decreases with increasing pressure.

The variation of the molar radioactivities with carbon number for runs over the doubly promoted catalyst is illustrated by the curves in Fig. 1. Their qualitative features are quite similar, even though they were carried out at different pressures. The plots all show a maximum in the C_3–C_4 region and a trend toward a local minimum in the curves at about C_5.

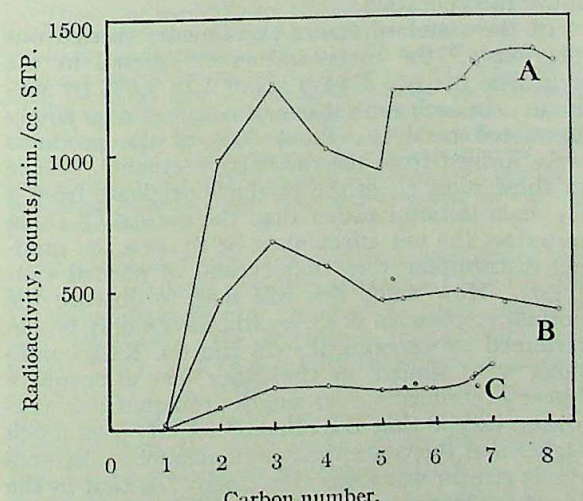

Fig. 1.—Influence of pressure in ethanol tracer runs over doubly promoted iron catalysts, D3001: A, H7, 1 atm., 245–275°; B, H19, 7.5 atm., 241°; C, H15, 21 atm., 242°.

K13 R Co	On kieselguhr	187	1.0	53	0.04	0.07
K16 R Co	On kieselguhr	190°C.	1.0	52	1.5	1.6

[a] The symbols R and N refer to reduction and nitriding, respectively. [b] This is an average value for the whole run. [c] This is the volume % ethanol in the synthesis gas. [d] % incorporation = $\frac{\text{activity products } (C_2^+) \text{ c./m./cc.}}{\text{activity of added ethanol c./m./cc.}} \times 100$. [e] This doubly promoted catalyst was inferior to the singly promoted catalyst for synthesis at one atmosphere. In order to maintain even the low level of contraction the temperature was increased continuously throughout the run.

The effect of increased pressure on ethanol incorporation is clearly evident from Fig. 1. The average incorporation falls from 18 to 7 to 2.2% as the pressure is increased from 1 to 7.5 to 21 atm. In the case of one of these runs (H7), the catalyst was so unstable (see footnote *e* of Table III) that the *detailed* features of the plot of radioactivity *vs.* carbon number are questionable. For this reason, any general remarks made in the discussion pertaining to the shape of the activity *vs.* carbon number curves of all the tracer runs herein reported need not necessarily apply to run H7. In spite of this difficulty, it is clear that in this run as well as in runs H19 and H15 the ethanol is acting primarily as a chain initiator.

The effect of alkali on the incorporation of ethanol can be deduced from the data in Table III, where data obtained with the singly promoted iron catalyst at one atmosphere, run J4 previously reported by Kummer, *et al.*,[2] are compared with those obtained from run H7. In run H7, insofar as it was possible, the conditions were similar to those used in run J4, except that the doubly promoted catalyst was used. Incorporation in these two runs was found to differ by a factor of 2, with the run over the doubly promoted catalyst showing the lower incorporation.
